During defrost operation, outdoor units will generate condensate. Inadequate condensate management may lead to slip/fall hazards. Air-source VRF outdoor units can be installed indoors with manufacturer-specific duct and ambient temperature requirements. Even in applications where designers choose to locate the outdoor units indoors, adequate condensate disposal methods and condensate freeze protection must be factored into the design.

Oil Recovery Management

During normal operation, oil may migrate out of the compressor, so manufacturers may include an oil separator for each compressor in the outdoor unit(s). The oil separator uses compressor discharge velocity to spin refrigerant out to the separator's shell, where oil collects on the walls, then drains by gravity to the bottom and back to the compressor's oil sump.

Oil separators collect most of the oil; however, a small amount of oil remains entrained in the refrigerant leaving the separator, and often collects in the piping system and indoor units. To reclaim oil that settles in the system and away from the sump, the controls open the EEV or LEV in all indoor units (even if they are not in operation) after a set period of compressor operation. The compressor switches to a predetermined speed or setting to ensure oil in the system flushes back to the compressor sump. The oil recovery cycle generally engages after the compressor has been operating for a predetermined number of hours, and may factor in operational capacity to adjust the frequency of the cycle, or use an oil level sensor. Oil recovery typically lasts from 3 to 6 min and may affect operational mode, as defined by the manufacturer.

Humidity Control

Zone comfort and associated indoor unit output are controlled based on a dry-bulb temperature set point in the space or at a central location. The sensible-to-total-cooling ratio is typically in the 70 to 80% range, depending on airflow across the unit and ambient air or condenser water temperatures. The rated capacities of the installed indoor units typically match the peak total heating or cooling load for the specific zone's total, sensible, and latent elements. Indoor unit output follows the load profile curve for that specific zone. The sensible-to-latent-load ratio changes with indoor and outdoor ambient conditions in most cooling applications.

Some indoor units include a dry mode that could provide dehumidification once zone temperatures rise above a dew-point temperature threshold. In dry mode, the indoor unit operates at a low fan speed to keep the coil cold, and at sufficient capacity to remove moisture from the air without significantly lowering room temperature. If the zone temperature drops below a designated set point (depending on individual manufacturer's specifications), the indoor unit may shut off.

If a **dedicated outdoor air system (DOAS)** is applied to a VRF system, the lower off-coil temperatures at the DOAS allow the DOAS to manage a significant proportion of the outdoor air's latent cooling load. This lets the indoor units of the VRF system manage the majority of sensible and latent cooling loads of the indoor air.

In winter heating cycles where humidification is required to maintain zone comfort, a supplemental humidification unit can be used through the ventilation air system. An energy recovery ventilator (ERV), as opposed to a heat recovery wheel or core ventilator, as part of the ventilation air system can help reduce latent loads during cooling mode. In winter heating mode, cool, dry outdoor supply air is partially humidified by moist exhaust air. In summer cooling mode, moisture from outdoor supply air is transferred to the

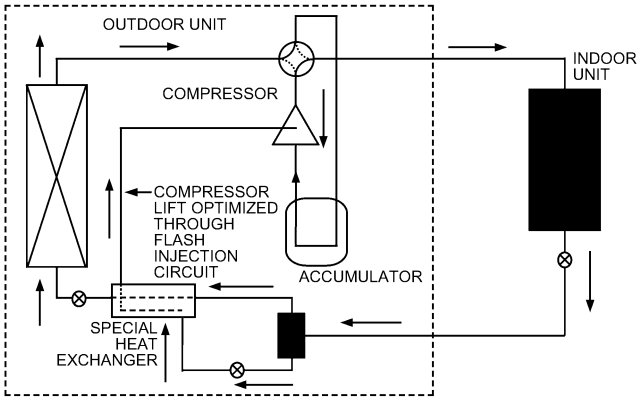

Fig. 11 Flash Injection Schematic

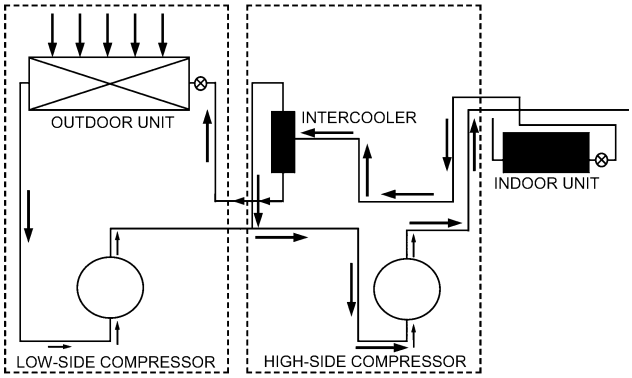

Fig. 12 Staged Compression Cycle Schematic

dry exhaust air, thus reducing the latent load on the VRF indoor units.

High-Heating-Performance Air-Source VRF Units

To deliver higher heating performance of air-source VRF systems in low-ambient-temperature conditions, manufacturers have developed refrigeration cycles so that 100% nominal heating performance can be maintained as low as –15°C ambient, and with approximately 80% heating output at –25°C. Strategies to achieve these heating performance levels include flash injection and a staged compression cycle. In some climates, supplemental heating may still be required to meet peak heating loads for the zone.

Flash Injection. Some air-source VRF systems include flash injection technology on a single-compressor refrigeration circuit to offer increased heating output at lower ambient temperatures. Such systems offer nominal heating output at ambient temperatures as low as –18°C. The flash gas flow is modulated to an intermediate point in the compression process based on the difference between the required heating output and external ambient conditions. Compressor speed is optimized based on the circuit load (Figure 11).

Staged Compression Cycle. An alternative approach to achieving higher-temperature outputs at lower ambient conditions is to use compound compression with intermediate economizers (Figure 12).

4. MODELING CONSIDERATIONS

Computer-based, whole-building energy performance modeling and simulation is an effective method to predict and evaluate the energy and cost benefits of various building technologies. Energy performance modeling is also an important tool for building energy labeling and certification programs and for developing model energy codes. A comprehensive review of energy estimating and modeling methods is provided in Chapter 19 of the 2021 *ASHRAE Handbook—Fundamentals*. Additional guidance may also be found in ASHRAE *Guideline* 41.

VRF equipment has recently been added to the most commonly used building energy modeling programs, allowing engineers and architects to compare the energy efficiency and life-cycle costs of VRF to other systems in various climate zones. Modeling considerations specific to VRF equipment include

- Matching the sizing ratio of the total indoor terminal unit rated capacity and the total outdoor unit rated capacity (i.e., connected capacity) to manufacturer specifications
- Part-load performance of the heat pump's variable-speed compressor
- Losses associated with the refrigerant piping lengths
- Heat recovery (simultaneous cooling and heating) in some energy models

5. DESIGN CONSIDERATIONS

When designing a project, many factors should be considered for VRF systems, including

- New construction or retrofit applications
- Construction schedule
- Building orientation and layout
- Building occupancy characteristics (including future zoning)
- Peak heating and cooling load profiles (including occurrence)
- Integration of renewable energy sources
- Zone-specific design considerations, such as acoustic performance levels
- Building space allocation for mechanical equipment
- Opportunities for capturing waste heat in the mechanical system
- Application-specific ventilation air requirements
- Life-cycle performance and green-building certification expectations
- Local design weather conditions
- Local/remote control/monitoring requirements
- Opportunities for simultaneous heating and cooling for comfort conditioning

After all factors are analyzed, the engineer may choose from a range of VRF system types.

Water-Source VRF Systems

Water-source VRF systems can be applied in the same design scenarios as air-source systems. They can also be used in a range of building application types but must be integrated with geothermal heat sinks or boiler/cooling tower systems. If applied to year-round cooling applications, water-source VRF systems allow optimizing water-loop temperatures, along with compressor power input in correspondence with ambient wet bulb. The need for supplemental boiler/heating systems depends on the design.

Depending on the application design parameters, water-loop systems offer performance advantages over air-source systems, such as

- High annual system COP levels (depending on system)
- Consistent performance because of smaller fluctuations in loop temperature
- Low- or high-ambient heating or cooling
- No defrost cycles
- Multilayer heat recovery

Nominal capacities for water-source systems are typically based on an entering water temperature of 21°C for heating, and 29°C for cooling. For appropriate system operation during standard heating and cooling modes, the entering water temperature can range from 10 to 45°C but can operate with loop fluid temperatures as low as

–10°C (e.g., in geothermal applications). Each manufacturer has its own specific performance characteristics.

The rated heated capacity of a water-source VRF system is not directly affected by the external ambient temperature. The condenser water-loop heat source, which can be a boiler or ground/well, can be sized to minimize or eliminate a reduction in heating capacity due to low ambient temperatures. The condenser water loop must be maintained at a predetermined temperature set point to ensure nominal heating output.

Air-Source VRF Systems

Air-source VRF systems have been applied in many design conditions, including

- External ambient cooling design applications between 46 and –29°C
- High-sensible-heat-ratio cooling applications
- External ambient heating-dominant applications lower than –25°C

Low External Ambient Heating-Dominant Applications

Heating capacities of air-source VRF outdoor units are derated as ambient temperature decreases, down to approximately 60% heating capacity at –20°C. There are three strategies for decreasing the effect of lower ambient temperatures on VRF systems during the heating operation:

- Sizing air-source VRF units to meet the design heating load
- Integration with supplemental heating sources
- Locating the air-source unit in a temperate or controlled ambient environment (e.g., equipment room, parking garage)

Integration with Supplemental Heating Sources

In some climates, supplemental heating may still be required to meet peak heating loads for the zone. VRF systems can be integrated with supplemental perimeter or duct-mounted electric, gas-fired, or hot-water-based heating systems. Supplemental heating components can be enabled based on a preset ambient temperature measured at the outdoor unit, and/or on a zone-by-zone basis using the indoor unit and a preset dead band between design space temperature and actual space temperature. If the application calls only for zone-by-zone activation, size the supplemental heating component based on the difference between the rated mechanical heating capacity at design conditions and peak design zone heat load. In some instances, full supplemental heating may need to be factored into the design.

Outdoor Air Economizer

The model building energy codes [ASHRAE/IES *Standard* 90.1 and the *International Energy Conservation Code*® (IECC®) (ICC 2015)] each have a prescriptive requirement for the use of air-side economizers, which use outdoor air instead of mechanical cooling to cool the indoor space. Air-side economizers are not required by the codes in every application. Climate zones 1a and 1b are exempt from this requirement, and in ASHRAE/IES *Standard* 90.1, for the remaining climate zones, indoor units (sometimes called fan-coil units, evaporator units, or air-handling units) with a cooling capacity under 15.8 kW are exempt. Both model codes also provide exceptions related to increased energy efficiency for equipment in certain climate zones. Some state energy codes provide an exemption to the economizer requirement for VRF systems with heat recovery (simultaneous cooling and heating).

Table 3 Minimum Fan-Cooling Unit Size Requiring Economizer for Comfort Cooling

Climate Zone	Cooling Capacity Requiring Economizer
1a, 1b	No economizer requirement
2a, 2b, 3a, 4a, 5a, 6a	≥16 kW
3b, 3c, 4b, 4c, 5b, 6b, 7, 8

Generating Radiant Heating/Cooling and Domestic Hot Water

VRF systems can generate chilled or hot water for space cooling or heating purposes, or domestic hot water for other applications. In such applications, a refrigerant/water indoor heat exchange module with integrated controls is included in the system format. VRF manufacturers use different strategies to achieve each capability.

In some zones, indoor units could be replaced by a radiant floor or cooling/heating panel that receives water from a refrigerant-to-water heat exchanger. Adopting a similar strategy, the VRF system can generate domestic hot water with leaving water temperatures up to 71°C by using a heat exchanger with a booster refrigeration cycle. The refrigerant-to-water heat exchanger could also be used for preheating purposes in some applications. The refrigerant-to-water heat exchanger is selected based on design peak cooling/heating capacity, cooling/heating leaving water temperature, water-side design temperature difference, and water flow rates.

6. VRF SYSTEM DESIGN EXAMPLE

Performing a Load-Profile Analysis

The complete specification of a VRF system requires careful planning at the design stage, and a detailed analysis of project needs and the building's annual cooling and heating load profiles are required before equipment is selected and sized.

For example, an engineer is designing an HVAC system for a 465 m^2, single-story office commercial building in Nashville, Tennessee, with an east/west layout orientation. Nashville has a local design ambient condition of 34°C db for summer and –9°C db for winter. For the building's cooling and heating load profile, see Table 4.

System Type Selection, Zoning, and Potential for Heat Recovery

VRF system selection, whether heat pump versus heat recovery or air-source versus water-source, is driven by many factors, most notably the best balance between operating costs and capital costs per unit area. A complete energy analysis of the building is necessary to evaluate which system type is most appropriate for the application.

After studying the peak load profile, the designer could divide the building into three main zones with similar occupancy profiles, with each zone served by a dedicated heat pump system. For the

Table 4 Peak Load Profile

Zone	Cooling at 3 PM in August, kW	Cooling at 11 AM in August, kW	Heating at 8 AM in January, kW	Indoor Unit Capacity, kW
Office 1	4.3	2.6	4.5	4.4
Office 2	3.1	1.8	2.9	3.5
Office 3	3.1	1.8	2.9	3.5
Office 4	3.8	2.3	3.3	4.4
Reception	3.9	6.6	5.5	7.0
Office 5	1.4	2.3	2.2	2.3
Corridor	0.4	0.6	0.3	N/A
Electrical Room	7.6	8.2	N/A	10.6
Total Peak	**27.6**	**26.2**	**21.6**	—

electrical room, the dedicated system (either water-source or low-ambient air-source) would operate in cooling mode all year.

- West zone: Offices 1, 2, 3, and 4
- East zone: Reception, Office 5, and Corridor
- Cooling-only zone: Electrical room

There is potential, however, for heat recovery operation in this building. Waste heat from the cooling-only electrical room zone can be recovered and redistributed to other zones when those zones are in heating mode. The building's east/west orientation indicates that, during the April/May and September/October shoulder seasons, some zones may need heating while others may need cooling. Changing peak occupancy levels may also offer opportunities for heat recovery. When in simultaneous heating and cooling, waste energy from the reception area can be applied to other areas of the building if those areas require heat during shoulder seasons (Figure 13). If necessary, waste heat from the cooling-only electrical room zone could also be used to generate or preheat domestic hot water for the building. These factors offer a short payback period on any capital premium that the air-source heat recovery system has over the air-source heat pump system. Building analysis reveals that a VRF heat recovery system would be appropriate for this application.

Accurately Sizing Air-Source Outdoor and Indoor Units

Many factors must be considered before sizing the outdoor and indoor units. Outdoor unit size is based on the actual peak cooling or heating load, whichever is higher. Most VRF manufacturers have selection software that provides detailed information, taking into account correction factors for each specific operation to ensure proper design and sizing of system components. The following examples are provided to show how the software addresses adjustments to system capacity based on factors such as line lengths, ambient temperatures, and connected capacities of indoor units.

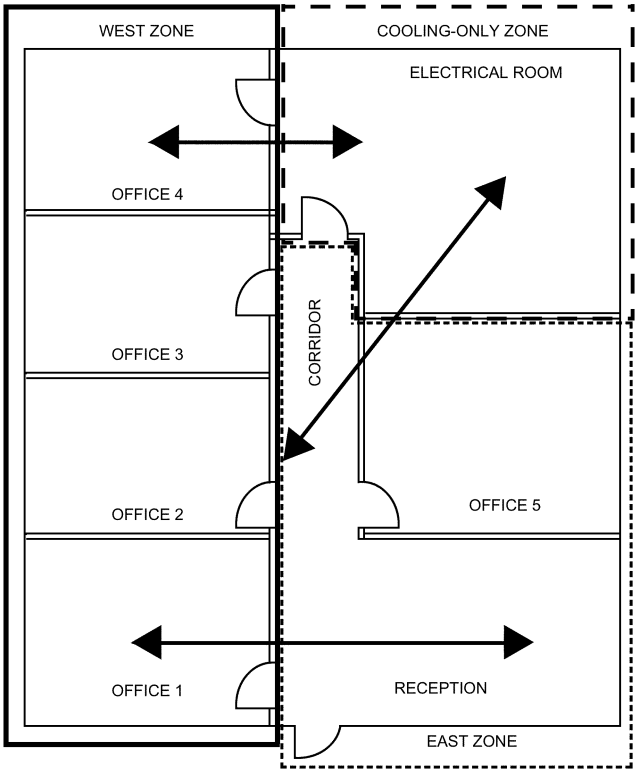

Fig. 13 Example System Zoning

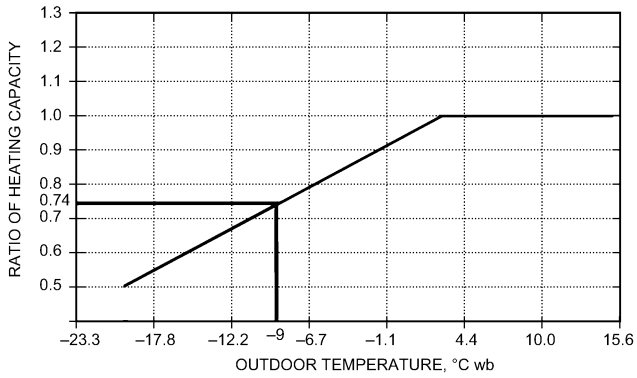
In the example, the peak cooling load is approximately 27.6 kW, occurring at 3 PM in August; the peak heating load is 21.6 kW, occurring at 8 AM in January. The outdoor unit should be sized based on the peak cooling load of 27.6 kW; thus, one 28 kW outdoor unit with 28 kW for cooling and 31.7 kW for heating should be chosen.

The effect of local ambient conditions on system performance also should be considered. As with all heat pump systems, the system may have reduced heating output at lower ambient conditions, or may operate in defrost more often than is desired. Designers should include the derating factor to verify that the chosen system will provide the required capacity at the necessary design temperatures. For the example, at the winter ambient design temperature of –9°C, a 28 kW air-cooled outdoor unit's heating output is derated by a factor of 0.74 (Figure 14).

Thus, 0.74 × 31.7 = 23.5 kW, which fulfills the peak heating load of the building. Additionally, the VRF system's heating output can be derated based on the maximum refrigerant piping length from the outdoor unit to the farthest indoor unit. This capacity correction factor reflects the compressor energy expended when moving refrigerant through the VRF system. In the example, the maximum refrigerant piping length is 37 m, so the heating capacity correction factor is 0.98 (Figure 15).

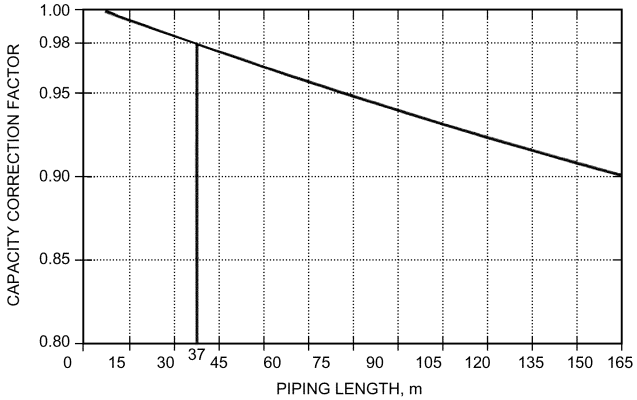
Design winter ambient = –9°C, Derate factor = 0.74
Refrigerant piping length correction factor at 37 m = 0.98
Corrected heating capacity = 31.7 × 0.74 × 0.98 = 23 kW

A similar process should be used when confirming the proposed system's cooling performance. The rated condition temperature for outdoor unit cooling capacity is 35°C. In this example, the summer



Note: Representative data. Not specific for each manufacturer.

Fig. 14 Heating Output Derating Chart



Note: Representative data. Not specific for each manufacturer.

Fig. 15 Maximum Refrigerant Piping Length Capacity Correction Factor

ambient design temperature is 34.4°C; therefore, derating is not required (Figure 16).

The system must be derated for refrigerant piping length. In the example, the maximum refrigerant piping length is 37 m, and, as in the heating calculations, the cooling capacity correction factor is 0.98 (see Figure 15).

Design summer ambient = 34.4°C db, Derate factor = 1.00
Refrigerant piping length correction factor at 37 m = 0.98
Corrected cooling capacity = 28.2 × 0.98 = 27.6 kW

Designers also must verify that the connected nominal capacity of the indoor units is within the operating parameters of the selected system. VRF heat pump systems can operate with a connected nominal capacity of up to 130% of the outdoor unit nominal capacity. General industry design practices are to design systems with up to 130% nominal capacity. Connected capacities above 130% are not typical. If the designer desires to exceed 130% connected capacity, caution must be used. During the design phase, the designer must consult with the manufacturer to validate that the design is acceptable. VRF heat recovery systems can operate with a connected nominal capacity of up to 150%, or, for some special applications, up to 200% of the outdoor unit nominal capacity. Connected capacity ratios depend on the system's ability to meet peak cooling and heating loads; connected capacity ratio is calculated by indoor unit connected nominal capacity divided by outdoor unit nominal capacity.

For the example, the total indoor unit connected capacity is 35.7 kW; the nominal outdoor unit capacity is 28 kW: 35.7 kW/28 kW = 128%.

The 128% is within the connected capacity allowed for VRF heat recovery systems.

Selecting Indoor Units

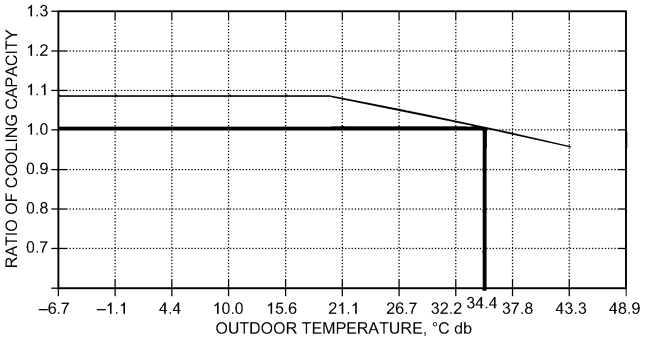
Indoor units are selected for each zone based on style and additional design considerations, such as the following:

- Peak cooling and heating capacities
- Ratio of sensible to latent cooling load
- Air change rate
- Sound performance criteria
- Terminal unit air-side distribution and location restrictions
- Ventilation air strategy (following ASHRAE *Standard* 62.1 criteria)
- Integration with supplemental heating components, if any

For the example, the designer may include different indoor unit styles to satisfy project requirements (Figure 17). In the cooling-only zone (the electrical room), the sensible-to-latent cooling ratio is high; the indoor unit rating must be selected to match the requirements for the space.

Office 1 requires other design considerations:

Peak cooling load = 4.3 kW
Peak heating load = 4.5 kW



Note: Representative data. Not specific for each manufacturer.

Fig. 16 Cooling Output Derating Chart

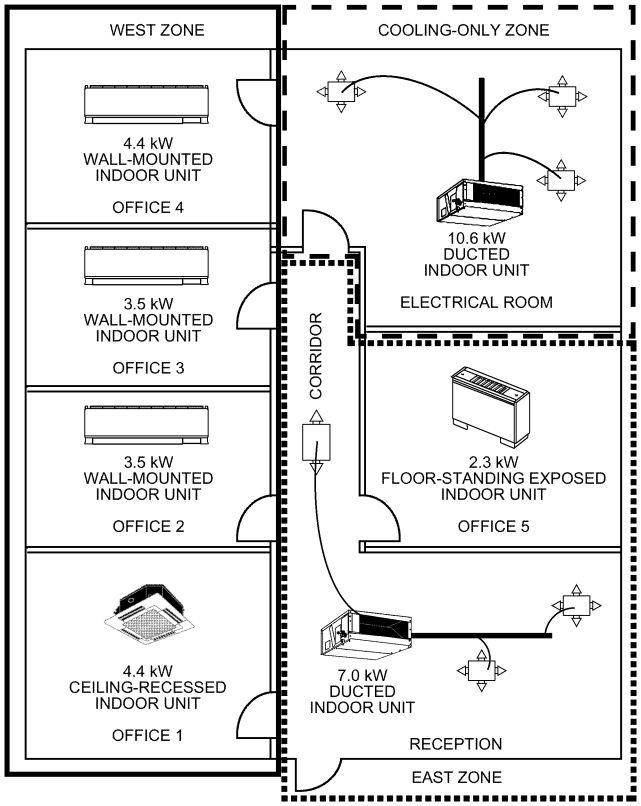


Fig. 17 Indoor Unit Layout

Air change rate = 4 ach
Sound performance criteria = NC 35
Ventilation supply = 40 L/s (see the Ventilation Air Strategy section)

The designer could choose a ducted indoor unit with

Nominal cooling output of 4.4 kW
Nominal heating output of 5.0 kW
Sound performance rating of NC 30
Nominal airflow rate of 225 to 315 L/s

Ventilation Air Strategy

Designers can select many different types of ventilation equipment to complement a VRF system. There are three main strategies: direct, integrated, and decoupled. Selection depends on climate, application, and equipment type.

Direct Method

Outdoor air is mixed with return air and conditioned by the VRF indoor unit. The mixed air temperature from the ventilation system should have sufficient mixing factored in to enable effective coil performance. Consult the manufacturer for guidance on entering coil limitations. Consider the effect of mixed air conditions when the VRF indoor unit is not actively heating or cooling.

- Used for applications in mild to moderate climates, and/or situations requiring small amounts of outdoor air.
- Reduces system complexity and initial equipment costs.
- Climate or ventilation volume requirements must be treated with caution where outdoor air could increase humidity levels to an unacceptable level in the space. For example, a high volume of outdoor air could result in high humidity levels in a conference room during unoccupied periods when the cooling load is reduced. Note that, to ensure minimum ventilation requirements, the VRF indoor unit fan must run at design fan speed at all times.

Integrated Method

Outdoor air is pretreated by mechanical means such as a 100% outdoor air unit, a DOAS, a heat recovery ventilator (HRV), or an energy recovery ventilator (ERV) before being supplied to the VRF indoor unit through the return air or supply ductwork.

- Allows the dedicated ventilation system to handle all or part of the outdoor air load. The VRF indoor unit is sized for the internal space load, and possibly part of the outdoor air load.
- Used for applications in moderate to extreme climates.
- VRF indoor unit provides final tempering of the mixed airstream and should be sized accordingly.
- Allows reduced overall VRF equipment capacity and increased application flexibility.
- Maintains ventilation air quantity by indoor unit fan operation.

Decoupled Method

Ventilation air is supplied directly to the conditioned space. Both a decoupled dedicated ventilation system, such as a DOAS, and a VRF system can be installed. The function of the VRF system is to maintain comfort in the conditioned space.

- Allows the dedicated ventilation system to handle the entire outdoor air load. The VRF system is sized only for the internal space load.
- Used for applications in any type of climate, and situations requiring any amount of outdoor air.
- Can introduce large amounts of outdoor air as needed. The VRF indoor unit fan can be programmed to cycle on/off based on heating and cooling requirements, regardless of ventilation demands, thus increasing system efficiency.
- Allows reduced VRF equipment capacity and increases application flexibility.
- DOAS system must be designed properly so that incoming outdoor air does not cause short-circuiting issues with return air of the VRF indoor units, or influence any temperature sensors. The supply temperature of the ventilation system should be carefully controlled to limit cold and hot drafts.

Other Considerations

- Verify that the selected indoor unit type can handle the required amount of outdoor air, taking into account latent and sensible loads, and mixed-air wet-bulb temperatures.
- Location of the space temperature sensors must be considered. Most VRF indoor units can be factory configured to measure space temperature from their respective return air sensors. Integrating outdoor air with the indoor unit can affect this temperature measurement and influence operation, possibly by overcooling or overheating the space. In this situation, a temperature sensor, such as a remote temperature sensor or a sensor located in the VRF system local controller, could be used to establish the actual space temperature.

Refrigerant Piping

Each VRF manufacturer recommends different refrigerant piping sizes and maximum to minimum vertical and horizontal lengths, based on refrigerant volumes and velocities required for efficient and stable system operation. Refer to manufacturer guidelines for specific details and industry and local codes for compliance. System refrigerant charge is a calculated value, whereas additional charge is determined by liquid-line volume.

Manufacturer-specific design software provides detailed refrigerant piping specifications and parameters for each project and application, such as

- Refrigerant liquid and gas piping sizes
- System design verification based on maximum height and length differences
- System design verification based on the ratio of indoor unit to outdoor unit nominal capacity
- Equipment bill of materials/quantities, including system refrigerant piping and charge
- Project numbering and product specifications
- Control and power schematics

Refrigerant Piping Guidelines

Refrigerant piping should be carefully considered, taking into account applicable codes and using risk management strategies. Many national, state, and local building codes require compliance with ASHRAE *Standard* 15 in the design, construction, and installation o f refrigerant piping. It is necessary to follow national, state, and local building codes and work with the local authority having jurisdiction (AHJ) to ensure best practice. Considerations include the following:

- **Inspection:** keep site-installed pipe joints exposed to view until all pressure and vacuum tests are completed and passed.
- **Ventilated spaces**
  Know the refrigerant concentration limit (RCL) and how it applies to each occupied space.
  Evaluate connected spaces beyond the zone and connected ductwork:
  - Plenums: determine whether the space above the ceiling is part of the supply or return system.
  - Closures: if an indoor unit supplies multiple spaces and uses dampers, confirm the minimum open position.
  - Transfer openings: determine whether there is a transfer duct, transfer grill, undercut door, or other permanent opening to an adjoining space.
- **Location of piping and refrigerant bearing components:** know where refrigerant may come from if a leak were to occur.
  - Determine whether the VRF indoor unit coil is in the space.
  - Determine whether refrigerant piping is exposed or in a connected space.
  - Determine whether refrigerant piping is enclosed with a ventilated double-wall jacket.
- **Protect refrigerant piping**
  - Exposed piping
    - Ensure exposed piping is at least 2.2 m above the floor or is against the ceiling.
    - Ensure exposed piping is not installed in an enclosed public stairway, stair landing, or means of egress; consider enclosing piping with gastight and fire-resistive material to isolate from such areas.
  - Shafts and penetrations
    - Ensure piping is not located inside any elevator, dumbwaiter, or other shaft containing moving objects.
    - Ensure piping shaft is not open to living quarters or means of egress.
    - Use riser shafts with proper support between floors.
    - Use protective sleeves to protect piping from abrasions where it passes through walls, obstructions, or other materials.

Controls

VRF manufacturers offer factory-packaged controls that communicate through their system-specific protocol; most use two low-voltage control wires, which must comply with applicable local and national electrical codes. Various individual unit and/or system controllers are available, with the application dictating which controllers need to be installed. Simple controllers include the most basic functions such as operation mode, temperature control, and fan speed. More sophisticated controllers have scheduling, diagnostic functions, and more. Each manufacturer offers centralized control-

lers, which allow the user to monitor and control VRF systems and ancillary equipment from a single location or through the Internet. Manufacturers also offer open protocol communication gateways for higher-level monitoring using BACnet® or LonWorks®, but special programming may be required.

VRF system controls can be subdivided into

- Integral equipment controls
- Local system controls
- Central system controls
- Gateway controls to integrate with open protocol systems

Integral Equipment Controls. VRF air-source outdoor units, water-source units, heat recovery control units, and indoor units include refrigerant and air-side sensing and control devices, which allow the system to optimize its output (e.g., compressor speed, discharge temperatures, fan speed) based on inputs from a remote device. VRF equipment can function as a stand-alone system based only on local inputs.

Local System Controls. VRF indoor units can be controlled individually by their own local controllers, with temperature sensing at the return air or local controller, or several indoor units can be grouped together under one local controller (see Figure 6). Each of the grouped indoor units may operate on or off according to the sensed return air temperature, independent of the other indoor units in the group, but all grouped indoor units will be in the same mode (heating or cooling) to provide air conditioning. Local system controls can include functions such as local set-point control, scheduling and setback capability, cooling/heating/auto modes, and indoor unit fan speed control. Depending on the maximum number of zones served by the local controller and on other factors, additional operation features may be included.

Central System Control. Central control interfaces for VRF systems allow users to monitor and optimize the operation of multiple zones, including any decentralized compatible energy recovery ventilators (see Figure 6). This level of control offers added functionality over local controllers such as seasonal scheduling, remote monitoring and diagnostics, ability to integrate building plans and schematics, and system energy management such as sliding temperature control, optimized start-up control, and setback capabilities. See manufacturer guidelines for specific details. Many of these controls can allow users remote access to operate, monitor, and optimize the VRF system as well as ancillary devices or equipment (e.g., lighting, ventilation, third-party HVAC equipment) without requiring a building-based automation or management network. Access can typically be secured through web-based access licenses or other manufacturer-specific software tools (see Figure 6).

Gateway Control to Integrate with Open Protocol Systems. Open protocol communication gateways allow higher-level monitoring and basic control of set points, fan speeds, mode, etc., via LonWorks or BACnet. Information may be used by the building management system to control other ancillaries such as lighting.

Safety Considerations for Refrigerants

As with any HVAC equipment, VRF systems must include design and application safeguards that protect occupants. The appropriate information for the design, construction, testing, installation, operation, and inspection of mechanical refrigeration systems is ASHRAE *Standard* 15. It is necessary to follow national, state, and local building codes and work with the local AHJ to ensure best practice.

Designers also need to refer to ASHRAE *Standard* 34, which lists the most current information related to refrigerant designations, safety classifications, and refrigerant concentration limits (RCLs). ASHRAE *Standard* 34 refers to common names of refrigerants used in HVAC systems, instead of using the chemical name, formula, or trade name. The standard establishes a uniform system for assigning reference numbers and safety classifications to refrigerants (including blends).

To successfully apply refrigerant safety requirements to a project, the designer must know the following:

- Classification and RCL of refrigerant used
- Classification of occupancy type in which indoor unit and/or piping will be located
- Total amount of refrigerant used in the system
- Individual occupied zone(s) geometry and connected zones, if applicable
- Methodology to calculate the maximum amount of refrigerant that can be safely dispersed into a specific zone

The smallest space in which any of the indoor units or piping could be located must be capable of safely dispersing the refrigerant charge of the entire VRF system in the unlikely event of a catastrophic leak or failure. Examples of spaces that may require additional consideration include bathrooms, small offices, or fire-resistance-rated exit access corridors (as defined in ASHRAE *Standard* 15). It is recommended that the designer use a "fault tree analysis" similar to the following to evaluate the HVAC systems.

Fault Tree Analysis

A fault tree analysis of the installed HVAC systems should be completed to evaluate the placement of system components to minimize the potential for refrigerant leaks into the conditioned space.

The following items serve as a starting point for the fault tree analysis to ensure that all factors are considered to minimize the potential for a refrigerant leak into the conditioned space:

- Identify system components that are in the conditioned space.
- Identify refrigerant piping that is in the conditioned space.
- Identify the smallest occupied space in each HVAC system area and show compliance with the RCL of the refrigerant in use.
- Identify connecting spaces and list the dimensions of the opening between the spaces and the air movement that achieves compliance with the RCL.
- Identify the worst-case refrigerant leak scenario for each system.

Options available to manage smaller spaces where the RCL would otherwise be exceeded include the following:

- If cooling is required in the occupied space, one option is to increase the actual space volume by providing a connected space, as defined in ASHRAE *Standard* 15.
- A ducted indoor unit could serve several smaller offices, thus increasing the overall occupied space served by the system.
- Central VRF systems can be subdivided into a series of smaller systems so that the total charge in a given system does not exceed the RCL limitations for a given space.
- A dedicated system could serve the smaller space(s) so the total charge does not exceed the RCL limitations for a given space.
- Allow the code-required ventilation to maintain conditions in the space.

In summary, complying with ASHRAE *Standard* 15 may only require simple adjustments to the project's design: carefully considering the building's zones, determining connected spaces, and optimally placing the piping and indoor units. With sound engineering practices, a VRF system can be designed to comply with all refrigerant safety requirements and other applicable code requirements.

Integrating VRF Systems to Minimize Environmental Impact

VRF systems include features that make them highly efficient, and that should be applied effectively to optimize system performance and support sustainability. The part-load capabilities of VRF

systems, along with their modular design, zoned approach, heat recovery operation (on some systems), and use of variable-frequency-drive (VFD) compressors, provide comfort conditioning while being optimized to use less energy. VRF systems use industry-accepted refrigerants chosen for their performance and adherence to global protocols. Depending on design outdoor air conditions, building heating loads, and capabilities of the VRF system, the heat pump cycle alone may provide enough heating without adding electric resistance heat.

There has been an increased desire for buildings to be sustainable and energy efficient, and several rating systems and documentation requirements are available that can lead to a "green" building certification. Examples include the Leadership in Energy and Environmental Design (LEED®) certification program developed by the U.S. Green Building Council (USGBC), and the National Green Building Certification developed by National Association of Home Builders (NAHB) in partnership with the International Code Council. These rating systems focus on efficient use of several resources (e.g., water, energy, materials) and promote certain criteria such as an appropriately ventilated indoor environment.

VRF system design has the largest effect on energy use for LEED certification, and may help earn points in the following categories:

- Correct sizing.
- System control: VRF system operations can be controlled centrally through a web-based portal.
- Proper maintenance.
- Correct installation.
- Maximizing heat recovery potential.
- Zone control and energy performance optimization: VRF system operations such as airflow direction control, fan speed, and temperature set points can be controlled through a wall-mounted local remote controller, or centrally through web-based control. Many VRF systems use an inverter-driven compressor, feature simultaneous heating and cooling operation, and include an integrated control system that allows scheduling of equipment in each room. An energy recovery ventilator (ERV) can be installed to further reduce energy usage.
- Commissioning: a VRF controls network assists building commissioning by allowing easy testing, setting, and adjusting of the HVAC system.
- Measurement and verification: energy savings can be estimated using building energy modeling software and comparing the building design with a baseline as defined by ASHRAE *Standard* 90.1. Some VRF system manufacturers offer software or integration to building management systems for ongoing accountability and optimization of building energy consumption, and for monitoring and logging energy consumption, heat recovery cycles, static pressure, and ventilation air volumes. Actual energy usage data can be compared to the model.

VRF systems can also help obtain points for indoor air quality (IAQ):

- Some VRF systems can meet minimum outdoor air requirements through ventilation connections of the indoor units.
- In applications where more outdoor air is required, an ERV can be installed; when used with adequate air distribution from ducted units, this can increase ventilation rates above ASHRAE *Standard* 62.1 requirements.
- In a construction IAQ management plan, the ERV can be used to flush the building before occupancy.
- For indoor chemical and pollutant source control, many VRF system indoor evaporator units can be installed with a filter (consult a designer to ensure adequate static pressure is available to provide desired airflow performance). An ERV can also be integrated with a sensor to monitor CO_2 levels, and then operate accordingly.

7. COMMISSIONING

Effective commissioning of a VRF system is fundamental to future system performance (e.g., space comfort, operating efficiency, expected life cycle). The installed VRF system should be thoroughly pressure and vacuum tested before joints are insulated or closed in the wall, to identify leaks or other system related issues. Should system defects be identified, they must be resolved before the commissioning process can be completed. This resolution may involve repurging the lines with nitrogen, rebrazing piping connections, and/or reassembling flared joints, etc. Follow the manufacturer's recommendations on pressure and vacuum testing.

The VRF system should then be thoroughly evacuated to remove all air and moisture. Evacuation can also identify leaks that do not show up during pressure testing. Evacuation can take several days to effectively implement, especially if the system is large or contains a significant amount of moisture.

Accurately establishing and verifying the design system refrigerant charge is critical. Manufacturers piping design software typically provides the contractor with an additional system charge calculation based on liquid pipe length and diameter. Verification of total charge requirements based on the installed system parameters and via manual calculations as directed in equipment installation and operating documentation is recommended. Under- or overcharging can result in performance issues.

Because standard VRF systems are equipped with comprehensive diagnostic tools, the manufacturer's full commissioning procedure must be carried out to obtain full benefit and verify that the complete system is operating correctly in all modes. Detailed commissioning checklists should be completed to demonstrate that the procedure has been followed, and to record the data for future reference.

Air Dispersion Systems 19.12
Underground Ducts 19.12
Ducts Outside Buildings 19.13
Seismic Qualification 19.13
Sheet Metal Welding 19.13
Thermal Insulation 19.13
Specifications 19.13

THIS chapter covers construction of HVAC and exhaust duct systems for residential, commercial, and industrial applications.

1. BUILDING CODE REQUIREMENTS

New construction and renovation projects are normally governed by local ordinances or state laws requiring compliance with specific health, safety, property protection, or energy conservation regulations. The relationship between laws, ordinances, codes, and standards that affect design and construction of HVAC duct systems is shown in Figure 1 (note that the figure may not list all applicable regulations and standards for a specific locality). Local building ordinances typically invoke NFPA *Standard*s 90A and 90B, or some variation thereof, along with one or more national building codes for HVAC duct system construction and installation.

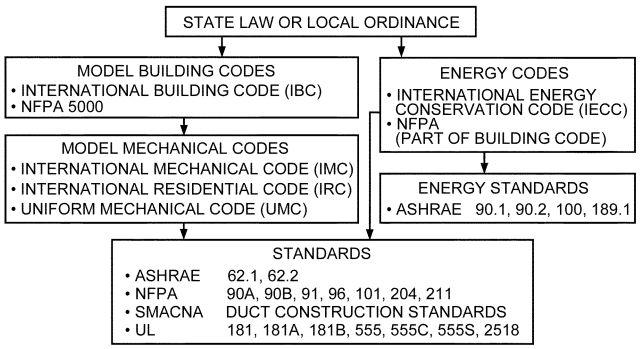

Fig. 1 Hierarchy of Building Codes and Standards

Since codes and standards are developed independently and revised on consistent or non-consistent schedules, the most recent edition of a code or standard may not have been adopted by a local jurisdiction or locality. Local jurisdictions may also include amendments and additions to various sections of a referenced building code. HVAC designers must know which code edition applies to their designs. If a provision conflicts with the design intent, the designer should resolve the issue with local building officials. New or different construction methods can be accommodated by the provisions for equivalency incorporated into codes.

2. PRESSURE CLASSIFICATIONS

Duct construction static pressure classifications typically used on contract drawings and specifications are summarized by Table 1. The classifications are from SMACNA (2020) for sheet metal ductwork, and NAIMA (2002a) for fibrous glass duct board. Negative-pressure flat oval duct systems can be designed by using 2500 Pa sheet gages with the negative-pressure rectangular duct reinforcement members mechanically attached or welded to the duct. The most common flexible air ducts and air connectors are listed up to 2500 Pa maximum positive-pressure ratings and anywhere from 125 to 500 Pa negative-pressure ratings, but there are listed flexible ducts with pressures as high as 4000 Pa and as low as –3000 Pa. Designers should refer to the specific flex duct manufacturer's recommended operating conditions for continuous performance recommendations.

Air conveyed by a duct adds both static pressure and velocity pressure loads on the duct's structure. The load from static pressure differential across the duct wall normally dominates and the mean static pressure is generally used for duct pressure classification. Turbulent airflow adds relatively low but rapidly pulsating loading on the duct wall.

The preparation of this chapter is assigned to TC 5.2, Duct Design.

Table 1 Pressure Classification for Ductwork[a]

	Static Pressure Class, Pa													
Type Duct	**+125**	**–125**	**+250**	**–250**	**+500**	**–500**	**+750**	**–750**	**+1000**	**–1000**	**+1500**	**–1500**	**+2500**	**–2500**
Rectangular	●	●	●	●	●	●	●	●	●	●	●	●	●	●
Round						●				●		●	●	●
Spiral flat oval													●	●[b]
Longitudinal flat oval													●	●[b]
Fibrous glass duct board[c]	●	●	●	●	●	●								
Flexible duct[d] (wire: helix type)	●	●	●	●	●	●	●	●	●	●	●	●	●	●

Notes:
[a]Columns with a dot indicate that construction standards are available for the pressure classes shown.
[b]Same reinforcement as rectangular duct, except reinforcement mechanically attached to duct.
[c]Fibrous glass duct board must be UL *Standard* 181 listed.
[d]Flexible duct must be UL *Standard* 181 listed and labeled.

Duct design is based on **total pressure** calculations as discussed in Chapter 21 of the 2021 *ASHRAE Handbook—Fundamentals*. From these calculations, the designer should specify the static pressure classification of the various duct sections in the system. All modes of operation must be considered, especially in systems used for smoke management and those with fire dampers that must close when the system is running.

3. DUCT CLEANING

Ducts can collect dirt and moisture, which can contribute to microbial growth. Design, construct, and maintain ducts and attached HVAC system components to minimize the opportunity for growth and dissemination of microorganisms. As described by NIH (2015), recommended control measures to reduce duct contamination include (1) locating air intakes away from contaminant sources, (2) providing and maintaining proper air filtration, (3) sealing ductwork during construction to prevent debris from entering, (4) inspecting new ductwork for oil or debris prior to system startup and cleaning if needed, and (5) implementing good housekeeping in occupied spaces.

Owners should routinely inspect ducts for cleanliness. If cleaning is needed, contaminant sources should be identified and controlled before cleaning is performed. NADCA (2021) and NAIMA (2002b) provide specific information and procedures for cleaning ducts. Fabric duct systems should be cleaned (washed) in accordance with manufacturer's instructions. To minimize air leakage after duct sections are opened or disconnected, attention should be given to properly closing, connecting, and resealing them (see the section on HVAC System Leakage). Also, any duct insulation removed must be replaced, and vapor barriers (if used) must be resealed.

Commentary: According to the Air Duct Council (ADC 2021), the "cleaning" of air ducts, including flexible ducts, has become a common practice. If cleaning of flexible ducts is undertaken, the ADC recommends that dust and debris be removed from inside flexible ducts by qualified technicians following procedures outlined by the National Air Duct Cleaners Association (NADCA) or other nationally recognized duct cleaning organization. ADC has investigated the removal of dust and debris from the inside of flexible ducts using the rotating brush and vacuum process per NADCA procedures. Investigation after the use of this process did not indicate damage caused to the inner liner of the flexible ducts caused by the cleaning process. ADC does caution that flexible duct inner liners may be damaged by overly aggressive contaminant removal techniques, such as high-pressure blow guns, air skipper, and air whips. When the process is completed, any flexible duct connections that were opened to clean the duct must be properly resealed to maintain airtightness and duct thermal properties. Whenever dust and debris removal from flexible ducts is considered, the owner should consider replacement, especially if the air distribution system is 15 years old or more. The opportunity to replace a duct system using new ducts that meet or exceed current R-value insulation requirements and much tighter installation methods would not only provide clean ducts, but also provide lower energy costs to operate the system.

4. HVAC SYSTEM LEAKAGE

For the purposes of this chapter, **ductwork** includes straight duct, flexible duct, sheet metal and rigid fiberglass plenums, and fittings (e.g., elbows, transitions, tees, wyes) for distribution and extraction of air. It does not include duct-mounted components (e.g., terminal units, access doors/panels, attenuators, coils, fire/smoke dampers, balancing and control dampers). A **system** consists of the supply air handler, return fan, exhaust fan, plenums, and all ductwork that connects the air handler to the conditioned space. The system also includes duct-mounted components where leaks through joints or penetrations can occur. However, leakage from the occupied space into a return air plenum is not included.

Commentary: Return air plenums are part of the air path from the conditioned space back to the air handler. Therefore, they are part of the system. As described in the examples that follow in this section, the thermal effects of unintended leakage directly from the supply system into the return plenum must be accounted for differently than if the supply system leaked directly to the conditioned space. UMC (2021) does not allow plenum return systems for health care facilities.

HVAC system air leakage increases building energy consumption. It also reduces the system's ability to control and deliver intended flows and pressures, and to manage the extraction and dilution of contaminants. Also, leakage can cause noise problems, drafts in the conditioned space, and dirt and dust deposits on the duct exterior. Leakage energy impacts depend on building and system type. For small buildings with single-zone air distribution systems served by equipment such as packaged rooftop cooling units and furnaces (e.g., houses, commercial buildings with floor area less than 2300 m^2), 75 to 95% of the HVAC site energy is used for space heating and cooling (Thornton et al. 2010; Walker and Sherman 2008; Zhang et al. 2010), and the impacts are mostly on the thermal side. For large buildings with central multizone air distribution systems served by equipment such as central chillers and boilers (e.g., mid- and high-rise offices, supermarkets and retail stores with a floor area of 2300 m^2 or more), 20 to 80% of HVAC site energy is used by fans (Huang et al. 1991; Leach et al. 2009, 2010) and the impacts are also on fan power. All these effects are strongly influenced by the location of leaks relative to conditioned space.

If supply air leaks to an unconditioned attic or crawlspace, or to the outdoors, the lost heating or cooling must be replaced. In this case, heating or cooling fluid flows or temperature differences must increase, or the system must run longer to meet the load. If, instead, supply air leaks to a ceiling return plenum adjacent to conditioned spaces, the fan must run faster or longer, and the largest impact may be on fan power. The heat associated with this added fan power also creates an additional cooling load. The effects of return leakage can also be significant. For example, leaks from a hot attic into a return duct heat the return air, which in turn reduces system cooling capacity.

Because the relationship between fan power and airflow is somewhere between a quadratic and cubic function, depending on the system type (Sherman and Wray 2010), an increase in airflow to provide the desired service and compensate for system leakage means that fan energy consumption increases significantly. Field measurements by Diamond et al. (2003) showed that a leaky VAV system (10% leakage upstream and 10% downstream of terminal box inlet dampers at operating conditions) uses 25 to 35% more fan energy than a tight system (2.5% upstream and 2.5% downstream at operating conditions). For an exhaust system with 20% leakage, the fan has to move 25% more air to meet the specified flows at the grilles, which causes fan power to increase 95%.

System Sealing

It is recommended that all ductwork and plenum transverse joints, longitudinal seams, and duct penetrations, including damper shafts, be sealed. Longitudinal seams are joints in the direction of airflow. Transverse joints are connections of two duct sections, with the connections oriented perpendicular to airflow. Openings for rotating shafts, wires, and pipes or tubes should be sealed with bushings or other devices that minimize air leakage but that do not inter-

fere with shaft rotation or prevent thermal expansion. Sealing that meets these requirements is in compliance with ASHRAE *Standards* 90.1-2022 and 189.1-2017, the *International Mechanical Code*® (IMC 2021), the *International Energy Conservation Code*® (IECC 2021), the *International Residential Code*® (IRC 2021), and the *Uniform Mechanical Code*® (UMC 2021). Spiral lock seams need not be sealed.

Sealing that would void product listings, such as for fire/smoke dampers, is not recommended. However, low-leakage duct-mounted components, including terminal units, reheat coils, and access doors, should be specified so that the combined HVAC system air leakage will not exceed criteria set by the designer, *ASHRAE Handbook*, standards, and codes. For example, some manufacturers of UL-listed and -labeled fire/smoke dampers allow sealing and gasketing of breakaway duct/sleeve connections; all can provide sealed non-breakaway duct/sleeve connections.

Sealants

General. All tape, mastic, rolled mastic sealants, aerosol/spray applied sealants, gaskets, and nonmetallic mechanical fasteners should

- Be used in compliance with the manufacturer's instructions
- Be tested to UL *Standard* 723 (ASTM *Standard* E84) and have a flame spread index equal to or less than 25 and a smoke developed index equal to or less than 50
- Maintain their airtightness over the service life of the component to which they are applied

Sheet Metal Ductwork. All joints, longitudinal and transverse seams, and connections in sheet metal ductwork should be securely fastened and sealed with welds, gaskets, tapes, mastics, mastic-plus-embedded-fabric systems, rolled mastic sealants, or aerosol sealants. Sealants should be (1) UL listed, labeled, and used in accordance with their listing; and (2) tested for durability using the accelerated aging procedure in ASTM *Standard* E2342. Sherman (2005) recommended that the time-to-failure acceptance criterion should be at least 60 days, because this time period delineated which tapes failed early using accelerated aging compared to tapes that lasted much longer.

Tapes should be used only on joints between parallel surfaces, or on right-angle flat joints. If mastic or tape is used to seal openings greater than 6 mm, the combination of mastic or either mesh or tape should be used. Heat-sensitive and heat-activated tapes, which are designed specifically to seal fibrous glass ductboard, should not be used as a sealant on metal ducts. Cloth-backed, rubber-adhesive duct tape should not be used, regardless of UL designation, unless such tape is used in combination with mastic and draw bands or it has been approved by the authority having jurisdiction for use without mastic.

For exterior applications, mastics should be tested using ASTM *Standard* C732 artificial weathering tests and show no signs of visible degradation (e.g., washout, slump, cracking, loss of adhesion) after being exposed to artificial weathering.

Commentary: Apart from UL *Standard* 723, there is no UL standard for sealant performance when it is applied to sheet metal ductwork. It is recommended that a standard be developed for sheet metal applications and it should include or refer to a durability test.

Rigid Fiberglass Ductwork. Rigid fiberglass ductboard should be sealed following the NAIMA (2002a) standard using materials listed and labeled to the UL *Standard* 181A standard. There are three closure and air sealing systems for fiberglass duct board. The first two use tapes (marked "181A-P" or "181A-H"); the third system is a fiberglass mesh and mastic system (marked "181A-M"). In the latter case, a layer of mastic is applied to the joint, a strip of fiberglass mesh is embedded into the mastic, and then a finish coat of mastic is applied over the mesh.

Flexible Duct. Tapes and mastics used to close flexible air ducts and air connectors should be listed and labeled to UL *Standard* 181B, Part 1 or Part 2; be marked "181B-FX" or "181B-M," respectively; and be used in accordance with their listing.

Mechanical fasteners for use with nonmetallic flexible air ducts and air connectors should be either stainless steel worm-drive gear clamps or nonmetallic straps listed and labeled to UL *Standard* 181B, Part 3, and be marked "181B-C." Nonmetallic fasteners should have a minimum tensile strength rating of 670 N and be suitable for continuous use at the maximum temperature to which they will be exposed. When nonmetallic fasteners are used, beaded fittings are required, and the maximum duct positive operating pressure should be limited to 1500 Pa.

Commentary: Sherman (2005) showed that some nonmetallic flexible duct core-to-collar clamps have unacceptable high-temperature performance. Most of the standard nylon straps failed before the two-year test period was completed. Sherman concluded that UL *Standard* 181B testing of these clamps does not adequately address this issue, and recommended that straps be rated for continuous use at 93°C. A more flexible requirement is that they be suitable for continuous use at the maximum temperature to which they will be exposed. A new test method for determining the durability of clamping systems should be developed to test the actual failure modes found in the field. Such a test could be incorporated in UL testing or be a separate ASTM (or equivalent ANSI) test method.

Leakage Testing

Rationale. System leakage testing, including ducts and duct-mounted components, is recommended, because leakage data collected by researchers over several years (1998 through 2004) for 10 systems in nine U.S. large commercial buildings (see Figure 2 in Wray et al. [2005]) showed that seven had substantial leakage flows (10 to 26%). The other three systems had much smaller leakage flows (3 to 4%). These data include variable-air-volume (VAV), constant-air-volume (CAV), and dual-duct systems, and both high-pressure (main) and low-pressure (branch) system sections. The distinction between main and branch sections is their location relative to terminal box inlet dampers. For VAV systems, data include fan-powered and cooling-only boxes. Most systems supplied air through square diffusers, but some used slot diffusers. Ductwork pressurization tests conducted by Lawrence Berkeley National Laboratory (LBNL) on the same nine buildings at a test pressure of 250 Pa also showed that, on average, the leakage area for branches was about three times more than for mains (see Figure 1 in Wray et al. [2005]).

Scope. It is recommended that supply air (both upstream and downstream of the VAV box primary air inlet damper, when used), return air, and independent exhaust air systems be tested for air leakage at operating conditions to verify (1) good workmanship, and (2) the use of low-leakage components as required to not exceed the maximum allowable system air leakage. An independent exhaust air system comprises air discharged from a space to the outdoors by a system not coupled to supply or return air systems.

Testing these particular systems is important because of the potentially significant energy impacts. As a minimum, 25% of the system, based on duct surface area, should be tested and another 25% if any of the initial sections fail. If any section of the second 25% fails, the entire system should be tested. Sections should be selected randomly by the owner's representative. These leakage tests should be conducted by an independent party responsible to the owner's representative after the system sections to be tested are

fully assembled but before the installation of insulation and concealment of ductwork.

To ensure that a system passes its air leakage test at operating conditions, ductwork sections should be leak tested by pressurization during construction. To supplement these construction-phase tests, leakage of duct-mounted components should be determined by specification and certified leakage data provided with equipment submittals. Leakage of air-handling units should be determined by specification and verification leakage tests.

Procedures. Test procedures based on ductwork pressurization should comply with industry practice (e.g., AABC 2016, Chapter 5; ASHRAE *Standard* 126-2020: Section 7; EUROVENT 2/2 1996; SMACNA 2012: Sections 4, 6, and 7).

Leakage test procedures currently used by industry focus on determining component airtightness (e.g., for supply air ductwork located upstream of terminal box inlet dampers). Airtightness alone, however, is insufficient to determine leakage airflows. It is important to also then estimate system pressures during operation to fully determine these flows. Determining the location of every leak and the pressure difference across individual leaks is practically impossible for most systems, and such an approach can lead to significant uncertainty and error.

To eliminate the uncertainty associated with estimating pressure differences across leaks, ASHRAE *Standard* 215-2018 (RA 2021) provides a method of test for determining leakage airflows and fractional leakage during system operation (either for the whole system or for selected parts). Flows into and out of the section being tested are measured at a repeatable reference operating condition: the only variable is leakage flow. It can be used for both new and existing buildings, but is currently limited to single-duct supply and independent exhaust air systems. The method outlined in this standard does not replace ductwork pressurization leakage testing.

Acceptance Criteria. It is important to differentiate between standards that describe how ducts or systems are to be pressure tested for leakage (e.g., AABC 2016, Chapter 5; ASHRAE *Standard* 126-2020: Section 7; EUROVENT 2/2 1996; SMACNA 2012: Sections 4, 6, and 7) and standards that dictate maximum permitted leakage (e.g., ASHRAE *Standard* 90.1-2022; 2022 California Green Building Standards Code). The former may contain recommendations for the amount of leakage that can be expected for certain types of construction. However, these recommendations should not be mistaken for the maximum permitted leakage in building codes, energy codes, or owner requirements. It is recommended that duct and system leakage requirements be clearly stated in the contract documents.Figure 2

To enable proper accounting of leakage-related impacts on fan energy use and space conditioning loads, the design engineer should establish the maximum allowable system leakage for each fan system as a percentage of fan airflow at a reference system operating condition. Recommended test pressures and maximum system leakage fractions are shown in Table 2.

Five percent system leakage is attainable in large commercial buildings, as evidenced by the supply systems with low leakage (3 to 4%) reported by Wray et al. (2005). Also, Wray and Matson (2003) indicate that system leakage operating cost impacts are about $1.50 to $1.94 per square metre of duct surface area for a 20% leaky supply system compared to a 5% leaky system in a large commercial building with ceiling return plenums. System sealing costs vary with fitting-to-straight-duct ratio, pressure class, and other system variables. According to Tsal et al. (1998), an upper bound for the one-time cost of duct sealing is $2.71/m^2 of duct surface area. Using these costs, the payback period for achieving 5% leakage compared to 20% leakage is about 1 to 2 years. The recommended 5% value may be modified when further life-cycle cost analysis data become available.

Supply and return sections that leak to/from outdoors should be tighter than indoor sections, because the added thermal losses/gains from these leaks increase energy impacts. For example, an airtight VAV supply system with a design fan pressure rise of 1000 Pa, a design fan flow of 6600 L/s, and a total efficiency of 60% will require about 11,000 W of power. With 5% leakage and applying an exponent of 2.4 to the flow ratio (1.05), the fan power increases by about 12% or 1400 W. Assuming that 12.8°C air is supplied to maintain a room temperature of 23.3°C, the supply air energy lost to outdoors by the 350 L/s of leakage is about 4600 W and the total energy impact of the leakage is about 6000 W. To achieve the same total energy impact as only the fan power increase with 5% leakage, leakage for the outdoor sections would need to be limited to about 1%.

However, this analysis is overly simplified, because it ignores the thermal impacts of leakage if the supply sections were located indoors instead. In some cases, the thermal impacts of leakage from indoor sections may be as much as the related fan power impacts. Accounting for these thermal effects is more complicated because of interactive system effects (e.g., supply-leakage-related cooling of a ceiling return plenum, which in turn reduces ceiling heat transfer to adjacent cooler conditioned spaces, and thus reduces supply airflows needed to manage space cooling loads). Energy simulation programs have been used to conduct detailed analyses of the time-varying thermal and fan power effects of supply leakage in large commercial buildings (e.g., Wray and Matson 2003; Wray and Sherman 2010). The simulation results are generally consistent with field measurements (e.g., Diamond et al. 2003), but further validation of coupled load and system leakage models, such as those in EnergyPlus, is still needed.

For buildings without static pressure control of the conditioned space (e.g., a midrise apartment building), exhaust sections that draw in indoor air through leaks need to be tighter than outdoor exhaust sections because the leakage flow also tends to depressurize the building and increase building air infiltration (assuming that the fan has been adjusted to still provide the design airflow at the exhaust inlets). The ratio of the change in infiltration flow to the change in exhaust flow from leakage depends on environmentally driven pressures, which can vary widely depending on weather. A reasonable average for this ratio is about 0.6 (Woolley et al. 2014). For example, an exhaust system with a design fan pressure rise of 500 Pa, a design fan flow of 2360 L/s, and a total efficiency of 60% requires about 2300 W of power. With 5% leakage and applying an exponent of 3 to the flow ratio (1.05), the fan power increases by about 16%, or 310 W. Using a ratio of 0.6, the change in infiltration due to the 5% leakage (about 123 L/s) will be about 75 L/s. If the outdoor design temperature is 0°C and the conditioned space is heated to a temperature of 22.2°C, the energy associated with increased infiltration is about 3900 W and the total energy impact of the leakage is about 4200 W. To achieve the same total energy impact as only the fan power increase with 5% leakage, leakage in this case will need to be limited to about 0.4%. Even tighter systems are required for colder outdoor design temperatures, whereas outdoor temperatures closer to the conditioned space temperature will allow more leakage (to a maximum of 5%).

As a compromise so that the designer does not need to carry out additional calculations for supply and return sections that leak to/from outdoors and for exhaust sections that draw in indoor air through leaks, it is recommended that leakage for these sections be limited to 2%.

Leakage Class. Leakage class, as specified by ASHRAE *Standard* 90.1-2022, can be translated to fractional (%) leakage using Equation (1) or Table 3.

Table 2 Recommended Maximum System Leakage Percentages

Type of System	System Condition	Test Pressure,[a,b] Pa	Maximum Fan System[c] Leakage
1. Fractional kilowatt systems, small exhaust/return systems, residential systems	Operating	Operating pressure	5%
	During construction	125	5%
2. Single-zone supply, return, or exhaust systems	Operating	Operating pressure	5%
	During construction	500	5%
3. Multizone supply, return, or exhaust systems	Operating	Operating pressure	5%
	During construction	500	5%
4. Dual-duct supply systems, both hot and cold ducts	Operating	Operating pressure	5%
	During construction	1500	5%
5. VAV[d] and CAV[d] supply systems	Operating	Operating pressure	5%
	During construction	Upstream box: 1000	5%
		Downstream box: 250	5%
6. VAV[d] or CAV[d] return systems	Operating	Operating pressure	5%
	During construction	Downstream box: 750	5%
		Upstream box: 250	5%
7. Chilled-beam systems	Operating	Operating pressure	5%
	During construction	1000	5%
8. High-pressure induction systems	Operating	Operating pressure	5%
	During construction	1500	5%
9. Supply and return ductwork located outdoors	Operating	Operating pressure	2%
	During construction	750	2%
10. Exhaust ductwork located indoors	Operating	Operating pressure	2%
	During construction	750	2%
11. Air-handling units	Site test by manufacturer	Specified design pressure	1%

Notes:

[a]Test pressure should not exceed duct pressure rating.
[b]It is recommended that duct pressure rating equal fan shutoff pressure if possibility of fan shutoff exists either in VAV systems or in systems with smoke/fire damper control.
[c]A fan system includes ductwork upstream and downstream of the fan. The fan system also includes components mounted to that ductwork where leaks through joints or penetrations can occur. However, leakage from the occupied space into a return air plenum is not included. Separate leakage specifications should be used for upstream and downstream sections.
[d]Assuming primary air damper located at box inlet. If damper is at box outlet, then box should be included in upstream leakage testing.

$$Q_{leak,frac} = 100 \frac{C_L \Delta p^{0.65}}{Q_{fan,norm}} \quad (1)$$

where

$Q_{leak,frac}$ = leakage fraction of fan airflow, %
C_L = leakage class, L/s per $Pa^{0.65}$ per 10 m^2 of duct surface area
Δp = system pressure difference, Pa
$Q_{fan,norm}$ = normalized fan airflow, L/s per m^2 of duct surface area

For example, for a leakage class of 0.0056 L/s per $Pa^{0.65}$ per m^2 of duct surface area with a pressure difference of 750 Pa and an inlet flow of 10.2 L/s per m^2 of duct surface area, the fractional leakage is 4.1%. For a pressure difference of 1500 Pa, the fractional leakage is 6.4%.

Calculating Test Section Allowable Leakage. Determine from the drawings the airflow and duct surface area in each section and then calculate the allowable leakage (see Example 1).

If an entire system or section of ductwork is not to be tested, determine the allowed leakage in the test section. To do this, determine the surface area of the test section, and divide that by the total surface area of the entire section. Multiply this test section leakage percentage by the section airflow to determine the test section leakage airflow.

Example 1. A system consists of three sections, with airflow and surface areas as summarized in Table 4. Determine the allowable leakage for a 836 m^2 surface area section of Section 1 identified by the owner's representative. Branch 3 is located outdoors.

Solution. Table 5 summarizes the calculations. By test, the 464 m^2 test section cannot exceed 330 L/s at 1000 Pa.

Responsibilities

Refer to definitions of terms **ductwork** and **system** found at beginning of HVAC System Leakage section.

The **engineer** should

- Specify HVAC system components, duct-mounted equipment, accessories, sealants, and sealing procedures that together can meet the system airtightness design objective.
- Inspect the system during construction for quality of workmanship and to verify that correct duct-mounted components and air-handling units are installed.
- Specify the *construction-stage* ductwork leakage test standard or procedures
- Specify the *construction-stage* test pressures to the nearest 25 Pa that are expected during operation at design conditions and that do not exceed the pressure class rating of the ductwork.
- Specify the *construction-stage* maximum allowable leakage class for ductwork, and the maximum allowable leakage for system components, duct mounted equipment, and accessories.
- Specify the maximum allowable *operating system* leakage airflow, the corresponding fractional leakage, and their maximum allowable uncertainty, as determined using ASHRAE *Standard* 215-2018 (RA 2021).
- Review and approve the sheet metal and test contractors' leakage test reports. If any system has a leakage failure, the engineer should discuss remedies with the sheet metal contractor, vendor, and/or owner's representative.

Table 3 Leakage as Percentage of Flow

Airtightness Class EUROVENT,* L/s per 10 m² per Pa^0.65	Q_{fan}/A_S, L/(s·m²) Duct Surface Area	Static Pressure, Pa								
		125	250	500	750	1000	1250	1500	2000	2500
K (0.81)	10.2	18.4	28.9	45.3	58.9	71.1	82.2	92.5	100	100

	15.2	0.2	0.2	0.4	0.5	0.6	0.7	0.8	0.9	1.1
	20.3	0.1	0.3	0.3	0.4	0.4	0.5	0.6	0.7	0.8
	25.4	0.1	0.1	0.2	0.3	0.4	0.4	0.5	0.6	0.6

*Airtightness classes K and D are not EUROVENT 2/2 (1996) designations, but are used by some countries in Europe.

Table 4 Example 1 System Parameters

Section	Airflow, L/s	Surface Area, m²	L/(s·m²)	Allowable Leakage, %	Allowable Leakage, L/s
1 (main)	11 800	836	14.1	5	590
2 (branch)	4 700	372	12.6	5	235
3 (branch)	7 100	464	15.3	2	142
Total	23 600	1672	14.1	4.1	967

Table 5 Solution for Example 1

Section	Surface Area, m²		Test Section Leakage, % (Test Section Area Fraction, m² / Section Surface Area, m²)	Section Airflow, L/s	Allowable Leakage, %	Allowable Leakage, L/s
1 (main)	Under test	464	0.56	6608	5	330
	Not tested	372	0.44	5192	5	260
Total		**836**	**1.00**	**11 800**	**5**	**590**

The **sheet metal contractor** should

- Construct the system using quality workmanship and correct duct-mounted components and air-handling units. If any installed duct-mounted equipment appears to be leakage suspect, the contractor should discuss remedies with the engineer and/or owner's representative.
- Conduct *ductwork* leakage pressurization tests during *construction*. As a minimum, 25% of the ductwork (based on duct surface area) should be tested during construction, and another 25% if any of the initial sections fail. If any section of the second 25% fails, all of the ductwork should be leak tested.
- Provide connections for test apparatus, and separate test sections from each other as needed so that the test apparatus capacity is not exceeded.

- Report test results and, where required, take corrective action to seal ductwork and absorb the cost for conducting related additional leak tests.

The **test contractor** should

- Conduct the *operating system* leakage test in compliance with ASHRAE *Standard* 215-2018 (RA 2021).
- Report test results, including reasons for any failures.

It should be the responsibility of the **owner or owner's representative** to provide direction upon request.

5. AIR-HANDLING UNIT LEAKAGE

Custom-designed air-handling units (AHUs) should be leak tested after the AHU is reassembled on site with all penetrations (e.g., for controls, electrical, and piping) in place and sealed. Leakage tests should be conducted by the AHU manufacturer in accordance with ASHRAE *Standard* 126-2020, Section 7, at design operating pressures (positive and negative) specified by the design engineer, and be witnessed by a representative of the owner. AHUs should be shipped with blankoffs and a round flanged opening for the flow meter/blower leakage test unit.

It is recommended that packaged AHUs also be leak tested. The casing leakage for AHUs should not exceed 1% of design airflow at the specified design pressure.

6. RESIDENTIAL AND COMMERCIAL DUCT CONSTRUCTION

Terminology

Construction materials for nonmetallic rigid and flexible ducts are listed in UL *Standard* 181.

Air duct. A rigid or flexible duct that passes all applicable UL *Standard* 181 tests. These tests include surface burning characteristics (ASTM *Standard* E84), flame penetration, burning, corrosion, mold growth and humidity, temperature, puncture, static load, impact, erosion, pressure, collapse, tension, torsion, bending, and leakage. Flexible air ducts are identified with a square or rectangular listing mark indicating the product is a Class 0 or Class 1 air duct.

Air connector. A flexible duct tested to 13 of the 16 required UL *Standard* 181 tests. Flame penetration, impact, and puncture testing are not required for air connector approval. Flexible air connectors are identified with a round listing mark indicating the product is a Class 0 or Class 1 air connector.

Class 0. Air duct or air connector having a flame spread index and smoke developed index of zero determined in accordance with UL *Standard* 723 (ASTM *Standard* E84).

Class 1. Air duct or air connector having a flame spread index not over 25, without evidence of continued progressive combustion, and a smoke developed index of not over 50, determined in accordance with UL *Standard* 723 (ASTM *Standard* E84).

Flexible air connector. See *air connector*.

Flexible air duct. See *air duct*.

Flexible duct. A *flexible air duct* or *flexible air connector*.

Commentary:

1. Listed flexible air ducts and flexible air connectors are required by UL 181 to have a listing label applied every 3.0 m or fraction thereof during the manufacturing process as part of their listing. However, installed ducts can be shorter than 3.0 m; thus, a label might not be present under the current labeling requirements.
2. It is recommended that UL 181 markings be increased in size, prominence, and frequency to facilitate verification of duct classification between flexible air duct and flexible air connector.

Specifications should indicate the requirement for the use of flexible air ducts or flexible air connectors as appropriate for the conditions under which they are to be installed.

Buildings and Spaces

Typically, codes (IMC, IRC, UMC, IAPMO) and local ordinances invoke NFPA *Standards* 90A and 90B or some variation thereof. NFPA *Standard* 90A covers the following buildings and spaces:

- Buildings of combustible construction (Types III, IV and IV; for definition of construction types, see IBC [2015], Chapter 6) over three stories in height, regardless of volume
- Spaces over 708 m^3 in volume
- Buildings and spaces not covered by other applicable NFPA standards

NFPA *Standard* 90B covers the following dwellings and spaces:

- One- and two-story dwellings
- Spaces not exceeding 708 m^3 in volume in any occupancy

NFPA 90A Materials. Ducts must be constructed of steel, aluminum, copper, concrete, masonry, clay tile, or Class 0 or Class 1 flexible air duct tested in accordance with UL *Standard* 181 and installed in conformance with the conditions of their listing. Flexible ducts must not be used as vertical ducts serving more than two adjacent stories in height and must not penetrate fire-resistance-rated assemblies or construction.

Steel and aluminum construction must comply with *SMACNA Duct Construction Standards—Metal and Flexible* (2005). Refer to Tables 6A, 6B, and 6C for the relationship between gage and nominal/minimum thickness for galvanized steel, uncoated steel, and stainless steel sheet thickness. For galvanized ducts, a Z180 coating (ASTM *Standard* A653M) is commonly used for dry indoor applications because the small amount of corrosion that may occur causes only discoloration in 20 to 30 years. For outdoor exposures or wet indoor applications, the galvanized duct coating should be Z270 minimum. The average years to first rust for Z275 coatings located outdoors depends on the environment: 3 to 7 years for severe industrial, 15 to 20 for rural, 7 to 10 for Atlantic coast marine, 12 for suburban, and 10 for urban (Stratton 2000).

NFPA 90B Materials. Supply ducts must be made of the following materials:

- Galvanized steel or aluminum having a minimum thickness per the standard/code having jurisdiction (NFPA 90B [2021: Table 4.5.1.1.1]; IMC [2021: 603.4], IRC [2021: Table M1601.1.1]; UMC [2021: Article 602.1]), or
- Class 0 or Class 1 rigid or flexible air duct tested in accordance with UL 181 and installed in conformance with the conditions of their listing. Rigid or flexible ducts must not be used as a vertical duct that is more than two stories in height and must not penetrate fire-resistance-rated assemblies or construction.

Return ducts governed by NFPA 90B (2021) must be constructed of metal, 25 mm nominal wood boards, or other material provided that the material is not more flammable than 25 mm wood boards. Return ductwork under the jurisdiction of a code is commonly constructed in accordance with SMACNA (2020). For galvanized ducts, a Z180 coating is recommended (ASTM *Standard* A653M).

Commentary. UMC (2021) and IAPMO (2018) do not have steel duct construction requirements for single-dwelling units.

For spaces not exceeding 708 m^3 in volume (light commercial), it is recommended that duct systems be Z180 minimum galvanized

Table 6A Galvanized Sheet Thickness

Gage	Thickness, mm		Nominal Mass, kg/m²
	Nominal	Minimum*	
30	0.399	0.319	3.20
28	0.475	0.395	3.81
26	0.551	0.471	4.42
24	0.701	0.601	5.64
22	0.853	0.753	6.86
20	1.066	0.906	8.08
18	1.311	1.181	10.52
16	1.613	1.463	12.96
14	1.994	1.784	16.01
13	2.372	2.162	19.07
12	2.753	2.523	22.12
11	3.132	2.902	25.16
10	3.510	3.280	28.21

*Minimum thickness is based on thickness tolerances of hot-dip galvanized sheets in cut lengths and coils (per ASTM *Standard* A924M). Tolerance is valid for 1220 and 1524 mm wide sheets.

Table 6B Uncoated Steel Sheet Thickness

Gage	Thickness, mm			Nominal Mass, kg/m²
		Minimum*		
	Nominal	Hot-Rolled	Cold-Rolled	
28	0.378		0.328	3.05
26	0.455		0.405	3.66
24	0.667		0.587	4.88
22	0.759		0.679	6.10
20	0.912		0.832	7.32
18	1.214	1.084	1.114	9.76
16	1.519	1.369	1.389	12.20
14	1.897	1.717	1.767	15.25
13	2.278	2.101	2.456	18.31
12	2.656	2.456	2.506	21.35
11	3.038	2.838	2.888	24.40
10	3.416	3.216	3.266	27.45

Note: Table is based on 1220 mm width coil and sheet stock; 1524 mm coil has same tolerance, except that 16 gage is ±0.18 mm in hot-rolled coils and sheets.
*Minimum thickness is based on thickness tolerances of hot-rolled and cold-rolled sheets in cut lengths and coils (per ASTM *Standards* A1008M, A568M, and A1011M).

Table 6C Stainless Steel Sheet Thickness

Gage	Thickness, mm		Nominal Mass, kg/m²	
			Stainless Steel	
	Nominal	Minimum*	300 Series	400 Series
28	0.384	0.334	3.09	3.04
26	0.452	0.372	3.65	3.58
24	0.597	0.517	4.82	4.72
22	0.744	0.644	6.01	5.89
20	0.902	0.802	7.28	7.14
18	1.219	1.089	9.84	9.65
16	1.511	1.361	12.20	11.96
14	1.908	1.728	15.39	15.10
13	2.286	2.056	18.45	18.10
12	2.677	2.447	21.60	21.19
11	3.048	2.798	24.60	24.13
10	3.429	3.129	27.67	27.14

*Minimum thickness is based on thickness tolerances for hot-rolled sheets in cut lengths and cold-rolled sheets in cut lengths and coils (per ASTM *Standard* A480M).

steel, aluminum, or stainless steel in compliance with SMACNA (2020) or flexible duct in compliance with UL 181.

Round, Flat Oval, and Rectangular Ducts

Round Ducts. Round ducts are inherently strong and rigid, and are generally the most efficient and economical ducts for air systems. The dominant factor in round duct construction is the material's ability to withstand the physical abuse of installation and negative pressure requirements. SMACNA (2020) lists construction requirements as a function of static pressure, type of seam (spiral or longitudinal), and stiffeners if required. Proprietary joint systems are available from several manufacturers. *Round Industrial Duct Construction Standards* (SMACNA 2013) provides pressures from 7.5 kPa up to 12.5 kPa.

Flat Oval Ducts. SMACNA (2020) also lists flat oval duct construction requirements. Seams and transverse joints are generally the same as those allowed for round ducts. However, proprietary joint systems are available from several manufacturers. Flat oval positive- and negative-pressure ducts should meet the functional requirements of Section 3.3 of SMACNA (2020). Hanger designs and installation details for rectangular ducts generally also apply to flat oval ducts.

Rectangular Ducts. *HVAC Duct Construction Standards—Metal and Flexible* (SMACNA 2020) lists construction requirements for rectangular steel ducts and includes combinations of duct thicknesses, maximum distance between reinforcements, and support length. Transverse joints (e.g., standing drive slips, pocket locks, and companion angles) and, when necessary, intermediate structural members and tie rods are designed to reinforce the duct system. Proprietary joint systems are available from several manufacturers. *Rectangular Industrial Duct Construction Standards* (SMACNA 2007) provides pressures up to ±37 kPa.

Fittings must be reinforced similarly to sections of straight duct. On size change fittings, the greater fitting dimension determines material thickness. Where fitting curvature or internal member attachments provide equivalent rigidity, such features may be credited as reinforcement.

Nonferrous Ducts. SMACNA (2020) lists construction requirements for rectangular (±750 Pa) and round (±500 Pa) aluminum ducts. *Round Industrial Duct Construction Standards* (SMACNA 2013) gives construction requirements for round aluminum duct systems for pressures up to ±7.5 kPa12.5 kPa.

Fibrous Glass Ducts

Fibrous glass ducts are a composite of rigid fiberglass and a factory-applied facing (typically aluminum or reinforced aluminum), which serves as a finish and vapor retarder. Fibrous glass ducts must be constructed from UL Class 1 air duct material in accordance with the manufacturer's instructions and meet the requirements of UL *Standard* 181 for rigid air ducts. Fibrous glass duct are available in molded round sections or in board form for fabrication into rectangular or polygonal shapes.

Duct systems of round and rectangular fibrous glass are generally limited to 12 m/s and ±500 Pa. Molded round ducts are available in higher pressure ratings. *Fibrous Glass Duct Construction Standards* (NAIMA 2002a; SMACNA 2021) and manufacturers' installation instructions give details on fibrous glass duct construction. SMACNA (2021) also covers duct and fitting fabrication, closure, reinforcement, and installation, including installation of duct-mounted HVAC appurtenances (e.g., volume dampers, turning vanes, register and grille connections, diffuser connections, access doors, fire damper connections, electric heaters). AIA (2006) includes guidelines for using fibrous glass ducts in health care facilities.

Phenolic Ducts

A phenolic duct system comprises phenolic panels, fabrication methods, coupling systems, and accessories to produce preinsulated rectangular ductwork in sections up to 4 m long. Phenolic panels are 22 mm thickness and 30 mm thickness (SMACNA 2015). Phenolic ducts must be UL Class1 and meet the requirements of UL *Standard* 181 for rigid air ducts.

Phenolic panels comprise a fiber-free rigid thermoset phenolic insulation core faced with silver aluminum foil on one side and plain silver aluminum foil on the other. In addition, there are several transverse joint systems available to suit different installation and project specification requirements. They include panel fastener systems, aluminum grip type flange systems, and a four-bolt system.

Technical data for such ducts are necessary to properly design air distribution duct systems. To address that issue, RP-1764 (ASHRAE 2018) measured the relative and absolute roughness of phenolic duct systems connected with a four-bolt flange and cleat joint. An experimental program was conducted to measure the relative and absolute roughness of phenolic duct systems connected with a four-bolt flange and cleat joint. Ducts with seven distinct rectangular cross sections (internal aspect ratios $1 \leq W/H \leq 4$) were investigated. In every instance, the duct material thickness was 22 mm, with smooth aluminum foil covering the internal surface between flanges. For unreinforced phenolic ducts with 3.0 m sections connected by four-bolt flanges, the relative roughness $\varepsilon/\Delta h$ ranged from 0.0002 to 0.0005, with an average value of 0.0003. For similar ducts having 1.5 m duct sections (double the number of flanges per test section), the relative roughness range and average doubled. It appears that the flanges are the dominant effect on relative roughness and that the ducts tested have about 1.5 to 2.8 times more absolute roughness than the average value for galvanized steel ducts described in the *ASHRAE Handbook*. One additional case considered in RP-1764 indicated that the zero-length loss coefficient for an individual internal cross reinforcement $C = 0.080$, assuming that each reinforcement assembly contributed equally to the overall pressure loss in the test section. When compared at the same volume flow rate to unreinforced ducts, the presence of internal cross reinforcements more than doubled the measured pressure loss per unit length, for the specific geometry of reinforcement and duct cross section considered. Note that the resulting loss coefficient applies only to the specific geometry of reinforcement and duct cross section considered in RP-1764, and further investigation is suggested if other types of reinforcement are used.

Flexible Ducts

Flexible ducts are categorized by their UL listing as either **air duct** or **air connector** (see the section on Definitions). Air ducts and air connectors may be metallic or nonmetallic and are listed and labeled as Class 0 or Class 1 by UL *Standard* 181. These ducts must be installed per the conditions of their listing and the manufacturer's installation instructions provided. The maximum allowed temperature inside flexible ducts (air ducts and air connectors) is 121°C per their listing and NFPA 90A and 90B requirements.

Commentary: The IMC (2021), IRC (2021), and UMC (2021) require installation instructions on or within the package or there must be specific directions referring to the manufacturer's web site for instructions. Generally, minimum instructions are provided on or inside the package, with reference to the website for more detailed instructions. Also see the section on Installation.

Flexible Air Connectors. Air connectors are limited-use flexible ducts that can be used in lieu of air ducts in NFPA 90A and 90B buildings provided that they comply with the following limitations:

1. Length does not exceed 4.3 m. Connecting multiple sections of flexible air connectors using sheet metal couplings to obtain a total air connector run greater than that allowed by code is not allowed.
2. The flexible air connector does not pass through any wall, partition, or enclosure of a vertical shaft having a fire resistance rating of 1 hour or more.
3. The flexible air connector does not pass through floors.
4. An air connector shall not be interrupted by a short collar or any other fitting on one side and then connected to another air connector on the other side where penetrating a floor or a wall, partition, or enclosure of a vertical shaft that is required to have a fire-resistance rating of 1 hour.

Commentary:

- Uniform Mechanical Code (UMC 2021) limits flexible air ducts and flexible air connectors to no longer than 1.5 m in length for nonresidential systems and does not allow their use in lieu of rigid elbows or fittings, except when connected to terminal devices.
- In addition to NFPA 90A (2021) and 90B (2021), the International Mechanical Code (IMC 2021) also limits flexible air connectors to 4.3 m in length.

For commercial systems, Chapter 21 of the 2021 *ASHRAE Handbook—Fundamentals* recommends flexible ducts be limited to 2 m maximum, fully stretched.

Hangers and Supports

SMACNA (2020) covers HVAC system hangers for rectangular, round, and flat oval ducts. When special analysis is required for larger ducts, loads, or other hanger configurations, AISC and AISI design manuals should be consulted. To hang or support fibrous glass ducts, the methods detailed by NAIMA (2002a) and SMACNA (2021) are recommended.

Flexible air ducts and flexible air connectors should be supported at intervals not exceeding 1.2 m when installed horizontal and 1.8 m when installed as vertical risers. Flexible duct supports should be minimum 38 mm wide and of sufficient rigidity to maintain this width to prevent any restriction of the internal duct diameter when the weight of the supported section rests on the hanger. Cloth hangers should not be used.

Installation

Sheet metal ducts must be installed in accordance with *HVAC Duct Construction Standards—Metal and Flexible* (SMACNA 2020).

Fibrous glass ducts must be installed in accordance with the industry fibrous glass duct construction standards (NAIMA 2002a; SMACNA 2021).

Flexible ducts must be installed in accordance with *Flexible Duct Performance and Installation Standards* (ADC 2021), and as follows:

1. Owner's representative should review flexible duct markings to verify that the flexible duct is (1) a UL listed "Air Duct" or "Air Connector," and (2) installed per applicable code limitations.
2. Flexible air ducts and flexible air connectors should be installed fully extended with minimal compression. Excess length should not be allowed for future relocation of VAV boxes, registers, or other system components.
3. Install flexible ducts so that bends equal or exceed one duct diameter bend radius based on the inside duct diameter. Ducts should not be bent across sharp corners such as pipes, wires, posts, joists, or trusses.

4. For recommended flexible air duct and flexible air connector spacing, refer to the section on Hangers and Supports.
5. The maximum sag between horizontal duct supports should be 42 mm per m.
6. Tape and mastic used for sealing flexible duct to metal fittings should be listed and labeled to UL *Standard* 181B. For details, consult the HVAC System Leakage, Sealants sections "General" and "Flexible Duct."
7. Do not install flexible duct upstream of VAV boxes. Instead, use rigid ducts in these locations as described by Taylor (2015).
8. When installing flexible air ducts and flexible air connectors in inaccessible spaces, the use of metal worm-gear clamps is recommended. Nonmetallic fasteners (plastic straps) are not recommended.
9. Do not penetrate nonmetallic flexible duct inner core with sheet metal screws unless the flexible duct manufacturer's installation instructions specifically allow the use of screws as part of the closure method.
10. When installing flexible air ducts and flexible air connectors in inaccessible spaces, attention should be given to the ability to clean the flexible duct (see the section on Duct Cleaning).
11. For insulated ducts, the outer vapor barrier should be pulled back over the core and fitting and secured using two wraps of UL 181B-FX tape. A clamp may be used in place of or in combination with the tape.
12. Fittings used in combination with flexible air ducts and air connectors should have a 50 mm minimum rigid attaching collar with a bead. Flexible duct inner cores should be installed at least 25 mm onto the fitting and past the bead prior to taping and application of the mechanical fastener past the bead. Beaded fittings are not required when metal worm-gear clamps are used.

Plenums and Apparatus Casings

SMACNA (2020) shows details on field-fabricated plenum and apparatus casings. Sheet metal thickness and reinforcement for plenum and casing pressure outside the range of –750 to +2500 Pa (gage) can be based on *Rectangular Industrial Duct Construction Standards* (SMACNA 2020).

Carefully analyze plenums and apparatus casings on the discharge side of a fan for maximum operating pressure in relation to the construction detail being specified. On the fan's suction side, plenums and apparatus casings are normally constructed to withstand negative air pressure at least equal to the total upstream static pressure loss. Accidentally stopping intake airflow can apply a negative pressure as great as the fan shutoff pressure. Conditions such as malfunctioning dampers or clogged louvers, filters, or coils can collapse a normally adequate casing. To protect large casing walls or roofs from damage, it is more economical to provide fan safety interlocks, such as damper end switches or pressure limit switches, than to use heavier sheet metal construction.

Apparatus casings can perform two acoustical functions. If the fan is completely enclosed within the casing, fan noise transmission through the fan room to adjacent areas is reduced substantially. An acoustically lined casing also reduces airborne noise in connecting ductwork. Acoustical treatment may consist of a single metal wall with a field-applied acoustical liner or thermal insulation, or a double-walled panel with an acoustical liner and a perforated metal inner liner. Double-walled casings are marketed by many manufacturers, who publish data on structural, acoustical, and thermal performance and also prepare custom designs.

Acoustical Treatment

Metal ducts are frequently lined with acoustically absorbent materials to reduce noise. Although many materials are acoustically absorbent, duct liners must also be resistant to erosion and fire and have properties compatible with the ductwork fabrication and erection process. For higher-velocity ducts, double-walled construction using a perforated metal inner liner is frequently specified. Chapter 49 of the 2023 *ASHRAE Handbook—HVAC Applications* addresses design considerations, including external lagging. ASTM *Standard* C423 covers laboratory testing of duct liner materials to determine their sound absorption coefficients, and ASTM *Standard* E477 covers acoustical insertion loss of duct liner materials. Designers should review all the tests in ASTM *Standard* C1071. A wide range of performance attributes (e.g., vapor adsorption and resistance to erosion, temperature, bacteria, and fungi) is covered. Health and safety precautions are addressed, and manufacturers' certifications of compliance are also covered. AIA (2006) includes guidelines for using duct liner in hospital and health care facilities.

Rectangular duct liners should be secured by mechanical fasteners and installed in accordance with *HVAC Duct Construction Standards—Metal and Flexible* (SMACNA 2020). Adhesives should be Type I, in conformance to ASTM *Standard* C916, and should be applied to the duct, with at least 90% coverage of mating surfaces. Good workmanship prevents delamination of the liner and possible blockage of coils, dampers, flow sensors, or terminal devices. Rough edges should be sealed to prevent airborne fibers and erosion of lining. Avoid uneven edge alignment at butted joints to minimize unnecessary resistance to airflow (Swim 1978).

Rectangular metal ducts are susceptible to rumble from flexure in the duct walls during start-up and shutdown. For a system that must switch on and off frequently (for energy conservation) while buildings are occupied, duct construction that reduces objectionable noise should be specified.

7. INDUSTRIAL DUCT CONSTRUCTION

NFPA *Standard* 91 is widely used for design, construction, installation, and maintenance of duct systems conveying particulates and removing flammable vapors (including paint-spraying residue), and corrosive fumes. Industrial duct systems are generally classified as follows:

- **Class 1** covers nonparticulate applications, including makeup air, general ventilation, and gaseous emission control.
- **Class 2** is imposed on moderately abrasive particulate in light concentration, such as that produced by buffing and polishing, woodworking, and grain handling.
- **Class 3** consists of highly abrasive material in low concentration, such as that produced from abrasive cleaning, dryers and kilns, boiler breeching, and sand handling.
- **Class 4** is composed of highly abrasive particulates in high concentration, including materials conveying high concentrations of particulates listed under Class 3.
- **Class 5** covers corrosive applications such as acid fumes.

For contaminant abrasiveness ratings, see SMACNA's (2013, 2007) round or rectangular industrial duct construction standards. See Chapters 15 to 34 of the 2023 *ASHRAE Handbook—HVAC Applications* for specific processes and uses.

Materials

Galvanized steel, uncoated carbon steel, or aluminum are most frequently used for industrial air handling. Aluminum ducts are not used for conveying abrasive materials; when temperatures exceed 200°C, galvanized steel is not recommended. Duct material for handling corrosive gases, vapors, or mists must be selected carefully. For the application of metals and use of protective coatings in corrosive environments, consult *Accepted Industry Practice for Industrial Duct Construction* (SMACNA 2008), the *Pollution Engineering Practice Handbook* (Cheremisinoff and Young 1975), and publications of the National Association of Corrosion Engineers (NACE) and ASM International (www.asminternational.org).

Round Ducts

SMACNA (2013) provides information on selecting material thickness and reinforcement members for spiral and nonspiral industrial ducts. Spiral-seam ducts are only for industrial duct Class 1, 2, and 5 applications. The tables in this standard are as follows:

Class (Industrial Duct). *Steel*: Classes 1, 2, 3, 4, and 5. *Aluminum*: Class 1 only. *Stainless steel*: Classes 1 and 5.

Pressure classes for steels and aluminum. –7500 Pa to 12 500 Pa, in increments of 500 Pa.

Duct diameter for steels and aluminum. 100 to 2400 mm, in increments of 50 mm. Equations are provided for calculating construction requirements for diameters over 2400 mm.

Rectangular Ducts

Rectangular Industrial Duct Construction Standards (SMACNA 2007) is available for selecting hot-rolled steel, galvanized steel, or stainless steel thickness and reinforcement members for industrial ducts. The data in this standard give the duct construction for any pressure class and panel width.

The designer selects a combination of panel thickness, reinforcement, and reinforcement member spacing to limit the deflection of the duct panel to a design maximum. Any shape of transverse joint or intermediate reinforcement member that meets the minimum requirement of both section modulus and moment of inertia may be selected. The SMACNA data, which may also be used for designing apparatus casings, limit the combined stress in either the panel or structural member to 165 MPa and the maximum allowable deflection of the reinforcement members to 1/360 of the duct width.

Construction Details

Recommended manuals for other construction details are *Industrial Ventilation: A Manual of Recommended Practice* (ACGIH 2019), NFPA *Standard* 91, and *Accepted Industry Practice for Industrial Duct Construction* (SMACNA 2008a). For industrial duct Classes 2, 3, and 4, transverse reinforcing of ducts subject to negative pressure below –750 Pa (gage) should be welded to the duct wall rather than relying on mechanical fasteners to transfer the static load.

Hangers

The *Steel Construction Manual* (AISC 2017) and the *Cold-Formed Steel Design Manual* (AISI 2017) give design information for industrial duct hangers and supports. SMACNA standards for round and rectangular industrial ducts (SMACNA 2007, 2013) and manufacturers' schedules include duct design information for supporting ducts at intervals of up to 10 m.

8. ANTIMICROBIAL-TREATED DUCTS

Antimicrobial-treated ducts are coated (as a precoating or after fabrication) with a substance that inhibits the growth of bacteria, mold, and fungi (including mildew). Antimicrobial-treated galvanized steel, stainless steel, and aluminum ducts can be used when the service temperature of the antimicrobial compound is not exceeded. Prefabricated coatings allow metal to be pressed, drawn, bent, and roll-formed without coating loss. Imperfections in metal ducts, such as spot welds and welded joints, can be repaired with a touch-up paint of the antimicrobial compound.

Fabrics can be made inherently antimicrobial by combining the antimicrobial chemistry into the polymer fibers of the product. Glass fiber duct liners can be made resistant to bacterial and fungal growth using a biocide that protects the airstream surface from microbial growth.

Flexible ducts can be manufactured using antimicrobial-treated film materials on the inside of the inner core. Consult the duct manufacturer's specific information to determine the viability of product performance claims.

All antimicrobial coatings or touch-up paints should be EPA-registered antimicrobial compounds, tested per ASTM *Standard* E84, survive minimum and maximum service temperature limits, and comply with NFPA *Standards* 90A and 90B. Coatings should have flame spread/smoke developed ratings not exceeding 25/50, and meet local building code requirements.

9. DUCT CONSTRUCTION FOR GREASE- AND MOISTURE-LADEN VAPORS

Factory-Built Grease Duct Systems

Manufactured grease duct systems are made in accordance with UL *Standard* 1978 and are UL or ETL listed. These systems are also classified in accordance with UL *Standard* 2221 for clearance to combustibles. Factory-built grease duct systems must be assembled in accordance with manufacturers' recommended instructions but are not required to be welded. Component assembly is by bands/sleeves, and the systems are watertight. The gages for metal ducts used in these systems are considerably lighter than for welded site-fabricated grease ducts, and there may be substantial installation savings because components are assembled with tools instead of welding. System segments classified for clearance to combustibles are typically provided as a metal inner and outer shell, with insulation or an air gap in the annular space.

Site-Built Grease Duct Systems

Installation and construction of ducts for removing smoke or grease-laden vapors from cooking equipment should be in accordance with NFPA *Standard* 96. Kitchen exhaust ducts that conform to NFPA *Standard* 96 must (1) be constructed from carbon steel or stainless steel sheet with a minimum thickness in compliance with NFPA *Standard* 96; (2) have all longitudinal seams and transverse joints continuously welded; and (3) be installed without dips or traps that may collect residues, except where traps with continuous or automatic removal of residue are provided. Test ports should not be installed in grease-rated ductwork, except for temporary measuring test holes, which are sealed by welding before equipment use. Because fires may occur in these systems (producing temperatures in excess of 1100°C), provisions are necessary for expansion in accordance with the following table. Ducts that must have a fire resistance rating are usually encased in materials with appropriate thermal and durability ratings.

Kitchen Exhaust Duct Material	Duct Expansion at 1100°C, mm/m
Carbon steel	15.8
Type 304 stainless steel	19.2
Type 430 stainless steel	10.8

Duct Systems for Moisture-Laden Air

Ducts that convey moisture-laden air must have construction specifications that properly account for corrosion resistance, drainage, and waterproofing of joints and seams. No nationally recognized standards exist for applications in areas such as kitchens, swimming pools, shower rooms, and steam cleaning or washdown chambers. Galvanized steel, stainless steel, aluminum, and plastic materials have been used. Wet and dry cycles increase metal corrosion. Chemical concentrations affect corrosion rate significantly. Chapter 50 of the 2023 *ASHRAE Handbook—HVAC Applications* addresses material selection for corrosive environments. Conventional duct construction standards are frequently modified to require welded or soldered joints, which are generally more reliable and durable than sealant-filled, mechanically locked joints. The number of transverse joints should be minimized, and longitudinal seams should not be located on the bottom of the duct. Risers should drain and horizontal

ducts should pitch in the direction most favorable for moisture control. ACGIH (2019) covers hood design.

10. RIGID PLASTIC DUCTS

The *Thermoplastic Duct (PVC) Construction Manual* (SMACNA 2017) covers thermoplastic (polyvinyl chloride, polyethylene, polypropylene, acrylonitrile butadiene styrene) ducts used in commercial and industrial installations. SMACNA's manual provides comprehensive polyvinyl chloride duct construction details for positive or negative 0.5, 1, 1.5, and 2.5 kPa. NFPA *Standard* 91 provides construction details and application limitations for plastic ducts. Model code agencies publish evaluation reports indicating terms of acceptance of manufactured ducts and other ducts not otherwise covered by industry standards and codes.

Physical properties, manufacture, construction, installation, and methods of testing for fiberglass-reinforced thermosetting plastic (FRP) ducts are described in the *Thermoset FRP Duct Construction Manual* (SMACNA 2017). These ducts are intended for air conveyance in corrosive environments as manufactured by hand lay-up, spray-up, and filament winding fabrication techniques. The term *FRP* also refers to fiber-reinforced plastic (fibers other than glass). Other terms for FRP are reinforced thermoset plastic (RTP) and glass-reinforced plastic (GRP), which is commonly used in Europe and Australia. SMACNA (2017) has construction standards for pressures up to ±7.5 kPa, temperatures up to 80°C, round duct sizes to 2440 mm, and rectangular duct panels widths to 2440 mm.

11. AIR DISPERSION SYSTEMS

Air dispersion systems are designed to both convey and disperse air in the space being conditioned. Diffusion options include linear vents, nozzles, orifices, and porous fabrics. There are three typical cross-sectional shapes: semicircular D-shape, quarter round, and cylindrical (most common). D-shape and quarter round are normally mounted to a surface (wall or ceiling), whereas cylindrical are suspended from the ceiling. The cross-sectional area is based on the interior air velocity.

Typically, these systems are made of fabric, but also include sheet metal or plastic film, including porous and nonporous options. UL *Standard* 2518 is the recognized standard to evaluate fabric air dispersion systems and their materials for safety and building code requirements.

Consult the manufacturer for design criteria for selecting air dispersion type [linear vents, orifices, nozzles, microperforated (porous weave) fabric], fabric (porous or nonporous, color, weight, and construction), suspension options (cable or track options), and installation instructions. In design, consider velocities of 5 to 8 m/s at static pressures of 75 to 250 Pa to ensure proper airflow performance. Excessively turbulent airflow (from metal fittings or fans) or higher inlet velocities can cause fabric fluttering, excessive noise, premature material failure, and poor air dispersion. Fabric airflow restriction devices are available to help balance static pressures, reduce turbulence, reduce abrupt inflation, and balance airflow into branch ducts.

Dispersion Types

Linear Vent Outlets. Air is delivered through linear vents providing linear air flow. This vent typically consists of small openings (6 to 25 mm diameter) set in an array that is long and narrow (Figure 2). Airflow typically ranges from about 8 to 93 L/s per linear metre of vent at 125 Pa and is usually installed far enough away from a surface that it is a free-air jet. These linear vents normally run the length of the product on both sides.

Orifice and Nozzle Outlets. Air is delivered through orifices or nozzles (Figure 3), providing jet-type air distribution. Typical applications are gymnasiums, pools, and manufacturing facilities. Nozzles can direct air perpendicularly away from the surface of the duct. Nozzles allow for changing flow direction, rate, and throw. Nozzles generally have the least entrainment of long-throw outlets. The sizes of orifices and nozzles typically range from 13 to 125 mm diameter.

Porous-Duct-Surface Air Distribution System. Airflow is discharged through a porous weave or microperforated fabric (Figure 4), resulting in air velocities 0.15 to 0.41 m/s at the surface of the fabric duct to minimize mixing between supply and room air. This air distribution system is typically used for food processing, cleanrooms, and laboratories where draft elimination and uniform air distribution are required.

NFPA *Standard* 90A and IMC requirements for fabric air distribution systems are as follows:

1. Install systems in entirely exposed locations.
2. Always operate these systems under positive pressure.
3. Do not allow any system component to pass through or penetrate fire-resistance-rated construction.
4. All systems and components must be listed and labeled in accordance with UL 2518.

12. UNDERGROUND DUCTS

No comprehensive standards exist for underground air duct construction. Coated steel, asbestos cement, plastic, tile, concrete, reinforced fiberglass, and other materials have been used. Under-

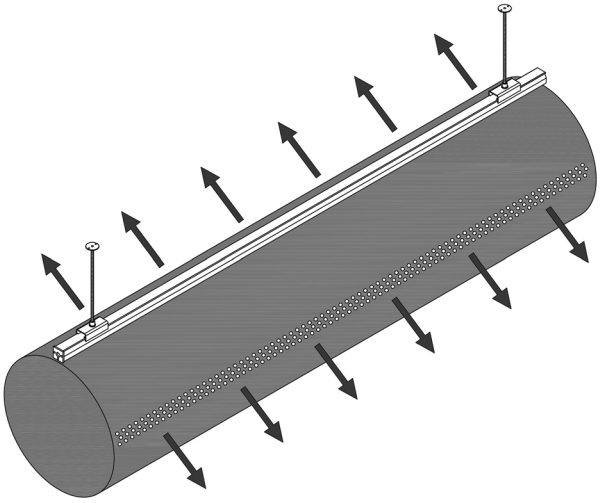

Fig. 2 Fabric Duct with Linear Vent Outlet

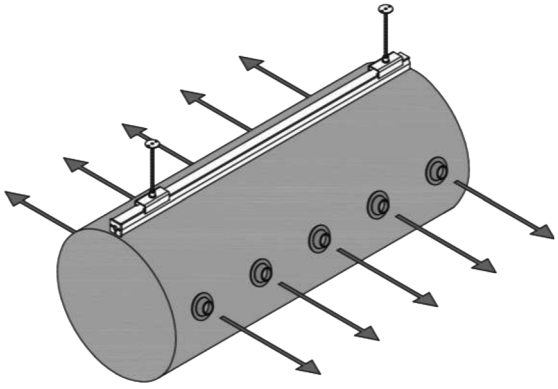

Fig. 3 Fabric Duct with Nozzle Outlets

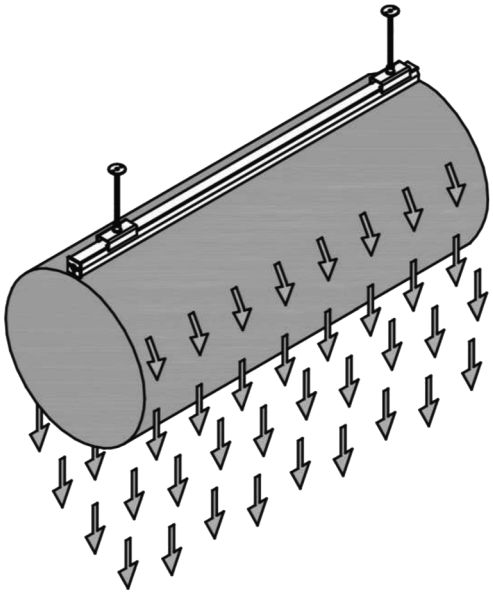

Fig. 4 Fabric Duct with Porous Material as Air Outlet

ground duct and fittings should always be round and have a minimum thickness as listed in SMACNA (2020), although greater thickness may be needed for individual applications. Specifications for construction and installation of underground ducts should account for the following: water tables, ground surface flooding, the need for drainage piping beneath ductwork, temporary or permanent anchorage to resist flotation, frost heave, backfill loading, vehicular traffic load, corrosion, cathodic protection, heat loss or gain, building entry, bacterial organisms, degree of water- and airtightness, inspection or testing before backfill, and code compliance. Chapter 12 has information on cathodic protection of direct-buried conduits. Residential installations may also be subject to the requirements in NFPA *Standard* 90B. Commercial systems also normally require compliance with NFPA *Standard* 90A.

13. DUCTS OUTSIDE BUILDINGS

Exposed ducts and their sealant/joining systems must be evaluated for the following:

- Waterproofing
- Resistance to external loads (wind, snow, and ice)
- Degradation from corrosion, ultraviolet radiation, or thermal cycles
- Heat transfer, solar reflectance, and thermal emittance
- Susceptibility to physical damage
- Hazards at air inlets and discharges
- Maintenance needs

In addition, supports must be custom-designed for rooftop, wall-mounted, and bridge or ground-based applications. Specific requirements must also be met for insulated and uninsulated ducts.

14. SEISMIC QUALIFICATION

Seismic analysis of duct systems may be required by building codes or federal regulations. Provisions for seismic analysis are given by the Federal Emergency Management Agency (FEMA 2009). Ducts, duct hangers, fans, fan supports, and other duct-mounted equipment are generally evaluated independently. Chapter 56 of the 2023 *ASHRAE Handbook—HVAC Applications* gives design details. SMACNA (2008b) provides guidelines for seismic restraints of mechanical systems and gives bracing details for ducts, pipes, and conduits that apply to the model building codes and ASCE *Standard* 7. FEMA (2013a, 2013b, 2014) has three fully illustrated guides that show equipment installers how to attach mechanical and electrical equipment or ducts and pipes to a building to minimize earthquake damage.

15. SHEET METAL WELDING

AWS (2018) covers sheet metal arc welding and braze welding procedures. It also addresses the qualification of welders and welding operators, workmanship, and the inspection of production welds.

16. THERMAL INSULATION

Insulation materials for ducts, plenums, and apparatus casings are covered in Chapter 23 of the 2021 *ASHRAE Handbook—Fundamentals*. Codes generally limit factory-insulated ducts to UL *Standard* 181, Class 0 or 1. *North American Commercial & Industrial Insulation Standards*, 9th ed. (MICA 2022) gives insulation details. ASTM *Standard* C1290 gives specifications for flexible fibrous glass blanket external insulation for ducts.

17. SPECIFICATIONS

Master specifications for duct construction and most other elements in building construction are produced and regularly updated by several organizations. Two examples are *MASTERSPEC* by the American Institute of Architects (AIA) and *SPECTEXT*® by the Construction Sciences Research Foundation (CSRF). *MasterFormat*™ (CSI 2014) is the organization standard for specifications. These documents are model project specifications that require editing to customize each application for a project. It is the design engineer's responsibility to create clear construction specifications.

MECHANICAL equipment and their control devices that affect air movement to and within spaces are collectively named **room air distribution equipment.** In addition to providing thermal comfort, acceptable indoor air quality is often achieved through air delivered and removed by this air distribution equipment. Supply air outlets, terminal units, chilled-beam units, in-room or plenum-mounted fan-coil units, air curtain units, and textile air dispersion products introduce air into conditioned spaces to obtain these desired indoor atmospheric environments. Return and exhaust air and airborne contaminants are removed from spaces through return and exhaust inlets (*inlet* and *outlet* are defined relative to the duct system and not the room, as shown in Figure 1). This chapter describes this equipment, details its proper use, and is intended to help HVAC designers select appropriate room air distribution equipment. Air distribution methods needed to properly specify this equipment are outlined in Chapter 58 of the 2023 *ASHRAE Handbook—HVAC Applications*, and air diffusion principles are presented in Chapter 20 of the 2022 *ASHRAE Handbook—Fundamentals.*

1. SYSTEMS OVERVIEW

This chapter describes outlets, terminal units, and cooling/heating delivery systems commonly used for effective room air distribution. An air distribution system is often used to provide adequate ventilation air, sensible space heating and cooling, and latent heating (humidification) and cooling (dehumidification) to provide comfortable and healthy indoor environments for occupants. All, some, or none of the conditioning of the delivered supply air is done within the room air distribution equipment, depending on the selected HVAC system types.

HVAC systems described in this chapter can be defined as either all-air or air-water (i.e., decoupled) systems. **Decoupled systems** that provide cooling can be further classified by whether they are intended to supplement both sensible and latent cooling or just sensible cooling; with the latter, the cooling coils included in the room air distribution equipment are intended to remain dry. Almost always, the equipment introduced in this chapter is intended to be installed indoors, protected from the weather. The exteriors of the nontextile devices are typically all or mostly galvanized steel or painted metal.

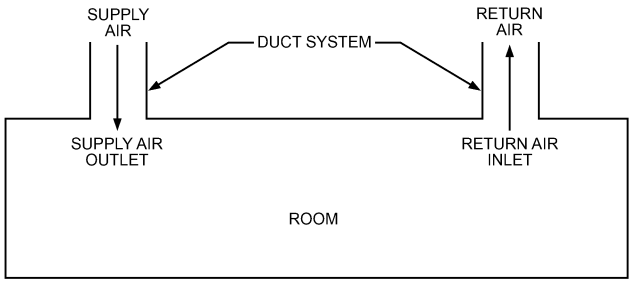

Fig. 1 Designations for Inlet and Outlet

All-Air Systems

All-air systems rely on conditioned air, delivered from central air-handling units via supply air ducts, to fulfill all of the space ventilation, heating, and cooling needs of the spaces. Zone airflow control devices such as dampers and fans often modulate the zone airflow delivery in response to the spaces' cooling and heating demands. Although zone-level reheat coils may be used to heat the air before its delivery, spaces' cooling and ventilation is provided by the air-handling units in all-air systems. Variable-air-volume (VAV, with constant or varying supply air temperature) systems are the prime example of all-air systems, although all-air systems can be constant air volume (CAV, with variable supply air temperature or on/off control).

Decoupled Systems

Decoupled systems' zone-level terminal units rely on receiving adequately preconditioned ventilation air from their air-handling unit, but typically the terminal units provide supplemental space sensible and latent cooling. The terminal units may also be specified with heating or reheating capacity. The decoupled cooling/dehumidification may be provided by either chilled-water or refrigerant coils within the zone terminal units, and the heating by hot-water, steam, heat pump, or electric-resistance coils. Terminal units' refrigerant-based coils, such as used in heat pump and variable-refrigerant-flow (VRF) systems, are not addressed in this chapter.

Sensible-Only Decoupled Systems

Decoupled sensible systems use the air-handling unit to provide fully conditioned ventilation air and all its zones' latent cooling requirements while the zones' terminal units provide most or all of the zones' sensible cooling. Heating capacity may or may not be provided in the terminal units. The terminal units' cooling coils use chilled water supplied at or above the space dew-point temperature to prevent condensation from occurring. The zone's sensible heat is removed from secondary air as it passes through the sensible cooling coil. Examples of decoupled sensible cooling systems include chilled beams and sensible cooling fan-powered chilled-water terminals; these are discussed further in this chapter.

The preparation of this chapter is assigned to TC 5.3, Room Air Distribution.

2. SYSTEM CLASSIFICATIONS

Room air distribution systems can be classified according to their primary objective and the method used to accomplish that objective. The objective of any air distribution system is to condition and/or ventilate the space for its occupants, to support processes within the space, or both.

Methods used to condition spaces can be classified as

- **Fully mixed** systems intend to produce uniform temperature and pollutant concentration with little or no stratification within the occupied and/or process space. Overhead air distribution, with both supply and return/exhaust above occupants or processes, is an example of this type of system.
- **Fully stratified** systems intend little mixing of air within the occupied and/or process space. Displacement ventilation, where the room air moves in a plug- or piston- type motion, is an example of this type of system.
- **Partially mixed** systems provide some mixing of air in the occupied and/or process space while creating stratified conditions in the volume above. Most underfloor air distribution designs (UFAD) are examples of this type of system.
- **Task/ambient** air distribution focuses on conditioning only a portion of the space for thermal comfort and/or process control. Examples of task/ambient systems are personally controlled desk outlets and spot-conditioning systems. Because task/ambient distribution requires a high level of individual control, it is not covered in this chapter, but is discussed in Chapter 20 of the 2021 *ASHRAE Handbook—Fundamentals*. Additional design guidance is also provided in Bauman (2003).

Figure 2 illustrates the spectrum between the two extremes (fully mixed and fully stratified) of room air distribution strategies.

Review the following publications when selecting systems and equipment for room air distribution:

- ANSI/ASHRAE *Standard* 55 establishes indoor thermal environmental and personal factors for the occupied space.
- ANSI/ASHRAE *Standards* 62.1 and 62.2 specify ventilation requirements for acceptable indoor air quality. These standards are adopted as part of many building codes.
- ANSI/ASHRAE/IES *Standards* 90.1 and 90.2 provide minimum energy efficiency requirements that affect supply air characteristics in various types of buildings in low-rise and non-low-rise buildings.

Local codes should also be checked for applicability to each of these subjects.

Other useful references on selecting air distribution equipment include AMCA *Standard* 222, Chapter 20 of the 2021 *ASHRAE Handbook—Fundamentals*, Chapter 58 of the 2023 *ASHRAE Handbook—HVAC Applications*, ASHRAE's (2013) *UFAD Guide: Design, Construction and Operation of Underfloor Air Distribution Systems*, Chen and Glicksman (2003), Rock and Zhu (2002), Skistad (2002), and ASHRAE/REHVA's *Active and Passive Beam Application Design Guide* (Woollett and Rimmer 2014).

2.1 FULLY MIXED SYSTEMS

In fully mixed systems, supply air outlets, properly sized and located, establish then control the air pattern in a room to obtain proper air mixing and temperature equalization.

Supply airflow from an outlet (**primary air**) entrains room air into the outlet's jet or jets. This entrained air (**secondary air**) increases the combined air (**total air**) in the jet as it proceeds farther from the outlet. The momentum of the primary jet remains constant, so the jet's velocity decreases as the mass increases. As the two air masses mix, the temperature of the jet from a properly selected, installed, and operated outlet approaches the room air temperature (Rock and Zhu 2002). Outlets should be sized to project air so that its velocity and temperature reach acceptable levels before entering the occupied zone of a space, often defined as the lowest 1.8 m of a room. **Throw** is the distance from the origin of the jet to the point where the velocity of the total air is reduced to a desired value.

Outlet locations and patterns also affect a jet's throw, entrainment, and temperature equalization capabilities. Some general characteristics include the following:

- When outlets are located close to a surface such as a ceiling, entrainment may be restricted, which can result in a longer throw.
- When the air pattern is spread horizontally in multiple directions, throw is reduced.
- Outlets with horizontally radial airflow patterns (e.g., from a round diffuser) typically have shorter throws than outlets with directional patterns.
- An outlet cannot discharge air properly and uniformly unless the air enters it in a straight and uniform manner.

Ceiling or sidewall outlets in cooling applications are often selected with supply air temperatures at or above 11°C. Special high-induction outlets are available for use with low-temperature

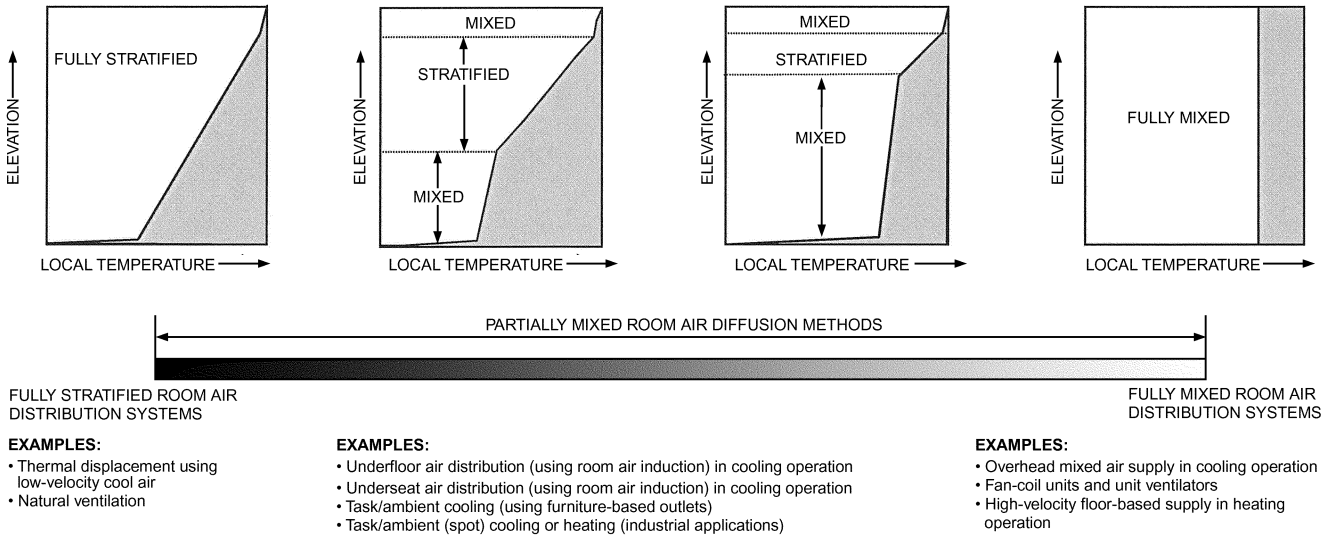

Fig. 2 Classification of Air Distribution Strategies

air distribution systems (i.e., those with supply air temperature below 11°C). These outlets include special features and rapidly mix cold supply air with room air at the outlet and effectively reduce the temperature differential between the supply and room air. For further information, designers can consult ASHRAE's (1996) *Cold Air Distribution System Design Guide*.

Accessories used with an outlet can regulate the volumetric flowrate of supply air and control its flow pattern. Accessories may also be necessary for proper air distribution in a space, so they must be selected and used according to the manufacturers' recommendations.

Factors That Influence Selection

Coanda (Surface or Ceiling) Effect. Via restricting secondary air entrainment, a jet moving adjacent to or in contact with an impermeable wall or ceiling creates a low-pressure area immediately adjacent to that surface, causing the air to remain in contact with the surface substantially throughout the length of throw. This **Coanda effect**, also referred to as the **surface** or **ceiling effect**, counteracts, to varying extents, the negative-buoyancy-driven the drop of a horizontally projected cool airstream.

Round and four-way horizontal-throw ceiling outlets exhibit a high Coanda effect because the discharge air pattern blankets the ceiling area surrounding each outlet. This effect diminishes with a directional discharge that does not blanket the full ceiling surface surrounding the outlet due to entrainment into the exposed sides of the jet. Sidewall outlets exhibit varying degrees of Coanda effect, depending on the spread of the particular air pattern, the angle of the jet, and the distance from the outlet's discharge to the surface.

When outlets are mounted such that they discharge into a free space not near an adjacent surface (e.g., exposed duct-mounted supply air grille applications), the airstream entrains air around the entire perimeter of the jet. As a result, the rate of entrainment is higher and the throw is shortened. More information on jet behavior can be found in Chapter 20 of the 2021 *ASHRAE Handbook—Fundamentals*.

Temperature Differential. The greater the temperature differential between the supply air projected into a space and the air in the space, the greater the buoyancy effect on the path of the supply airstream. Heated, horizontally projected air rises and cooled air falls, so this effect should be considered during outlet selection. Chapter 20 of the 2021 *ASHRAE Handbook—Fundamentals* has further discussion of the buoyancy effect.

Low-temperature supply air or cold building start-up in a humid environment may cause condensation. Consider the effect of condensation on outlet and space surfaces during outlet selection.

Sound Level. The sound level from an outlet is largely a function of its discharge velocity and transmission of HVAC system noise, such as from fans and air turbulence, and may be desirable for masking other sounds, or, if too high, may be considered noise by occupants. For a given air capacity, a larger outlet face area has a lower discharge velocity and correspondingly lower generated sound. However, a larger outlet also allows more system-generated sound to pass through the outlet, which may appear as outlet-generated noise to occupants. High-frequency noise can result from excessive outlet velocity but may also be generated in the duct by the moving airstream. Low-frequency noise is usually generated by mechanical equipment and transmitted through the duct and outlet to the room.

The cause of a noise complaint can usually be pinpointed as outlet or system sounds by removing the outlet's core during operation. If the noise remains essentially unchanged, the system is the source. If the noise is significantly reduced, the outlet is likely the source. The noise may be caused by a highly irregular velocity profile at the entrance to the outlet. ASHRAE research project RP-1335 (Landsberger 2011) and Chapter 58 of the 2023 *ASHRAE Handbook—HVAC Applications* have more details on the effects of inlet conditions on air outlets.

Variable-Air-Volume (VAV) Outlet. A VAV outlet is an air outlet that self-modulates its primary air flow rate with an integral air damper. Select outlets based on the total range of airflow needed for the space served. Outlet performance characteristics should be evaluated at both minimum and maximum flow. More information regarding selection of outlets can be found in Chapter 58 of the 2023 *ASHRAE Handbook—HVAC Applications*.

Outlet Selection Procedure

The following procedure is generally used in selecting and locating an outlet in a fully mixed system. More details and examples are available in Rock and Zhu (2002) and Chapter 58 of the 2019 *ASHRAE Handbook—HVAC Applications*.

1. Determine the design flow rates of air to be supplied to each room. (See Chapters 17 and 18 of the 2021 *ASHRAE Handbook—Fundamentals* to determine air quantities for heating and cooling modes.)
2. Select the type and quantity of outlets for each room, considering factors such as air quantity required, distance available for throw or radius of diffusion, structural characteristics, and architectural concepts.
3. Outlets may be sized and located to distribute air in the space to achieve acceptable temperature and velocity in the occupied zone. Select and locate outlets such that the air supplied reaches the breathing zone, as defined by ASHRAE *Standard* 62.1 for heating and cooling in many buildings.
4. Select the proper size outlet from the manufacturers' performance data according to air quantity, neck and discharge velocity, throw, distribution pattern, and sound level. Note manufacturers' recommendations regarding use. Also, obstructions to the primary air distribution pattern require special study. In an open space, the interaction of airstreams from multiple air outlets may alter a single outlet's throw, air temperature, or air velocity. As a result, manufacturers' data may be insufficient to predict air motion in a particular space. The **air diffusion performance index (ADPI)** is a useful tool in predicting outlet performance for fully mixed systems; see Chapter 58 of the 2023 *ASHRAE Handbook—HVAC Applications* for more information.

2.2 FULLY STRATIFIED SYSTEMS

Stratified room air distribution systems, typically called **thermal displacement ventilation**, generally rely on supply outlets with very low discharge velocities (e.g., 0.2 to 0.36 m/s based on total face area) to produce minimal room air entrainment so that much of the temperature difference between supply and the occupied zone's air is preserved. With outlets placed low, and when in cooling mode, cool supply air accumulates near the floor. Heat sources in the occupied zone create convection plumes that originate around the boundaries of the heat source and rise naturally because of their buoyancy. If these sources are near the supply airstream, supply air is entrained to fill the void of the rising convection plume.

The cooling-mode temperature differential between supply and room air is generally less than that commonly used for fully mixed systems. Exhaust air is generally higher temperature compared to fully mixed systems, especially with high ceilings. Stratified systems used in transient spaces where thermal comfort is less critical may, however, use air temperature differentials like those in fully mixed systems.

Factors that Influence Selection

Space Considerations. To maximize system efficiency, supply outlets are typically located below the occupant breathing level, so

installed low in the sidewall or in-floor. These supply outlets often take up considerably more surface area than outlets used in fully mixed systems. Wall recessed outlets are common but can be configured as quarter-round, semicircular, rectangular, or cylindrical to increase face area. Cylindrical air outlets are generally mounted in a room's open space, whereas the other configurations are mounted in corners, adjacent to the side wall, or flush with the wall.

Space Heating Considerations. Skistad (2002) reported that displacement ventilation can be combined successfully with radiators and convectors at exterior walls to offset space heat losses. Radiant heating panels and heated floors also can be used with displacement ventilation. When a secondary heating system is used, displacement outlets should supply air at least 1 K cooler than room temperature to maintain displacement airflow to the space.

System and Terminal Considerations. Low-velocity supply air outlets used in fully stratified systems can function properly with either constant- or variable-air-volume (CAV or VAV) supply air systems. For VAV applications, the supply air flow rate should be varied via a thermostat located in the space at a height of 1.2 to 1.5 m.

For fully stratified systems in humid climates, using series fan-powered terminal units or other mixing zone devices may allow supply air to be delivered from the central HVAC system at conventional temperatures and then blended with return/plenum air in the terminal unit to bring the air to an appropriate discharge temperature. However, this may compromise the space contaminant removal benefits of the displacement system.

Outlet Selection Procedure

Supply outlets used in stratified air systems tend to be mounted low in the sidewall or in-floor. They may also be mounted in the floor or risers beneath seats in public assembly facilities. Both mounting locations can produce adequately low discharge velocities; however, the outlets needed tend to be quite large. Because discharge velocities are very low, the supply airstream produces little momentum, and small obstacles, other than heat sources, in the flow path have little effect on its travel. Selection and application of air outlets for these systems is based primarily on the following considerations:

- Maintaining **vertical temperature gradients** within the occupied zone that conform to ASHRAE *Standard* 55. Further guidance on designing for conformance to this standard is presented in Chapter 58 of the 2023 *ASHRAE Handbook—HVAC Applications*.
- Maintaining a **clear zone** (also called **adjacent zone**) to the outlets that is acceptable to the function and occupancy of the space.
- Providing **acoustical performance** that conforms to the requirements of the space.

Supply outlets used in fully stratified systems are typically selected for a maximum face velocity of 0.2 to 0.36 m/s. Limitation of the face velocity is determined by noise requirements and proximity of occupants to the outlet. Where space noise requirements are not so stringent and stationary occupants are far away from diffusers, higher face velocities can be used. It is also important that the supply air outlet and its ductwork be designed to distribute airflow evenly across the outlet's entire discharge area to avoid excessive velocity deviations.

The area adjacent to the supply outlet where local velocities may exceed 0.25 m/s is defined as the adjacent zone, where local velocity/temperatures may combine to create drafty conditions. Manufacturers of outlets specifically intended for fully stratified systems publish predicted adjacent-zone values that depend on the outlet supply airflow rate and the initial temperature difference between the supply and room air. Stationary occupants should not be present routinely in the adjacent zone.

For applications requiring very low noise criteria, such as broadcast or recording studios or performing arts venues, acoustical performance is an important consideration. Because of their low-velocity discharge, these supply outlets can generally be selected to meet acoustical criteria for these applications.

2.3 PARTIALLY MIXED SYSTEMS

Partially mixed room air distribution systems are those whose design intent is to create mixed conditions in a portion of the room while maintaining thermal stratification in the remainder of the space. Supply outlets for these systems are usually designed and selected to discharge supply air from low sidewall or floor locations. These outlets produce high room air entrainment such that velocity and temperature differentials between supply and room air can be quickly dissipated. This results in relatively well-mixed room air conditions in some or all the occupied space, while stratified conditions are maintained throughout the remainder. Although most underfloor air distribution systems should be classified as partially mixed systems, underfloor air delivery can also produce fully mixed or fully stratified room air distribution.

Because supply air is introduced in the occupied zone, the supply air temperature is generally set above 16.7°C for cooling mode.

Factors That Influence Selection

Space Considerations. Partially mixed air distribution systems often rely on a pressurized plenum to deliver conditioned air to the supply air outlets; therefore, most of these outlets are not individually ducted. For example, underfloor air distribution systems commonly use the cavity beneath a raised access floor as a pressurized plenum. The supply outlets are mounted in the access floor tiles and can easily be relocated in response to space changes and workstation relocation.

Most supply outlets used in pressurized floor plenum applications can be easily adjusted for airflow by the space occupant. In such applications, it is usually effective to provide an adjustable outlet in every office or workstation to afford occupants control of their own environment. Many of these outlets can also be fitted with a thermostatically controlled damper that provides variable air flow rates to the space.

System and Terminal Considerations. Supply air outlets designed specifically for partially mixed room air distribution systems can use either CAV or VAV systems. For VAV applications, the supply air flow rates should be determined via a thermostat located in the space at a height of 1.2 to 1.5 m.

Outlet Selection Procedures

Supply outlets used in stratified air systems tend to be mounted low in the sidewall or in-floor. Because of their high degree of mixing supply and room air together, these outlets can be selected for much higher discharge velocities than those used in fully stratified systems, resulting in significantly smaller outlet discharge areas. Selection and application of air outlets for partially mixed systems is based primarily on the following considerations:

- Maintaining **vertical temperature gradients** in the occupied zone that conform to ASHRAE *Standard* 55. Further guidance on designing for conformance to this standard is presented in Chapter 58 of the 2023 *ASHRAE Handbook—HVAC Applications*.
- Maintaining an **adjacent zone** adjoining the outlets that is acceptable to the function and occupancy of the space.
- Providing **acoustical performance** that conforms to the requirements of the space.

Supply outlets should be selected such that their vertical projection achieves comfort and ventilation objectives. Limiting the vertical projection to a terminal velocity of 0.25 m/s of the supply air to below the respiration level, typically 1.4 m per ASHRAE *Standard* 62.1, allows convective heat plume formation around occupants to convey respiratory contaminants up and out of the occupied zone.

This creates breathing-level CO_2 concentrations like those associated with fully stratified room air distribution systems. Projections that exceed this level discourage formation of such plumes and result in space ventilation like that of fully mixed systems.

The area adjacent to the supply outlet where local velocities may exceed 0.25 m/s is defined as the **adjacent zone**, where local velocity/temperatures may combine to create drafty conditions. Manufacturers of outlets specifically intended for fully stratified systems publish predicted adjacent-zone values that depend on the outlet supply airflow rate and the initial temperature difference between the supply and room air. Stationary occupants should not be present routinely in the clear zone.

For applications requiring very low noise criteria, such as broadcast or recording studios or performing arts venues, acoustical performance is an important consideration. These supply outlets may be suitable to meet acoustical criteria for these applications.

3. EQUIPMENT

3.1 SUPPLY AIR OUTLETS

Typically, supply air grilles are used in high sidewall, sill, or floor applications, where supply air diffusers are most commonly used in ceilings or are mounted on exposed overhead ducts. Nozzles are typically installed on high-sidewall locations in large spaces.

High Sidewall. An adjustable double-deflection grille usually provides the most satisfactory solution. The vertical blades of the grille can be set for approximately 50° maximum deflection to either side, which can usually cover the conditioned space. Horizontal blades, if any, can be set to control the elevation of the discharge pattern. Upward deflection minimizes thermal drop in cooling applications, especially when the air jet can then attach to the ceiling.

Ceiling. Such installation is generally limited to ceiling diffusers or grilles with curved vanes that discharge parallel to the mounting surface. For high mounting locations (greater than 3 m above the occupied zone), vertically down discharge outlets may be preferred for these high bay applications. Supply outlets installed in 2.4 to 3 m high ceilings can achieve satisfactory performance if appropriate consideration is made for terminal velocities and temperature differentials in the occupied space. Discharging the airstream directly into occupied zone may result in unacceptable comfort conditions. Supply outlets needed for both heating and cooling from the same device should be carefully examined for use in both modes.

Sill. Linear bar grilles are commonly used in sill applications. The grille should be installed with the supply air jet directed vertically and away from the occupied space. When the device is mounted 300 mm or less from the wall, a device with 0° deflection is suitable. If the device is installed more than 300 mm from the vertical surface, a linear bar grille with a fixed 15 to 30° deflection is recommended. This device should be installed with the jet directed toward the wall. These grilles can be available with doors, removable cores, or other means of access to mechanical equipment that may be installed in the sill enclosure. The presence of window draperies or blinds and the effect of an impinging airstream must be considered in the selection. In high-humidity applications in cold locations, such as a natatorium in winter, special care is needed to prevent condensation on the glazing and other cold exterior surfaces.

Floor. Linear bar grilles are often used for floor applications. The designer should determine the traffic and floor loading on the grille; consult local building code for minimum rating requirements and determine the manufacturer's load limit for the grille. The grille should be placed in low-traffic areas. A floor-mounted grille is usually selected to discharge supply air along a wall or exterior surface. Install with the supply air jet directed vertically and away from the occupied space. When the device is mounted 300 mm or less from the wall, a device with 0° deflection is suitable. If the device is installed more than 300 mm from the vertical surface, a linear bar grille with a fixed 15 to 30° deflection is recommended. This device should be installed with the jet directed toward the wall. The presence of window draperies or blinds and the effect of an impinging airstream must be considered in the selection. Table 1 shows the types of supply air outlets and provides guidance for best use practices. This table is for guidance only; designers should consult manufacturers' literature for additional application information.

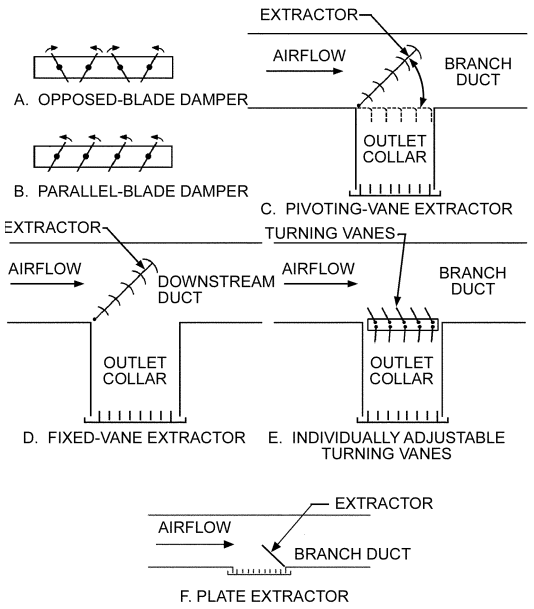

Fig. 3 Accessories for Supply Air Grilles

Underfloor air distribution (UFAD) typically employs swirl or linear bar grille type supply outlets recessed into the floor that discharge directly into the occupied zone. Displacement ventilation typically employs supply outlets fixed to the wall, sometimes mounted in the ceiling or floor, that discharge directly into the occupied zone. When sizing and locating the outlets, care should be taken to ensure occupant thermal comfort with either type.

3.2 RETURN AND EXHAUST AIR INLETS

Return air inlets may either be connected to a return duct or simply cover openings that transfer air from one area to another; the latter are commonly called **transfer grilles**. Exhaust air inlets remove air from a building and, therefore, are almost always connected to an exhaust duct and usually a dedicated fan. Velocity, sound, and pressure requirements for return and exhaust inlets are determined by size and configuration. In general, the same type of equipment, such as grilles, slot diffusers, and ceiling diffusers used for supplying air, may also be used for air return and exhaust. However, return/exhaust inlets do not require the flow deflection, equalizing, and turning devices necessary for supply outlets; their blades may be deflected for blocking lines of sight into ducts, if desired. Return and exhaust inlets may be mounted in practically any location (e.g., ceilings, high or low sidewalls, floors, and doors, the latter if fire code allows). Dampers such as the one shown in Figure 3A are sometimes used in conjunction with return and exhaust grilles to aid system balancing. When used in a partially mixed or fully stratified

system, the returns and exhaust outlets should be located above the occupied zone, either ceiling or high sidewall mounted unless superseded by other codes or standards.

3.3 GRILLES

A supply air grille usually consists of a frame enclosing a set of either fixed or adjustable vertical or horizontal vanes for a single-deflection grille, or both for a double-deflection grille. These are typically used in sidewall, ceiling, sill, and floor applications. Return and exhaust grilles usually have fixed vanes. Pressure drop and acoustic performance are optimized when blades are not angled, though blades may often be adjusted to achieve a desired throw pattern from supply grilles.

Types

Adjustable-Blade Grilles. This is the most common type used as a supply outlet. A single-deflection grille includes a set of either vertical or horizontal vanes or blades. Vertical vanes deflect the airstream in the horizontal plane; horizontal vanes deflect the airstream in the vertical plane. A double-deflection grille has a second set of vanes, typically installed behind and at right angles to the face vanes and controls the airstream in both horizontal and vertical planes.

Fixed-Blade Grilles. These are like the adjustable-blade grille except that the vanes or blades are not adjustable and may be straight or angled. For supply grilles, the angle(s) at which air is discharged depends on the deflection of the vanes. Fixed-blade grilles are more commonly used as return or exhaust air inlets. Angled blades reduce visibility into the ductwork.

Linear Bar Grilles. When used for supply, these outlets typically have fixed bars at the face. The bars normally run parallel to the length of the outlet and may be straight or angled. These devices supply air in a constant direction and are usually attached to a separate supply air plenum that has its own inlet. Linear bar grilles can be installed in multiple sections to achieve long, continuous lengths or installed as a discrete length. Also commonly used in underfloor air distribution systems, some linear bar grilles allow the discharge pattern to be changed using removable or adjustable cores. Many also incorporate a damper and actuator for automatic control of the supply air flow rate via a space thermostat. Linear bar grilles are sometimes manufactured with curved shapes for architectural purposes. When linear bar grilles are used for supply, similar grilles are also commonly used as return or exhaust inlets to provide a consistent architectural appearance.

Eggcrate Grilles. These fixed-blade grilles are only recommended for return or exhaust applications and typically have large free areas exceeding 90% of the face.

Transfer Grilles. These fixed-blade grilles are installed in an interior wall or door allowing air transfer from an enclosed room to an adjacent room or plenum to allow normalization of pressure between them.

Application-Specific Grilles

Security Grilles. Various fixed-blade grille types are available for high-security applications. Security grilles are available with additional features like heavy-duty construction, suicide deterrents, lattice faces, and tamperproof, nonremovable blade designs. Institutional guidelines exist for proper selection and placement of security grilles.

Heavy-Duty Grilles. Robust, heavy-duty designs are available for applications that require greater durability (e.g., industrial, gymnasium, institutional).

Spiral Duct Grilles. Grilles manufactured with a frame designed to be mounted directly onto the surface of a round duct without requiring an additional duct boot.

3.4 NOZZLES AND DRUM LOUVERS

Ball, jet, and adjustable nozzles and drum louvers direct high velocity air jets into the space. These devices typically have long throws and no or few vanes in their airflow paths. They are often installed in buildings as horizontally discharging high-sidewall outlets, in duct soffits (**fur-downs**) or in ductwork. Nozzles and drum louvers are typically used in large spaces. Aircraft and automobile ventilation systems also use smaller versions of these types of outlets (Rock and Zhu 2002).

The equations in Chapter 20 of the 2023 *ASHRAE Handbook—Fundamentals* can be used to estimate throw from many such simple duct terminations or orifices. For complex situations, physical experiments, or computational fluid dynamics (CFD) modeling, may be helpful in selection and design.

3.5 DIFFUSERS

Diffusers usually generate a radial or directional discharge pattern. For ceiling applications, this pattern is typically parallel to the mounting surface, thus creating a horizontal pattern. Diffusers may also include adjustable deflectors that allow discharge to be directed perpendicular to the mounting surface, creating a vertical pattern. A diffuser typically consists of an outer shell, which contains a duct collar, and internal deflector(s), which define the diffuser's performance, including discharge pattern and direction. Refer to the ASHRAE Handbook Online version of this chapter for illustrations of each diffuser.

Types

Round Diffuser. This diffuser is a series of concentric conical rings flush with the ceiling plane or with dropped inner cones, typically installed either in gypsum-board ceilings or on exposed ducts. Round ceiling diffusers are available in a broad range of sizes and capacities, and with or without adjustable inner cones that allow the diffuser to discharge air either horizontally or vertically.

Square Diffuser. This diffuser consists of concentric square, drawn louvers that radiate from the center of the diffuser. They are commonly mounted in suspended or gypsum-board ceilings or are attached to exposed ducts. Their necks can be round or rectangular, and the necks' sizes should be matched to the ducts'. Available with faces that are flush with the ceiling plane or with dropped inner cones, these diffusers have a fixed horizontal radial discharge pattern or an adjustable discharge pattern that allows the direction to be either horizontal or vertical. Special borders can be selected to accommodate various mounting applications; for example, pans are available so that a desired face size can be smaller than a suspended ceiling's grid size.

Perforated Diffuser. This diffuser consists of a duct collar and a single perforated plate that forms the diffuser's face, with typical free area of about 50%. The perforated face tends to create a slightly higher pressure drop and sound than similarly sized square ceiling diffusers. They are available with deflection devices mounted at the neck or on the face plate. The deflectors may be adjustable, to provide horizontal air discharge in one, two, three, or four directions. Special borders can be selected to accommodate various mounting applications.

Louvered-Face Diffuser. This diffuser consists of an outer border, which includes an integral duct collar, and a series of louvers or curved blades. Louvered-face diffusers typically provide a horizontal discharge perpendicular to the louver length. The louvers may be arranged to provide four-way, three-way, two-way opposite, two-way corner, or one-way discharge. Some louvered-face diffusers are available with adjustable louvers that can change the discharge pattern. Special borders are available to accommodate various mounting applications.

Plaque-Face Diffuser. This diffuser is constructed with a duct collar and a single plaque that forms the diffuser's face. This air outlet typically has a horizontal, radial discharge pattern. Special borders can be selected to accommodate various mounting applications.

Hemispherical Flow Diffuser. This diffuser provides a vertically radial air discharge pattern. The discharge penetrates the conditioned space perpendicular to the mounting surface. These diffusers are typically used for applications needing high air change rates, and/or low local velocities. Some outlet models are flush to the mounting surface; others protrude into the space below the ceiling. Most function similarly with or without an adjacent ceiling surface.

Laminar Diffuser. Sometimes called **nonaspirating**, this diffuser provides a unidirectional discharge perpendicular to the mounting surface. The free area of the perforated face is typically less than 35%. Most outlets are designed to develop a uniform velocity profile over the full face of the diffuser. This minimizes mixing with surrounding ambient air and reduces entrainment of any surrounding contaminants. These diffusers are typically used in hospital operating rooms, cleanrooms, or laboratories.

Linear Slot Diffuser. Linear slot diffusers may be installed in multiple sections to achieve long, continuous lengths, or installed as a discrete length. They can consist of a single slot or multiple slots and are available in configurations that provide vertical to horizontal airflow. Typically, a supply air plenum is provided separately and attached between the diffuser and the duct during installation. Other applications include field mounting the linear slot diffuser directly into a supply duct.

T-Bar Slot Diffuser. This diffuser is manufactured with an integral plenum and normally is installed in modular suspended (T-bar) ceilings. Available with fixed-deflection or adjustable-pattern controllers, these devices can discharge air from vertical to horizontal.

Light Troffer Diffuser. A light troffer diffuser serves as the combined plenum, inlet, and attachment device to an air-handling light fixture, which has a slot to receive the diffuser at or near the face of the lighting device, to discharge supply air into the space. Only the air-handling slot is visible from the occupied space.

Swirl Diffuser. This diffuser features a series of openings arranged in a radial pattern around the center of the diffuser face. This promotes a high degree of entrainment of room air, resulting in very high induction ratios, which maximize mixing in the area adjacent to the diffuser face. Swirl diffusers may be mounted in ceiling, sidewall, or floor locations. They are commonly used for UFAD applications where it is necessary to locate the supply outlets close to the space occupants. When mounted in floor locations, care should be taken to ensure that the diffuser can meet the floor loading requirements.

Displacement Diffuser. Typically located in floor or low-sidewall locations, this diffuser is designed to limit discharge velocities to 0.2 to 0.36 m/s to minimize mixing between supply and room air. These outlets tend be large to generate the low velocities required for thermal displacement ventilation: low-velocity discharge allows the cooler supply air to fall to the floor and remain there because its buoyancy is lower than that of the ambient room air above it. These outlets are available in various shapes and configurations that facilitate flush or adjacent mounting to the sidewalls or floor of the space.

Textile Air Dispersion System. This outlet system is designed to both convey and disperse air within the space being conditioned. Diffusion options include outlets selected for a full range of entrainment. The supply air is delivered through (1) the weave of the fabric, (2) microperforations, (3) a long and narrow pattern of small jets, (4) orifices, and/or (5) nozzles. Typically, these systems are made of fabric, sheet metal, or plastic film.

Variable-Air-Volume (VAV) Diffuser. A VAV diffuser is an air outlet that self-modulates its primary air flow rate with an integral air damper. Select outlets based on the total range of airflow for the space served. Outlet performance characteristics should be evaluated at both minimum and maximum flow. More information regarding selection of outlets can be found in Chapter 58 of the 2023 *ASHRAE Handbook—HVAC Applications*.

Variable Geometry Diffuser. One type of VAV outlet is a variable geometry diffuser. These diffuser assemblies vary their dis-

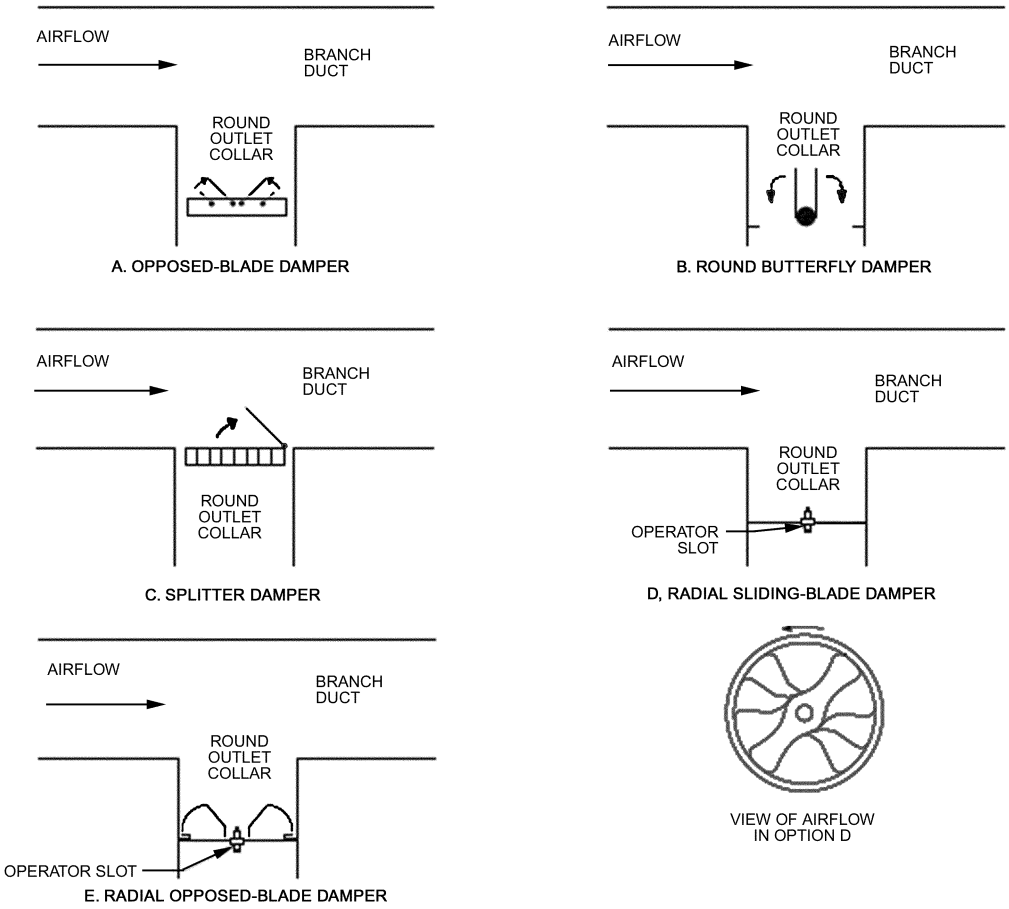

Fig. 4 Accessory Controls for Ceiling Diffusers

charge area or air pattern in response to changes in space or supply air temperature.

Supply Air Diffuser Accessories

Dampers can be attached to grilles (the combination of a grille and a damper is called a **register**), diffusers, or installed as separate units in the duct, to regulate the device's airflow rate:

- **Opposed-blade** damper vanes rotate in opposite directions (Figure 3A and 4A) and are available for round, square, or rectangular necks.
- **Parallel-blade** dampers rotate in the same direction (Figure 3B).
- **Adjustable-vane** dampers have individually adjustable vanes.
- **Butterfly** dampers are constructed with opposing damper plates that move in opposite directions and are adjusted from a center point (Figure 4B).
- A **splitter** damper is a single-blade device, hinged at one edge and usually located at the branch connection of a duct or outlet (Figure 4C). The device is designed to allow adjustment at the branch connection of a duct or outlet to adjust flow.
- **Radial** sliding dampers consist of multiple overlapping flat blades that rotate in the horizontal plane to restrict the airstream (Figure 4D).
- **Radial opposed blade dampers** consist of a series of radial blades that pivot to restrict the airstream (Figure 4E).

Other miscellaneous accessories, such as **remote control devices** to operate the dampers, and **travel limit stops**, are also available.

When these dampers are located on or near the air outlet, they may cause nonuniform airflow discharge and increased pressure drop and sound. In the 2023 *ASHRAE Handbook—HVAC Applications*, Chapter 49 describes the effects of damper location on sound level and Chapter 58 addresses the effects of damper location on sound, throw performance, and pressure drop.

Extractors are installed in duct-collar connections to the outlet and are used to improve the flow distribution into a supply outlet. The device shown in Figure 3C has vanes that pivot such that the supply airflow to the grille or register remains perpendicular to the face of the outlet. The device shown in Figure 3D has fixed vanes. Both devices restrict the area of the duct in which they are installed and should be used only when the duct is large enough to allow the device to open to its maximum position without unduly restricting airflow to the downstream duct. These devices may increase the system pressure requirement, thereby limiting downstream airflow and increasing the sound level. An extractor mounted directly to the grille, as shown in Figure 3F, is sometimes called a **scoop**.

Adjustable vanes, as shown in Figure 3E, are individually adjustable. Typically, two sets of vanes are used. One set equalizes flow across the collar, and the other set turns the air. The vanes should not be adjusted to act as a damper because balancing requires removing the grille to gain access and then reinstalling it to measure airflow.

Equalizing or **flow-straightening devices** or **grids** allow adjustment of the airstream to obtain more uniform flow to the diffuser.

Quadrant blank-off flat plates restrict airflow in one or more quadrant(s) of the diffuser inlet.

Other balancing devices are available. Consult manufacturers' literature as a source of information for other air-balancing devices.

3.6 TERMINAL UNITS

In air distribution systems, special control and acoustical equipment is frequently required to introduce conditioned air into a space properly. Airflow controls for these systems consist principally of terminal units, the most common of which historically were called **VAV boxes**, with which the airflow can be varied by modulating valves, fan controls, or both. Terminal units such as those listed here are supplied with or without cooling coils, fans, heat or reheat coils, and having either constant or variable primary airflow rate. Terminal units typically control the flow of conditioned air supplied through a duct from an air handler and deliver it to the occupied space, but sometimes, such as in the case of underfloor units located in a cooled supply air plenum, may take the air directly from the plenum with no primary duct. They may use a ducted or nonducted return plenum or room air induction to affect space temperature control while maintaining a constant or variable discharge airflow rate and/or temperature. Terminal units may also include, usually as accessories, sound reduction devices, diffusers, filters, or other air treatment devices.

This section discusses control equipment for forced air-conditioning systems. Chapter 49 of the 2023 *ASHRAE Handbook—HVAC Applications* includes information on sound control in air-conditioning systems and sound ratings for air outlets.

Terminal units are factory-made assemblies for affecting air distribution. A terminal unit manually or automatically performs one or more of the following functions: (1) controls air velocity, airflow rate, pressure, or temperature; (2) mixes primary air from the duct system with air from the treated space or from a secondary duct system; and (3) heats or cools the air. To achieve these functions, terminal unit assemblies are made from an appropriate selection of the following components: casing, mixing section, manual or automatic air control device, heat exchanger, induction section (with or without fan), sound reduction devices, and flow controller.

Terminal units are typically classified as constant or variable air flow rate devices. They are further categorized as either pressure-dependent, where airflow through the assembly varies in response to changes in system pressure, or pressure-independent or -compensating, where airflow through the device does not vary in response to changes in air pressure.

Variable-air-volume (VAV) reset controllers regulate airflow to a constant, fixed amount or to a variable, modulating amount calculated by room demand. These controllers can be electric (typically yielding pressure-dependent performance), analog, or digital electronic (giving pressure independence), or pneumatic with pressure-dependent or -independent flow. Pressure-independent controllers require an indication of actual airflow to reset the VAV airflow control device. Temperature inputs are also required for calculating room demand for comfort conditioning.

Terminal unit controls are categorized as (1) system-powered, in which the airflow control device derives the energy necessary for operation from supply air within the distribution system; or (2) externally powered, in which the airflow control device derives its energy from a pneumatic or electric outside source. Terminal units may be furnished with all necessary controls for their operation, including actuators, regulators, motors, and thermostats or space temperature sensors, or the controls may be furnished by someone other than the terminal unit manufacturer.

The unit's flow control device can be adjusted manually or automatically. If the unit is adjusted automatically, it is actuated by a control signal from a controller, thermostat, flow regulator, or building management system (BMS), depending on the desired function of the terminal unit.

Single-Duct Terminal Units

Single-duct terminal units can be cooling only, heating only, or cooling and heating. Terminal units for cooling modes often have reheat coils that add sensible heat to the supply air as part of the overall humidity control. Hot-water or steam coils, or electric resistance heaters, are placed in or attached directly to the air discharge of the terminal unit. This type of equipment can provide varying reheat, customized to the thermal zone being served.

The basic single-duct unit consists of an insulated casing, airflow regulator, and possibly also an actuator, airflow-measuring device, and selected controls. Accessory discharge attenuators, silencers, and multiple outlet attenuators are also common. In the lower and middle latitudes, typical applications include those with

- The supply air system is not tasked with the space heating requirements
- Variable airflow rate and temperature (VVT) or other auto-changeover controls
- Constant air volume
- Constant pressure control

A **single-duct unit with a reheat** can also be used in zones where heating-mode needs are low so that the reheat coil can serve dual purposes. The terminal unit usually reheats at the minimum airflow setting. An auxiliary higher heating setting may be available as an option with additional controls.

Interior zones, where ventilation requirements may be larger than the desired heating airflow, may require additional reheat capacity.

A **single-duct exhaust valve** is a type of single-duct ATU (air terminal unit) designed for exhaust air and consists of an insulated casing, airflow regulator, and possibly also an actuator, airflow-measuring device, and selected controls. Accessory inlet attenuators or silencers are sometimes used. Specialty materials may be needed for corrosion resistance. The designer should consider pressure drop and system effects.

A **venturi valve** is a type of single-duct ATU and can be used for either supply or exhaust. Traditionally, the device consisted of a round venturi valve body and an internal shaft that supports a cone assembly. Newer technologies remove the internal cone assembly and use damper blade assemblies to control airflow.

Cone Assembly Type. The cone assembly is spring-loaded on the shaft. As pressure in the primary duct increases, the cone compresses the internal spring and moves closer to the venturi throat, increasing resistance to the airstream. As pressure in the primary duct decreases, the spring retracts and the cone assembly moves farther from the venturi throat, decreasing resistance to the airstream. This is called **mechanical pressure independence**. If the venturi valve is provided with an actuator to allow for variable airflow, the actuator and positioning arm reposition the shaft, which in turn moves the cone assembly relative to the throat, changing the airflow.

Damper Assembly Type. The damper assembly is controlled by an actuator that responds to differential pressure between two different points along the venturi valve body or by other means. The damper modulates to control airflow as pressure fluctuates, yielding a **pressure-independent** system that directly measures airflow through the valve body. A controller is used to modulate the valve damper actuator and control the overall system sequence of operation, whether constant volume or variable volume.

Dual-Duct Terminal Units

Dual-duct terminal units are typically controlled by a room thermostat or sensor. They are each connected to two supply air ducts

that deliver two of warm, cold, recirculated, mixed, or outside air to provide desired room control. Volume-regulated units have individual airflow control devices to regulate the amount of air from the two supply ducts. Dual-duct units can have reheat coils too if mixing of the hot and cold ducts' air is insufficient for humidity control or space heating. When a single temperature control device regulates the relative amounts of both warm and cold air to control temperature, a separate airflow control device may function to control and limit total airflow from the unit. Specially designed baffles may be required inside the unit or at its discharge to mix varying amounts of warm and cold air and/or to provide uniform temperature distribution downstream. Dual-duct units can be equipped with constant- or variable-flow control. These are typically pressure independent, to provide consistent flow rate and temperature control. Dual-duct terminals may also be used with outdoor air conditioned and supplied by a primary air-handling unit and ducted to the terminal units; such systems' AHUs maintain the required volumetric flow of ventilation air into the spaces served. Dual-duct units with cooling and outdoor air may need a local heating device; these **primary-secondary** air distribution systems thus need careful analysis and design.

A **nonmixing dual-duct unit** is effectively two single-duct terminal units side by side. The basic unit incorporates separate cold and hot air inlets that are to be attached to the two primary-air ducts, with sometimes neutral-temperature air in one of the ducts (e.g., during mild weather). The units are usually applied in exterior zones in buildings where overhead heating and cooling are desired but not auxiliary heating, and when zero minimum airflow is acceptable during changeover between heating and cooling. Proper discharge configurations are required to reduce the likelihood of improper mixing.

A **mixing dual-duct unit** is the same, with an integral mixing/attenuator section on the downstream end of the terminal unit to minimize temperature stratification in the discharge airstream. They are often used in interior and exterior zones in buildings (e.g., hospitals) where overhead heating and cooling are desired, but an auxiliary heating coil is not, and zero minimum airflow is unacceptable during changeover between heating and cooling. Evaluate mixing performance to fit the application, and consider the additional pressure drop of mixing/attenuators sections.

Air-to-Air Induction Terminal Units

Induction terminals supply primary air or a mixture of primary and recirculated air to the conditioned space. They achieve this function with a primary air jet that induces recirculated air, known as secondary air in this application, via grilles to the ceiling plenum or from individual rooms via a return duct. Typically, the primary air is of higher design velocity than that delivered to other types of terminal units, and the extra momentum is used as the inducing energy source. The induction unit contains devices that are actuated in response to a thermostat to modulate the mixture of primary air and induced secondary air. Reheat coils may be required to meet interior load requirements. Historically, induction units were used with high-velocity ducts, and often produced much noise. Modern versions often work well with much lower-velocity air but require careful selection. Generally, induction units are considered where there is a desire for zone-level air distribution equipment, installed in or over occupied spaces, that have no fans or other components that may require frequent access for maintenance. Any terminal unit that uses recirculated air must have an air filter, and that filter should be readily accessible for inspection and periodic replacement.

Fan-Powered Terminal Units

Fan-powered terminal units are used as secondary-level air handlers in primary-secondary air distribution systems and are typically installed in return air plenums. They can be specified with either heating, reheating, or cooling coils, or a combination. They differ from air-to-air induction units in that they each include a blower, driven by a small motor, which moves air from the conditioned space, ceiling plenum, or floor plenum, that may be mixed with the primary air from the main air handler. The characteristics of fan-powered units are

- In heating mode, the primary air is mixed with usually warmer or cooler secondary air that then passes through the unit's heating coil.
- The unit's fan increases supply air pressure to deliver air to areas that otherwise would be short of airflow.
- With heating or cooling coils in the units, perimeter zones can be heated or cooled without operating the main air handler when ventilation with outdoor air is not required.
- In-room air velocities can be kept consistently high to improve mixing.
- Air velocities may be reduced in low-load conditions to decrease noise levels.
- The main air handler operating pressure can be reduced with series fan-powered units compared to other terminal units because the secondary-level fans provide some of the total needed supply air pressure differential and may yield some fan-energy savings.
- In thermal storage and other systems with relatively low supply air temperatures, series fan-powered terminal units may be used to mix the cold supply air with much warmer induced return or plenum air, to moderate the discharge air temperature.

Some units are equipped with special insulation and a vapor retarder to reduce condensation with below-dewpoint supply temperatures.

Fan-powered terminal units can be divided into two categories: (1) series, with all primary and induced air passing through a blower in the unit that operates continuously during the occupied mode; and (2) parallel, in which the blower operates only on demand when induced air or heat is required.

Fan-powered terminal units typically use fractional horsepower alternating current (ac) electric motors for their included blowers. Increasingly, high-efficiency electrically commutated motors (ECMs) are used instead of older, less efficient motor designs. The efficiency of the motor becomes more important as the units operate for more hours of each year.

A **series** unit typically has two inlets, one for primary air from the central air handler and one for secondary air recirculated from the spaces served, often via a ceiling or floor plenum. All air delivered to the zone passes through the blower. The blower operates continuously whenever the primary air fan is on and can be cycled as required when the primary fan is off. As the zone's load decreases, an airflow control device throttles the amount of primary air delivered to the blower. The blower makes up for this reduced amount of primary air by acquiring more air from the conditioned space or ceiling plenum through its secondary air inlet. Sometimes a series unit has two ducted inlets, like a dual-duct terminal unit, in addition to the induction air inlet, which may or may not have ducting to it. The second primary air duct is typically used for dedicated outdoor air systems. Fan airflow and primary air can be varied when the units are in part-load condition, but fan airflow should never be less than the total amount of air supplied to the unit by the ducted inlets.

Fan-Powered Series Flow. The basic unit consists of a single-duct unit, blower/motor, and selected controls where the motor and primary damper are arranged such that mixing occurs upstream of the blower; this unit is depicted in Figure 5. They also have been called **constant-volume** or **constant-fan** units. Supplemental heating coils, such as steam, hot water, or electric, are generally required. Electric-resistance heating coils are typically located on

the discharge of the unit; water coils may be on the discharge or the induction port. Heating coils on the induction port, and thus upstream of the unit's blower, increase ambient temperature at its motor and decrease motor life. Supplemental cooling coils are sometimes located on the induction port for some applications like when utilized in conjunction with dedicated outdoor air systems. A **low-profile** version of the fan-powered series flow unit is typically less than 300 mm tall and is commonly used where zoning requirements limit building height and the architect wishes to maximize the number of floors, because these units fit in a shallow ceiling plenum. Unlike standard fan-powered terminals, the fan/motor assembly is installed flat on its side with the wheel rotating in a horizontal plane.

Fan-powered series-flow units are generally used for

- Exterior zones where heating and cooling loads may vary considerably
- Buildings where heating is desired when the central system is shut down during unoccupied hours
- Allowing lower central system supply duct static pressure
- Where occupant comfort can be optimized, because the high-, sometimes constant-, volume variable-temperature air delivery produces consistent air distribution, acoustics, and ventilation air delivery

Dual Air Inlet Fan-Powered Series Flow. These units are similar in construction to the standard series-flow terminals but have an additional air inlet that provides a direct connection to the terminal unit for ventilation air. They are commonly used in buildings where ventilation air is supplied via a dedicated ventilation duct system to each terminal unit; this is generally done where it is desirable to monitor ventilation air quantities to each zone.

Low-Temperature Fan-Powered Series Flow. These units are the same as fan-powered series flow but have special construction to minimize the potential for condensation. They can be used with cold-water/ice storage systems that provide below-dewpoint temperature primary air to the zone terminals, or where standard terminals may be exposed to high humidity.

Underfloor Fan-Powered Series Flow. This type is a fan-powered series flow terminal unit designed to fit between the pedestal supports of raised- or access-floor systems. They are available in several unit sizes, but with limited height and width.

Primary and induction ports, if any, to such units may or may not be ducted. Typically, in cooling mode, cool primary air is supplied to the well-sealed floor plenum, and heated air may be ducted to the terminal unit that is then mixed with the cool air in varying amounts. In these cases, the control system must perform the proper damper sequence to control room air conditions.

Parallel fan-powered terminal units, in cooling mode, supply the primary air directly to the space, bypassing its fan. In heating mode, the blower section induces plenum air and is mounted in parallel with the primary airflow control device, this unit is depicted in Figure 6. A backdraft damper is included to limit the amount of primary air flowing through the blower section when the blower is not energized. The blower in these units is generally energized after the primary airflow has reached the minimum flow rate. Typically, the parallel unit provides constant-air flow rate heating and variable air flow rate cooling. Although it is not recommended due to control instability, these units are sometimes applied in CAV mode with electronically commutated motors programmed to maintain constant airflow rate discharge. The motor control algorithm gradually increases the unit's fan speed as the primary airflow is reduced. Parallel units are typically limited to one ducted supply inlet.

One weakness in parallel fan-powered terminals is leakage of primary air through the fan's backdraft damper and the mixing chamber housing. ASHRAE research project (RP-1292 (David 2007) demonstrated that much of the energy saving associated with

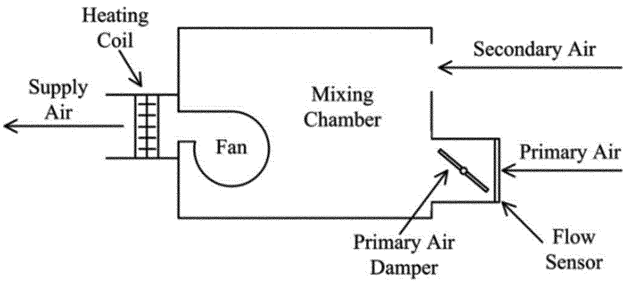

Fig. 5 Series Fan-Powered Terminal Unit

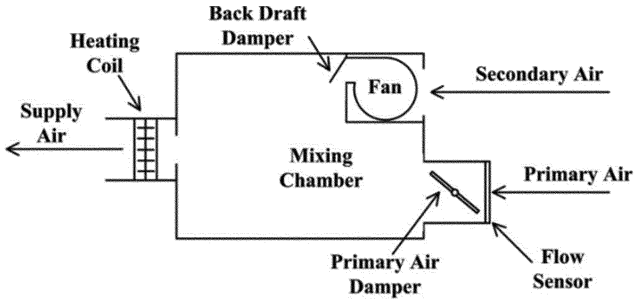

Fig. 6 Parallel Fan-Powered Terminal Unit

intermittent fan cycling is offset, and in fact may be significantly less than the energy loss caused by this leakage.

Fan-Powered Chilled Water Series Flow. This unit type takes all the features of a basic fan-powered series flow unit and incorporates a supplemental cooling coil on the induction port. Typically, this cooling coil is designed for sensible cooling only, to avoid condensation issues and in many cases, is used in conjunction with dedicated outdoor air systems.

Fan-Powered Parallel Flow. Sometimes called **variable-volume** or **intermittent-fan units**, these consist of a single-duct unit, blower/ motor, backdraft damper, and selected controls; the motor and primary damper are arranged such that mixing occurs downstream of the blower. Supplemental heating coils, either steam, hot water, or electric, are generally required. Electric-resistance heating coils are typically located on the discharge of the unit. Water coils may be on the discharge or the induction port, although the discharge location adds to the supply air system's static pressure requirements and increases leakage through the backdraft damper, as shown in ASHRAE RP-1292 (Davis 2007). Heating coils on the induction port increase the air temperature at the unit's fan motor and decrease its life.

Fan-powered parallel-flow units are used in exterior zones where heating and cooling loads may vary considerably, and in buildings where heating is needed when the central air handler is shut down during unoccupied hours.

Bypass Terminal Units. A bypass terminal unit handles primary air through its inlet. The unit bypasses primary air to the ceiling plenum or to ducts leading to the air handler's return to meet the needs of the conditioned space. Primary air, diverted into the ceiling plenum, returns to the central air handler as return air or building exhaust. This method provides a low first cost with minimum controls, but it is energy inefficient compared to other systems.

The basic bypass terminal consists of a diverter-type damper, actuator, bypass port, and selected pressure-dependent controls. A balancing damper is recommended ahead of the inlet.

Bypass terminals are used primarily with packaged rooftop air conditioning equipment with a direct-expansion (DX) coil where zoning is desired, but relatively constant airflows across the system

components (e.g., coils, fans) are required to minimize the potential for freeze-up. The system offers a lower initial cost design. It does not provide the energy-saving advantages of a VAV system with fan-speed control; almost all the energy savings are from the reduced motor speeds that occur except at full design-load conditions.

3.7 FAN-COIL UNITS

This section discusses the use of hydronic and direct-expansion (DX) fan-coil units to control the flow rate and temperature of air delivered to the space as required to maintain occupant thermal comfort and/or ventilation rate. Chapter 5 discusses how fan-coil units are integrated into the design of the building. Fan-coils operate independently of any central air distribution system or are used similarly to some fan-powered terminal units.

There are various fan-coil systems to choose from when designing a building. Choosing which one to use depends on the building owner's considering installation, application, operational cost, sustainability, thermal and acoustic performance, capacity, reliability, spatial requirements, code restrictions, water or refrigerant piping distribution, maintenance, and unit accessibility.

Fan-coil units are factory-made assemblies, and are typically much smaller than traditional, centrally installed air-handling units. The fan-coil performs some combination of the following functions: (1) temperature and humidity control, (2) ventilation of the conditioned space, (3) filtration, and (4) room air distribution, including providing air motion for comfort. Their blowers, when in operation, may provide beneficial acoustical masking in the spaces served. Fan-coil units are available in various configurations, including vertical or horizontal airflow paths and mounts for exposed or concealed locations in spaces. A zone temperature control device regulates the fan-coil airflow rate or discharge air temperature, or possibly both.

As shown in Figure 7, the basic components of fan-coil units are an integral or external filter frame, a heating or cooling coil, and fan. Both heating and cooling coils may be included, depending on the needs of the thermal zone. The zone temperature control device may be part of the fan-coil unit or supplied separately. Air entering the unit may be 100% recirculated air or a mixture of recirculated and outside air. The fan moves air from the conditioned space through the coil or coils, which then transfers heat to or from the air. Fans are usually placed after the coils (draw-through arrangements), but some fans are installed before the coils (blow-through). The coils use steam, chilled or hot water, or refrigerant (DX), or are electric resistance-heating elements. A filter is required at or upstream of the unit's inlet to minimize airborne particulates to keep downstream components cleaner. The fan and motor assembly are generally arranged for quick removal for servicing. The fan may be directly or indirectly driven by its electric motor. If the unit includes a dehumidifying cooling coil, it must be equipped with a drain pan and drain for the condensate; an insulated pan may be desirable. Fan-coil casings are typically galvanized or painted steel and may be prepped and painted after installation, but care is needed not to cover permanent informational labels. The casing may be internally insulated for both thermal and acoustic considerations.

Additional components are offered for many fan-coil units for specific applications, including fan controls (e.g., modulating fan controls), thyristor control, or electronically commutated motors (ECMs). A hydronic coil's water valve piping package can include such components as manual or automatic flow controls, pressure-independent water control valves, strainers, unions, pressure-temperature ports, air vents, hose connections, drains, and balancing valves. The coil in a DX system includes a fixed refrigerant expansion orifice device such as a capillary tube or a thermal expansion valve. Electric heating controls include magnetic contact closure or solid-state relays.

Fan-coil units are generally available in nominal sizes from95 to 1135 L/s or 2 to 21 kW, with direct drive permanent split capacitor (PSC) fan motors or ECMs for a wide range of applications. These units can be used in ducted or nonducted single or multiroom applications. They typically have multiple-row cooling coils and may have single- or multiple-row heating coils. If a two-pipe hydronic system for seasonal heating or cooling is used, only one coil may be included; however, four-pipe systems with separate heating and cooling coils are generally recommended for improved comfort and overall efficiency. If steam is used instead of hot water, it requires a separate coil. In a DX system, its coil is most often cooling-only, but heat pump applications are increasingly of interest. For heat pump applications, specifying an electric resistance heating coil is often also recommended. Fan-coil unit systems can

- Require less building interstitial space, because the water/refrigerant piping system has a higher energy density per unit fluid flow than an all-air system
- Provide individual-zone temperature and humidity control
- Enable retrofits to expand capacity beyond that of the existing air system.
- Allow individual dwellings in multifamily buildings to have individual electrical meters and separate air flows versus a central AHU
- Provide occupants with independent temperature controls

DX fan-coil systems also eliminate the need for a central chiller plant. However, for DX fan-coil units in high-rise buildings, the space required for mounting condensing units and the lift required for oil in refrigerant lines must be considered. Minisplit and VRF systems that use a ducted indoor fan-coil unit are available for high-rise and other applications, too.

Two- and Four-Pipe Hydronic Distribution Systems. When the heating and cooling heat transfer fluids, typically treated water, are supplied to a common coil in each terminal unit, it is called a two-pipe system, with one pipe for supply and one for return. These are also called a heating/cooling changeover system. A four-pipe distribution system has dedicated supply and return piping for the separate heating and cooling coils, or each circuit within a common coil. The four-pipe system generally has a higher initial cost; however, it provides (1) all-season availability of heating and cooling at each unit, (2) no summer/winter changeover requirement at the terminal units, (3) controllability to maintain an energy-saving dead band between heating and cooling, and (4) heating coil arrangements for either preheat or reheat.

A two-pipe system can only heat or cool, depending on the supply water temperature. During intermediate seasons or when the building requires simultaneous heating and cooling, supplemental electric heat is usually provided. The coil is typically sized larger for cooling, so careful consideration of the heating water temperature is required; often it is lower than for a dedicated hydronic heating coil.

Motors and Controls. When selecting a motor type, consider features such as control type, control scheme, and sequence of operation. The differences between a permanent split capacitor (PSC) versus an electronically commutated motor (ECM) affect the

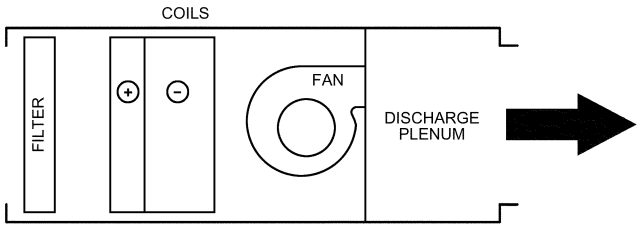

Fig. 7 Basic Fan-Coil Unit

sequence of operation, which in turn dictates type of room thermostats, controls, and water valves. When an ECM is used in a fan-coil, both the fan motor and water control valve are typically modulated by a controller based on room demand.

The most common control for fan-coils is a room thermostat. These thermostats come in both line voltage (i.e., same voltage as motor) and 24 VAC; generally, a lower control loop voltage is preferred due to safety expectations. Both thermostats offer simple on/off or multispeed control of fan motors and open/close control of water control valves, although programmable versions are readily available that adjust the temperature set point for expected occupancy variations (i.e., setback thermostats).

Analog controllers can provide high level of control for modulating components such as ECMs, water valves, and silicon-controlled rectifiers (SCRs). The most advanced level of building control is provided by direct digital control (DDC), which adds communication ability through a building automation system (BAS).

Additional information on fan-coil unit motors and controls can be found in Chapter 58 of the 2023 *ASHRAE Handbook—HVAC Applications.*

Unit Types and Configurations. Fan-coil units are available in many different configurations; however, not all configurations discussed here are available for all types of units. Orientation of airflow from return to supply, unit features, and dimensional characteristics constitute the major differences between configurations. Outdoor air can be mixed with recirculated air in the plenum or at the fan-coil unit or be delivered directly to the space separately from the fan-coil's supply air. Changes in industry standards have increased the use of coupling ventilation air to fan-coil units. The outdoor air can be pretreated or unconditioned and ducted or nonducted. Fan-coil units are available with a variety of options to handle outdoor air, such as mixing boxes, outdoor air duct collars, air measuring devices, or air control devices.

Vertical Units. Low-profile vertical fan-coil units (called sill units or cabinet heaters) are typically used beneath or adjacent to windows or exterior walls in concealed or exposed cabinets. The low silhouette sometimes limits filter area, serviceability, capacity, and cabinet geometry. Air is discharged vertically through grilles mounted on the top face of the enclosure. Controls and water valves are typically located in the enclosure, with access from the room for maintenance.

Vertical, high-output fan-coil units are designed for larger spaces or multiple rooms. The units are typically located in a closet, where a door allows easy access. Ducted discharge air supplies multiple outlets located throughout the space. The return is typically located near the floor of the closet and may or may not be ducted. Typically, one thermostat controls the air temperature supplied to all the spaces served.

Vertical stack fan-coil units, as depicted in Figure 8, are typically mounted in walls of or vertical chases in the conditioned space, such as near the window of a hotel or dorm room. Air is discharged into the space from high sidewall grilles or ducted to outlets throughout the zone. Multiple stack units may be connected to a common set of risers to serve adjacent spaces. The pipes can be in a cavity protected by fire-rated partitions separating multiple adjacent zones.

Floor-to-floor, vertical stack fan-coil units are typically supplied with chilled- and/or hot-water risers and return downcomers, and a condensate downcomer. VRF versions are available too, as are water-cooled heat pumps units. Vertical stack fan-coils with integral prefabricated risers located directly above one another can reduce installation labor and time. Evaluation of floor-to-floor centerlines is critical for riser and unit heights.

Horizontal Units. Horizontal overhead units may be concealed or exposed, and some have discharge or return ducts. Discharge ducts may supply several outlets in one or more rooms. Ducted units must be designed to handle higher external static pressure. Horizontal models conserve floor space, but when located in furred ceilings, consideration should be given to access and condensate removal. This type of fan-coil is oft-used, for example, in plenums over hallways in hotels, apartments, and condominiums. The cooling is most often a DX split-system, and heating is heat pump or electric resistance. Minisplit and VRF versions are available too.

Figure 9 shows a typical low-profile horizontal fur-down fan-coil unit. Horizontal fur-down units are generally less than 280 mm in height and mounted in a fur-down below the ceiling level or in a soffit area. The return is nonducted, typically through filter-return grilles; the interstitial area of the soffit is the return plenum, which otherwise must be very well sealed. Supply air is typically ducted to one or more two-way high-sidewall supply grilles. Horizontal fan-coil types are generally used in space-constrained applications. A variation of the horizontal furdown unit includes a larger return plenum, which has filter-frame accommodations and may be ducted to a return grille. The addition of a return plenum with an externally finished cabinet allows the fan-coil unit to be installed below the ceiling.

High-capacity, horizontal fan-coil units are generally up to 460 mm in height and mounted above the ceiling in a return air plenum. These models have a higher capacity than fur-down low-profile units, and generally serve multiple rooms with a ducted supply. The unit may have multiple plenum arrangements, like fur-down models do, but the interstitial area is typically the return plenum.

Underfloor Fan Coils. This fan-coil is like an underfloor fan-powered terminal, but it includes a cooling coil to boost the cooling load at the perimeter of zones or, for example, in conference rooms with raised floors. Another use may be in staircases or podiums. If the cooling coil is designed to condense water vapor when operating, care must be taken to provide for adequate drainage. Condensate pumps may be required. These fan-coils are available in several unit sizes, but with limited height and width to fit under the raised floor.

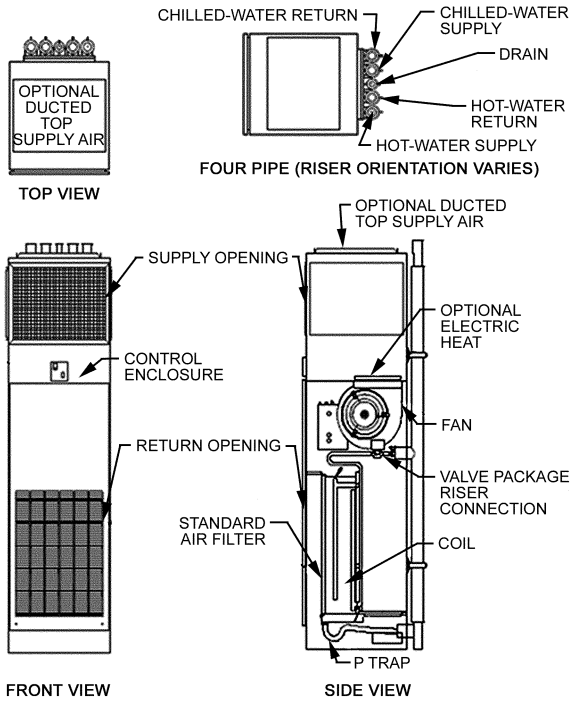

Fig. 8 Typical Vertical Fan-Coil Unit

For fan-coil applications in raised floors, typically either the supply or return air is ducted, and thus the plenum is used for unducted flow of the other. The plenum must, therefore, be very well sealed so that air does not leak in or out of unintended places; alternatively, both the supply and return can be ducted and well sealed. In all cases, the control system must have the proper damper sequence to control room air distribution to maintain the proper conditions in the occupied space.

Maintenance. Fan-coil systems require maintenance, which is generally done via the occupied areas. Unit accessibility is important for inspections and when performing routine maintenance such as filter replacement, coil and drain cleaning, and motor servicing. Large fire-rated hatches may be required when units are placed in small plenums, for example. When above suspended ceilings, the movable ceiling tiles may provide adequate access and fire rating.

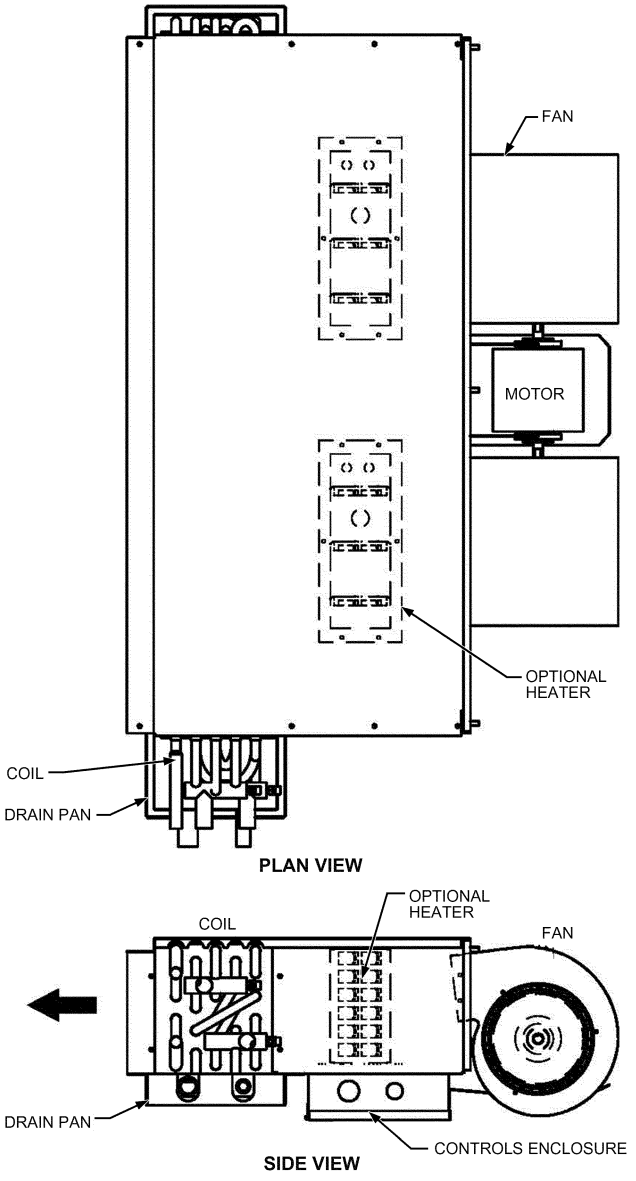

Fig. 9 Typical Horizontal Fan-Coil Unit

3.8 CHILLED BEAMS

Chilled-beam systems are designed to address most or all the zone's sensible heat gains or losses locally using water, allowing the flow rate of preconditioned air from the air-handling unit to be reduced to maintain only the required latent cooling and ventilation of the space. This often results in ducted design airflow rate reductions of 60 to 80%, and thus similar reductions in air distribution equipment capacity requirements. Chilled-water supply temperatures are maintained at or above the room air dew point to prevent condensation on the beam heat transfer coil(s). The zone must be very well sealed and air pressure differential optimized continuously to effectively eliminate infiltration of uncontrolled humid air. Chilled-beam systems perform the following functions:

- Temperature control (sensible cooling and heating)
- Latent cooling (when using drain pans or inductions units)
- Room air distribution
- Ventilation (active chilled beams)
- Humidity control (active chilled beams)

Beam Types and Configurations

Active beams, as shown in Figure 10A are induction terminals that consist of a primary air duct connection, a series of induction nozzles, hydronic heat transfer coil(s), supply outlet(s), and induced air inlet section(s). Primary air, discharged through the induction nozzles, creates a lower-pressure region that induces room air through the chilled- and/or hot-water coil(s). The room air is conditioned before being mixed with primary air, and then the mixture of primary and conditioned induced air is then discharged to the space. This mixture's temperature and/or flow rate is modulated in accordance with the space demand and control strategy. Active chilled beams are available in the following configurations:

- Linear (one-way or two-way discharge)
- Modular (four-way discharge)
- Recessed
- Floor mounted or cabinet style
- Induction units (with integral drain pans)

Active beams, when properly applied, generally produce fully mixed room air distribution, although displacement ventilation versions (cabinet style) are available as well. Their air distribution characteristics depend on the beam's supply outlet configuration, like those described in Table 1. Most active beams use linear slots on their discharge, and room air distribution is therefore characteristic of that outlet type because the induced air produces significant supply air velocity. The following piping configurations are generally used:

- Two-pipe
- Four-pipe
- Two-pipe changeover (six-way valve)

Cooling-only active beams use two pipes (supply and return) to their coils. Active beams can also be used for overhead heating; when applied as such, the beams are typically provided with four-pipe combined coils. These beams' coils have a common fin stack, but the tubing that passes through the stack is dedicated to either cooling or heating. In most cases, 75% of the tube passes are dedicated to cooling, and 25% are supplied hot water. The water flow rate through either circuit is varied by zone chilled- and/or hot-water control valves that are modulated the zone temperature sensor.

Where both heating and cooling are needed but two-pipe beams are used, six-port control valves can be effective. These valves incorporate four supply and return ports for both chilled and hot water. They then determine the water source that is required and modulate the flow to and from one or more two-pipe beams through a shared local two-pipe system. This can considerably reduce zone piping costs and allow the use of more efficient two-pipe circuitry in

the beam heat transfer coils; however, it loses the ability to heat or cool each beam individually, if jointly connected on a local two-pipe system.

Overhead beams, if so designed, may be used in suspended or finished ceilings, or independently mounted below. Although active beams are usually installed in the upper part of the space, they can also be located in sidewalls or at floor level, with their supply air delivered at high or low velocity, depending on the air distribution strategy (mixing or displacement) that is desired. Both active and passive chilled beams can be integrated with additional services (e.g., lighting or fire protection) as required.

Passive beams, as shown in Figure 10B, consist of a sensible cooling coil and a casing, and can be fitted into an architectural enclosure when exposed. They provide space sensible cooling mainly by negative-buoyancy-driven natural convection: the coil provides heat exchange between the chilled water and the induced room air. When cool water is circulated through the coil, room air between the fins is cooled and falls naturally into the room. Displaced room air then pushes air through the beam's coil.

There are two basic types of passive beams: exposed and recessed. Exposed passive beams are commonly used in spaces without suspended ceilings (i.e., in rooms with either finished or no ceilings).

Recessed passive beams are generally integrated into a suspended ceiling. When passive beams are installed in such a ceiling, a minimum clearance between the top of the beam and any surface above it should be provided to ensure a sufficient return air path. Generous shadow gaps, dummy beam sections, and/or return or transfer grilles are recommended for creating the near-zero pressure loss return air path from the room to the plenum.

Passive beams cannot be used effectively for heating spaces below them due to positive air buoyancy. Instead, a decoupled heating system (e.g., low-level finned tube or radiant panels or floors) is commonly used. However, the passive beams may be used at times to intentionally warm the plenum or floor above them somewhat, for comfort or freeze protection.

Space ventilation and dehumidification must be provided by a complementary air delivery system. Air delivery systems that promote fully stratified or partially mixed air distribution when in cooling mode are often preferred, because passive beams mounted high operate more efficiently in thermally stratified environments.

Additional information on active and passive beams can be found in Woollett and Rimmer (2014) and Chapter 58 of the 2023 *ASHRAE Handbook—HVAC Applications*.

3.9 AIR CURTAIN UNITS

Air curtain units (ACUs) are local devices that supply high-velocity planar airstreams that act as controlled barriers for environmental and thermal separation, as well as for resisting wind when a building's doors or windows are open.

When used as an environmental separation barrier, an ACU minimizes migration of gaseous or particulate contaminants, deters flying insects, and may convey contaminants toward local exhaust. As a thermal barrier, the ACU reduces cross migration of warm, lighter air flowing through the upper part of the opening and cold, heavier air flowing through the lower part of the opening. As a wind resistance barrier, it minimizes the effect of outdoor air blowing into a building's openings.

An ACU can reduce the energy consumption of HVAC systems when areas of different temperatures need separating, but physical barriers such as walls or doors cannot be used at certain or all times. ACU energy effectiveness is defined by the amount of energy saved (i.e., the energy loss through an opening prevented with an ACU) divided by the amount of energy that would have been lost without, represented as a percentage. The cost effectiveness can be calculated similarly. Research has demonstrated that air curtains can range in energy effectiveness from 60 to 90%, depending on the type of unit and application (Costa et al. 2006; Giráldez et al. 2013). See Chapter 58 of the 2023 *ASHRAE Handbook—HVAC Applications* for more information.

ACUs are constructed of a motor and fan, or a system of motors and fans, mounted inside a cabinet, and a specialized plenum for discharge. Air is drawn in through either a ducted or nonducted intake, specified with or without a filter, and discharged at a high velocity as an air curtain; this air curtain is sometimes referred to as the **ACU airstream**. The unit is normally mounted above or beside a door or window opening. Discharge across the opening is either vertical, when the unit is mounted above the opening, or horizontal, when the unit is mounted beside the opening. Due to fluid mechanics, air is entrained and mixed, from both sides, into the curtain. Thus, the direction of the jet produced is important, and is often adjustable or even actively controlled.

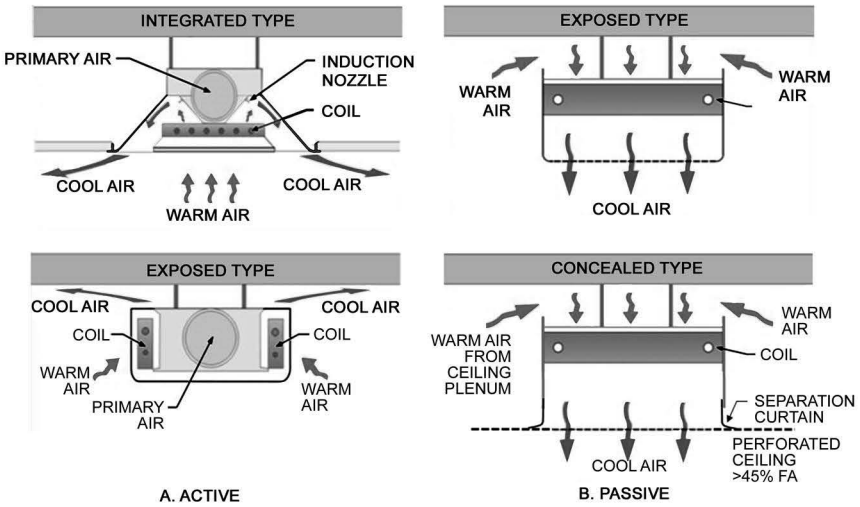

Fig. 10 (A) Active and (B) Passive Beams

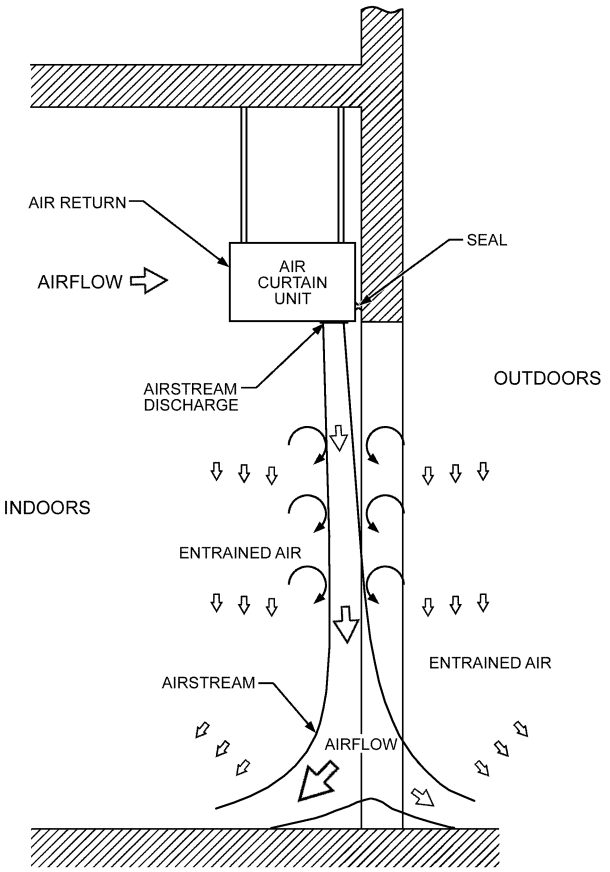

Fig. 11 Non-Recirculating, Horizontal-Mount High-Velocity Air Curtain Unit

(*Source*: AMCA *Standard* 222)

Unit Types and Configurations. ACUs are classified by two different types of construction: non-recirculating and recirculating. The major differences between the two systems are the airflow path, cabinet construction, range of effectiveness, and purchase and installation costs.

A **non-recirculating system** draws air into the unit directly from typically one indoor environment and is available in both horizontal and vertical applications; horizontal-mount, vertical-down discharge is depicted in Figure 11. An air curtain equipped with inlet ductwork that draws air from outdoors only is also considered to be nonrecirculating. This configuration is recommended for doorways that open frequently (e.g., 10 times or more per hour). Flying insect control applications use this type of unit exclusively because of its ability to generate a high-velocity airstream. It is the most common system for environmental separation because of its low initial purchase and installation costs. Nonrecirculating systems are typically used for special applications, due to their flexibility in construction and installation.

A **recirculating system** draws air from ductwork, which collects and returns much of the discharge air as well as entrained air to the ACU's inlet as shown in Figure 12. Applications often use a plenum with a floor return grille that is connected to the ACU's inlet with ductwork. An alternative construction includes horizontal flow, which discharges and returns from side to side. These systems are recommended for doorways that are opened for extended periods of time, with a high rate of traffic. Although its effectiveness rating is higher, this system is only suitable for thermal separation applications. Recirculating systems use lower velocities and are perceived as less obtrusive than non-recirculating systems.

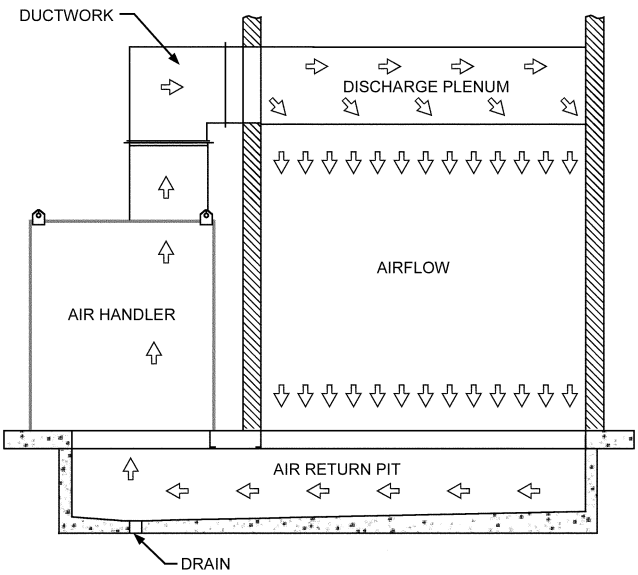

Fig. 12 Recirculating, Horizontal-Mount Air Curtain Unit

(*Source*: AMCA *Standard* 222)

Non-recirculating systems are normally self-contained systems that can be easily installed or retrofitted to existing openings with minimal planning and changes to the opening and its sequence of operation. Recirculating systems require preplanning and comprise a combination of components, including discharge and return plenums, which require integration into the construction of the opening and its sequence of operation.

The typical range of energy effectiveness for non-recirculating systems is 60 to 80%, whereas recirculating systems range between 80 to 90% (Costa et al. 2006; Giráldez et al. 2013). Non-recirculating systems also have a relatively low purchase and installation cost; recirculating systems can have significantly higher installed cost.

Optional features available for both ACU types include heating, cooling, filters, and special controls. Special casing materials and/or coatings may be required for outdoor mounting or harsh environmental applications.

The availability of integrated heating and/or cooling options depends on the intended application and cabinet construction requirements. Note that a heating or cooling option will not improve the air curtain's effectiveness; this serves as an enhancement to the application, independent of the protection provided by the airstream. A heat source may be added for local supplemental heat to reduce the windchill effect of the air curtain.

The most common heating types are

- Electric heating coils: open (helical) or fin-tube element
- Hydronic coil: hot water or steam
- Indirect gas-fired: furnace uses heat exchanger to separate combustion air from heated air curtain
- Direct gas-fired: burner fires directly into airstream being heated, so may not be acceptable for certain occupancies
- DX evaporator coil: direct-expansion vapor compression refrigeration cycle system

Cooling options are used for the same general reasons as the heating options: occupant comfort, supplemental cooling, or dehumidifying. Special care is needed in cooling applications to remove the condensate generated in the cooling apparatus, also accounting

for the higher face velocities across the coil so as not to blow water droplets off the coil. The most common types are

- Hydronic coil: chilled water
- DX evaporator coil: direct-expansion vapor compression refrigeration cycle system

Factors That Influence Selection. ACUs are typically considered for four different applications:

- Energy savings: indoor applications where doors or windows are used for pedestrian traffic or the transporting of goods where they would be open long enough to impact the designed load of the HVAC system. Examples include front or customer entry doors, loading docks, service windows, ovens, and coolers or freezers.
- Insect control (sanitation): indoor applications where doors or unscreened open windows could allow entrance of flying insects that would create an unsanitary environment.
- Code requirements: buildings that are being constructed to meet a jurisdictional code requirement.
- Process/special application: applications where the separation of two distinct environments is required to prevent cross contamination, fume/odor control, or a process that requires a direct stream of air to accomplish a specified task. Examples include cleanrooms, car washes, and assembly line drying or cooling by convection.

Chapter 58 of the 2023 *ASHRAE Handbook—HVAC Applications* provides details on these categories.

Product Selection. ACU selection depends on the width of the opening and installation height. To maximize effectiveness, the ACU must cover at a minimum the entire opening, and if possible should slightly overlap the opening's frame. On wide openings, two vertically mounted, low-air-velocity units can be used as an alternate solution to a single horizontally mounted, high-air-velocity unit. The ACU discharge must have a free and clear path to the entire opening for optimal performance.

Recent studies suggest that the minimum air velocity required at the floor to create an effective barrier is 2 m/s (Yang et al. 2019). When selecting air curtains, commercially available products are offered and designed specifically based on the opening size and application. Manufacturers' performance data should be consulted to determine the suitability of the ACUs used. Data to determine ACU performance should be obtained from recognized test standards such as ANSI/AMCA *Standard* 220.

Controls. ACU controls are essential to provide the correct air curtain velocity, temperature, and depth. They are also used to prevent unnecessary energy usage and overconditioning or overpressurizing the building entrance. Although supplemental heating and/or cooling can be provided by a so-equipped air curtain unit, it should not be seen as the primary source for conditioning internal areas. If an ACU is used for supplemental heating or cooling, the energy consumed during these control sequences should not be considered in the effectiveness rating of the unit. For convenience, user-operated controls are typically unit-mounted and configured to satisfy the building occupants' needs. To meet design, access, or security requirements, optional remote-mounted controls may be available. At the simplest level of control, only manual operation of the fan speed and heat output may be required. However, additional control options include

- Room thermostat
- Door contact switch
- Timer
- Step or modulating control of electric or water heating
- BMS control interface

The control unit may also have outputs for signaling failures or provide communication between the ACUs and the central control system (e.g., BMS, BAS, emergency management system [EMS]). ACUs can be equipped with controls as simple as a mechanical multispeed switch, or as sophisticated as an integrated interface with a touchpad or LCD panel. The LCD panel can control values such as discharge speed, heating/cooling status, indoor/outdoor set-point temperatures, failure reporting, and filter contamination level.

Maintenance. ACUs typically require biannual maintenance, depending on the application. Some designs may have motors and bearings that require periodic lubrication. Many designs use permanently sealed bearings instead. ACUs require only occasional cleaning of the blower impeller(s), cabinet interior, and heating apparatus, as well as filter cleaning or replacement if so equipped.

Fan Terminology 21.14
Symbols 21.17

A FAN uses a power-driven rotating impeller to move air or gas. The internal energy increase imparted by a fan to air or gas is limited to 25 kJ/kg. This limit is approximately equivalent to a total pressure rise of 30 kPa.

1. TYPES OF FANS

Fans are generally classified as centrifugal, axial, mixed flow, or cross flow according to the direction of airflow through the impeller. Figure 1 shows the general configuration of a housed centrifugal fan. The components of an axial-flow fan are shown in Figure 2.

Unhoused centrifugal fan impellers are used as circulators in some industrial applications (e.g., heat-treating ovens) and are identified as plug fans. In this case, there is no duct connection to the fan because it simply circulates the air within the oven. In some HVAC installations, the unhoused fan impeller is located in a plenum chamber with the fan inlet connected to an inlet duct or cone. This fan arrangement is identified as a plenum fan. Table 1 compares typical characteristics of some of the most common fan types. For definitions of common fan terms, see the section on Fan Terminology at the end of this chapter.

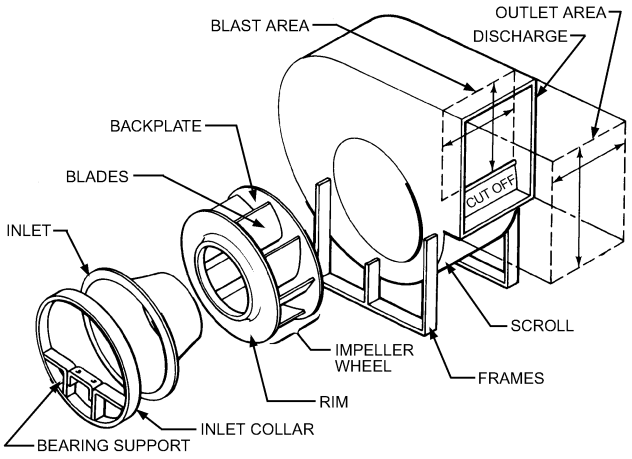

Fig. 1 Centrifugal Fan Components

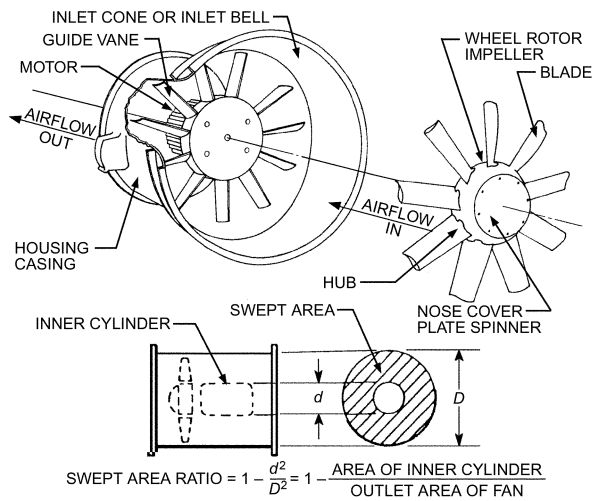
2. PRINCIPLES OF OPERATION

All fans produce pressure by altering the airflow's velocity vector. Velocity change is in the tangential and radial velocity directions for centrifugal fans, and in the axial and tangential velocity directions for axial-flow fans.

Centrifugal fan impellers increase pressure of air flowing through them by (1) centrifugal force created by rotating the air column between the blades and (2) kinetic energy imparted to the air by its velocity leaving the impeller. This velocity is a combination of rotational velocity of the impeller and airspeed relative to the impeller. When the blades are inclined forward, these two velocities are cumulative; when backward, oppositional. Fans with backward-curved blades are generally more efficient than ones with forward-curved blades.

Axial fan impellers increase pressure principally by the change in air velocity as it passes through the impeller blades, with none being produced by centrifugal force. These fans are divided into three types: propeller, tubeaxial, and vaneaxial. **Propeller** fans are nonducted fans customarily used at or near free air delivery, usually having a small-hub-to-tip-ratio impeller mounted in a fan panel, orifice plate, or inlet ring. Tubeaxial fans usually have reduced blade tip clearance and operate at higher tip speeds, giving them a higher pressure capability than the propeller fan. Vaneaxial fans are essentially tubeaxial fans with guide vanes and reduced blade tip clearance, which results in improved pressure, efficiency, and noise characteristics.



Note: The swept area ratio in axial fans is equivalent to the blast area ratio in centrifugal fans.

Fig. 2 Axial Fan Components

The preparation of this chapter is assigned to TC 5.1, Fans.

Table 1 Types of Fans

	Type	Impeller Design	Housing Design
Centrifugal Fans	Backward-Inclined (includes AF, BC, and BI)	 Blades inclined away from direction of rotation and can be single-thickness flat (BI), single-thickness curved (BC), or airfoil (AF) contour. Deep blades allow efficient expansion in blade passages. Air leaves impeller at velocity less than tip speed. For given duty, has highest speed of centrifugal fan designs.	 Single- or double-inlet scroll design for efficient conversion of tangential velocity pressure to static pressure. Maximum efficiency requires close clearance and alignment between impeller and inlet.
	Radial and Radial Tipped	 Blades are either fully radial (R) or backward inclined with a radial curve at outer edge (RT). Fully radial blades can have back plate and shroud, back plate only, or neither (open). Radial tipped blades normally have back plate and shroud.	 Single or double inlet scroll similar to other centrifugal fan designs. Fit between impeller and inlet not as critical as for backward inclined fans.
	Forward-Curved	 Large number of thin curved blades with outer edge tipped toward direction of rotation. Air leaves impeller with a high tangential velocity. Relies on scroll housing to convert this velocity pressure to static pressure. For given duty, has lowest speed of centrifugal fan designs.	 Single or double inlet scroll shaped design necessary for conversion of tangential velocity pressure to static pressure. Fit between impeller and inlet not as critical as for backward inclined fans.
	Plenum/ Plug	 Single inlet centrifugal impellers can be airfoil, backward curved, or backward inclined. Mixed flow or radial impellers can also be used for specific applications.	 No integral housing. The equivalent of a housing, or plenum chamber (dashed line), depends on the application. Due to the lack of a housing, all pressure development occurs in the impeller. The components of the drive system for the plug fan are located outside the airstream.
Axial Fans	Propeller	 Small number of blades (two to six), either airfoil or single thickness curved, attached to a relatively small hub.	 Simple circular ring, orifice plate, or venturi. Optimum design is close to blade tips and forms smooth airflow into impeller. Improved static efficiency can be obtained with an extension of the venturi into an expanding conical discharge.
	Tubeaxial	 Usually has four to eight blades with airfoil or single thickness cross section. Blades may have fixed or adjustable pitch. Hub is usually less than half the fan tip diameter.	 Cylindrical tube with close clearance to blade tips. Free inlet applications should use a bell mouth inlet to minimize entrance losses.
	Vaneaxial	 Typically has more blades than tubeaxial fans. Blades may have fixed, adjustable, or controllable pitch. Hub is usually greater than half fan tip diameter. Most efficient designs have airfoil blades.	 Cylindrical tube with close clearance to blade tips. Guide vanes upstream or downstream from impeller increase pressure capability and efficiency.
Mixed-Flow	Mixed-Flow	Combination of axial and centrifugal characteristics. Contoured back or hub; airfoil, curved, or straight blades, either shrouded or not. Airflow through impeller has both radial and axial components.	 The majority of mixed-flow fans have a tubular housing for use in ducted applications and include outlet turning vanes.

Table 1 Types of Fans (*Continued*)

Performance Curves*	Performance Characteristics	Applications
	Highest efficiency of all centrifugal fan designs, with peak efficiencies occurring at 50 to 60% of wide-open volume. Fan has a non-overloading characteristic, which means power reaches maximum near peak efficiency and becomes lower, or self-limiting, toward free delivery. Airfoil blades are most efficient, followed by curved and then flat blades.	General HVAC. Used in ducted applications covering a large range of pressures. Airfoil blades can be used for clean air industrial operations. For industrial applications where the environment may corrode or erode airfoil blades, consider using single thickness blades instead.
	Higher pressure characteristics than airfoil and backward curved fans. Power rises continually to free delivery, which is an overloading characteristic. Radial tipped blades are slightly more efficient than straight blades. Shrouded impellers are more efficient than nonshrouded.	Primarily for material handling in industrial plants where high duct velocities are required to keep materials airborne. Also for some high-pressure industrial requirements. Rugged impeller is simple to repair in the field. Choice of impeller type generally depends on materials being transported. Impeller sometimes coated with special material.
	Pressure curve less steep than that of backward-inclined fans. Curve dips to left of peak pressure. Highest efficiency occurs at 40 to 50% of wide open volume. Operate fan to right of peak pressure. Power rises continually to free delivery which is an overloading characteristic.	Primarily for low- to medium-pressure HVAC applications, such as residential furnaces, central station units, and packaged air conditioners. Slower speed and lower tonal noise characteristics allow them to be used closer to occupied spaces. A possible exception is central station air handling units because of low frequency noise that is more difficult to attenuate.
	Similar to housed airfoil/backward curved/backward inclined fans but slightly less efficient due to the lack of conversion of kinetic energy in the discharge airstream. Because plenum and plug fans do not have usable outlet velocity pressure, they should always be selected based on fan static pressure. Both fans are susceptible to performance degradation caused by poor inlet installation and insufficient clearance to surrounding	Plenum fans are used for HVAC equipment such as air handlers. Advantages include flexibility of equipment discharge and potential for smaller equipment footprint. Multiple plenum fans in parallel (fan arrays) can be used to further reduce the axial length of air handling equipment. Plug fans are commonly used for high-temperature process applications.
	High flow rate, but very low pressure capabilities. Discharge pattern circular or conical and airstream swirls.	For low-pressure, high-volume air-moving applications, such as ventilation through a wall without ductwork or air-cooled condenser fans.
	High flow rate, medium pressure capabilities. Pressure curve can dip to left of peak pressure at higher blade pitches. Avoid operating fan in this stall region. Discharge pattern circular and airstream rotates or swirls downstream of fan.	Low- and medium-pressure ducted HVAC applications where straight through flow and compact installation are required. Used in some industrial applications, such as drying ovens, paint spray booths, and fume exhausts.
	High pressure characteristics with medium volume flow capabilities. Pressure curve can dip to left of peak pressure. Avoid operating fan in this stall region. Guide vanes correct circular motion imparted by impeller, which improves pressure characteristics and fan efficiency.	General HVAC systems in medium- and high-pressure applications where straight-through flow and compact installation are required. Has swirl-free downstream airflow. Used in industrial applications in place of tubeaxial fans. More compact than centrifugal fans for same duty.
	Characteristic pressure curve between axial fans and centrifugal fans. Higher pressure than axial fans and higher-volume flow than centrifugal fans.	Similar HVAC applications to centrifugal fans or in applications where an axial fan cannot generate sufficient pressure rise.

Table 1 Types of Fans (*Concluded*)

	Type		Impeller Design	Housing Design
Cross-flow	Cross-flow (Tangential)		 Impeller with forward-curved blades. Typically impeller width is much greater than diameter.	 Specially designed housing for 90° or straight-through airflow. Housing causes air to enter the impeller at its periphery, flow through the impeller, and discharge at a different point of its periphery.
Other Designs	Inline Centrifugal		 Single-inlet centrifugal impellers can be airfoil, backward curved, or backward inclined.	 Cylindrical tube similar to vaneaxial fan, except clearance to impeller is not as close. Air discharges radially from impeller and turns 90° to flow through guide vanes. Variations include cylindrical and square housings with or without guide vanes. Square housings can include side discharge.
	Power Roof Ventilators	Centrifugal	 Single-inlet centrifugal impellers can be airfoil, backward curved, or backward inclined.	 Weather-protected housing with means of mounting to a building opening. Usually does not include configuration to recover velocity pressure component. Radial discharge from impeller can be directed either toward building or away from building.
		Axial	 Small number of blades (two to six), similar to an axial propeller fan.	 Similar housing to an axial propeller fan with added weather protection and means of mounting to a building opening. Can supply or exhaust air from a building, and housing can direct air either toward building or away from building.
	Induced-Flow Exhaust		 Centrifugal backward inclined or mixed flow.	 Can be scroll or tubular inline with converging cone or nozzle to increase nozzle velocity, which induces additional airflow through outlet.
	Jet Fan	Centrifugal	 Single-inlet centrifugal impellers can be airfoil, backward curved, or backward inclined.	 Rectangular, low profile. Outlet tapers to increase discharge velocity. May contain outlet straighteners and inlet protection guards.
		Axial	 Could be bidirectional or reversible in operation; similar flow rates in either direction is common.	 Tubular housing may or may not have guide vanes. Typically fitted with inlet and outlet silencers and protection screens.
		Circulating	 Includes small propeller fans up to large-diameter ceiling mounted fans. Typically two to eight blades, either airfoil or single-thickness curved, attached to a comparatively small-diameter hub.	 Often unhoused, but can have housing.

Table 1 Types of Fans (*Concluded*)

Performance Curves*	Performance Characteristics	Applications
	Similar to forward-curved fans. Power rises continually to free delivery, which is an overloading characteristic. Lowest efficiency of any centrifugal fan type.	Low-pressure HVAC components (e.g., fan heaters, fireplace inserts, electronic cooling, air curtains) where a long, narrow discharge is needed.
	Performance similar to backward-inclined fan, except capacity and pressure are lower. Lower efficiency than backward-inclined fan because air turns 90°.	Ducted HVAC applications with air discharging in axial direction (e.g., low- to medium-pressure return air systems in HVAC applications).
	Less efficient than scroll-type housed fan. Centrifugal units are slightly quieter than axial units.	Low-pressure ducted exhaust systems (e.g., general factory, kitchen, warehouse, some commercial installations).
	Usually installed without ductwork; therefore, operates at very low pressure and high volume.	Low-pressure exhaust or supply systems (e.g., general factory, kitchen, warehouse, some commercial installations).
	Performance similar to BI and MF but with reduced efficiency due to high velocity needed for induction. Outlet airflow greater than inlet airflow.	Typically used for laboratory or hazardous chemical exhaust where dilution is required and tall stacks are not desired.
	Performance measured and rated in thrust F_t. Designed for high-velocity discharge to add momentum to larger volume of air. Note that performance curves shown are not at a single speed, but at variable speeds N.	Unducted for space-constrained parking garages and emergency fire and smoke evacuation. Comparable initial cost with ducted solutions but more flexibility for exhaust and inlet air locations.
	Performance measured and rated in thrust F_t. Designed for high-velocity discharge to add momentum to larger volume of air. Typically operates at high speed, which necessitates inlet and outlet silencers. Note that performance curves shown are not at a single speed, but at variable speeds N.	Road or rail tunnels, parking garages, and emergency fire and smoke evacuation. Comparable initial cost with ducted solutions but more flexibility for the exhaust and inlet air locations.
	Performance typically measured and rated in airflow rate versus input power and impeller rotational speed N. Usually operated at free air with high-volume flow rate. Note that performance curves shown are not at a single speed, but at variable speeds.	Used for generating elevated air speeds to provide cooling of people or animals and prevent stratification of temperature or humidity (e.g., inside warehouses, airports, gymnasiums, barns). Can also be used for drying processes.

*These performance curves reflect general characteristics of various fans as commonly applied. They are not intended to provide complete selection criteria, because other parameters, such as diameter and speed, are not defined.

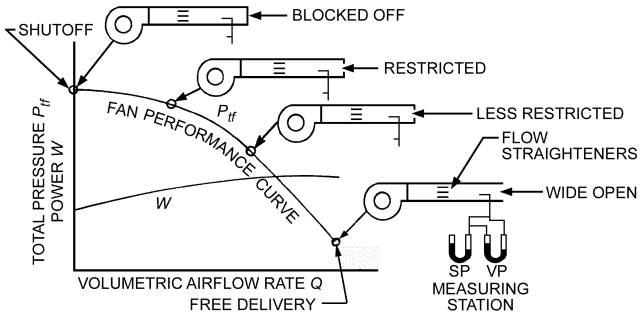


Fig. 3 Method of Obtaining Fan Performance Curves

Table 1 includes typical performance curves for various types of fans. These curves (unless otherwise stated in the table) show the general total or static pressure Pt_f of P_{sf}, total or static efficiency η_f or η_s, and fan input power H_i characteristics of various fans at a single constant operating speed as they are normally used. They do not reflect fan characteristics reduced to common denominators such as constant speed or constant propeller diameter, because fans are not selected on the basis of these constants. A particular fan (size, speed) must be selected by evaluating actual characteristics.

3. TESTING AND RATING

ASHRAE *Standard* 51 (AMCA *Standard* 210) specifies procedures and test setups to be used in laboratory testing fans and other air-moving devices. The most common type of test uses multiple nozzle inlet or outlet chambers. Figure 3 shows a pitot-static tube traverse procedure for developing characteristics of a fan. Fan performance is determined from free delivery conditions to shutoff conditions. At free delivery, outlet resistance is reduced to zero; at shutoff, the fan is completely blocked off. Between these two conditions, an auxiliary fan and various airflow restrictions are used to simulate various operating conditions on the fan. Enough points are obtained to define the curve between free air delivery and shutoff conditions. For each case, the specific point on the curve must be defined by referring to the airflow rate and corresponding fan total or static pressure. Other test setups described in ASHRAE *Standard* 51 should produce a similar performance curve, within the limits of each setup.

Fans designed for use with duct systems are tested with a length of duct between the fan and measuring station. The length of duct evens out the air velocity profile discharged from the fan outlet to provide stable, uniform airflow conditions at the plane of measurement. Pressure losses of the ductwork and flow straightener between the fan outlet and the plane of measurement are added to the measured pressure at the plane of measurement to determine the actual fan performance. Fans designed for use without ducts, including almost all propeller fans and power roof ventilators, are tested without ductwork.

Not all fan sizes are tested for rating. Test information and the fan laws may be used to calculate performance of geometrically similar larger fans, but such information should not be extrapolated to smaller fans. Test information and the fan laws can also be used to calculate performance at other speeds. To determine performance of one fan using the known performance of another, the two fans must be geometrically, kinematically, and dynamically similar. Strict similarity requires that the important nondimensional parameters (those that affect aerodynamic characteristics, e.g., Mach number, Reynolds number, surface roughness, gap size) vary in only insignificant ways. For more specific information, consult the manufacturer's application manual, engineering data, or Howden Buffalo (1999).

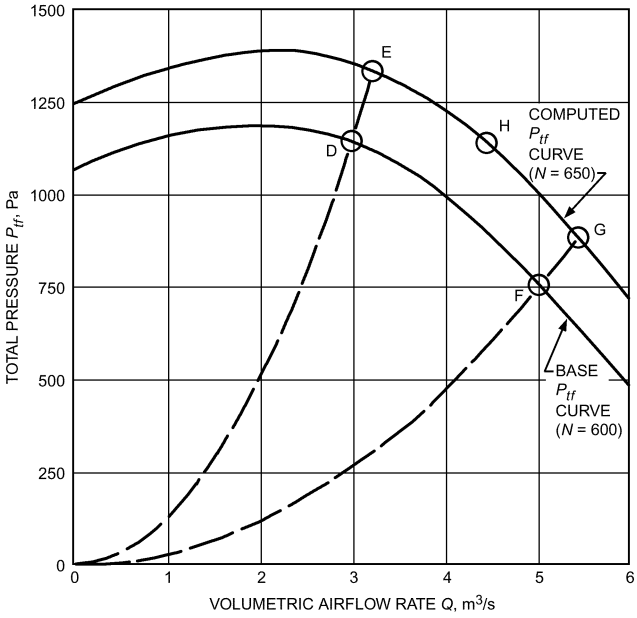

Fig. 4 Example Application of Fan Laws

4. FIELD TESTING OF FANS FOR AIR PERFORMANCE

Aerodynamic performance of a fan as installed almost always differs from the performance determined by laboratory testing. Performance differences primarily derive from system configuration differences between the field and laboratory setup, such as added elbows, obstructions in the path of the airflow, and sudden changes of duct cross-sectional area in the field installation.

Because of the performance differences, it is sometimes necessary to determine a fan's in situ performance. Typical reasons include the following:

- A general fan system evaluation to be used as the basis for modifying or adjusting fan drive components or the system to which the fan is attached
- A fan acceptance test (FAT) per specification in a sales agreement to verify quoted fan performance
- A proof of performance test in response to a complaint to demonstrate fan performance

In North America, most general fan system evaluations in the field can be accomplished using the guidelines outlined in AMCA *Publication* 203. When field testing is required and more accurate results are needed to meet a stringent contract, AMCA *Standard* 803 or ASME *Code* PTC 11 is often used. In Europe and other areas of the world, ISO *Standard* 5802 is sometimes used. Because finding a suitable flow measurement plane can often be difficult in the field, it is highly recommended to include provisions for a calibrated flow measuring station near the fan inlet and/or outlet or pressure ports on the fan as part of system design.

5. FAN LAWS

The classical form of the fan laws (see Table 2) relate performance variables for any geometrically, kinematically, and dynamically similar fans. They are a simplification of the generalized fan laws (Sardar 2001) in that they ignore Reynolds number effects. The variables are fan size D, rotational speed N, gas density ρ, volume

Table 2 Fan Laws

Law No.	Dependent Variables				Independent Variables
1a	Q_1	=	Q_2	×	$(D_1/D_2)^3(N_1/N_2)$
1b	P_1	=	P_2	×	$(D_1/D_2)^2(N_1/N_2)^2\rho_1/\rho_2$
1c	W_1	=	W_2	×	$(D_1/D_2)^5(N_1/N_2)^3\rho_1/\rho_2$
2a	Q_1	=	Q_2	×	$(D_1/D_2)^2(P_1/P_2)^{1/2}(\rho_2/\rho_1)^{1/2}$
2b	N_1	=	N_2	×	$(D_2/D_1)(P_1/P_2)^{1/2}(\rho_2/\rho_1)^{1/2}$
2c	W_1	=	W_2	×	$(D_1/D_2)^2(P_1/P_2)^{3/2}(\rho_2/\rho_1)^{1/2}$
3a	N_1	=	N_2	×	$(D_2/D_1)^3(Q_1/Q_2)$
3b	P_1	=	P_2	×	$(D_2/D_1)^4(Q_1/Q_2)^2\rho_1/\rho_2$
3c	W_1	=	W_2	×	$(D_2/D_1)^4(Q_1/Q_2)^3\rho_1/\rho_2$

Notes:
1. Subscript 1 denotes fan under consideration. Subscript 2 denotes tested fan.
2. For all fan laws $(\eta_t)_1 = (\eta_t)_2$ and (Point of rating)$_1$ = (Point of rating)$_2$.
3. P equals either P_{vf}, P_{tf}, or P_{sf}.
4. See Howden Buffalo (1999) for other considerations (e.g., compressibility effects are typically ignored for fan total pressure rises of less than 2500 Pa).

airflow rate Q, pressure P_{tf} or P_{sf}, impeller input power H, and total efficiency of the fan η_t. It is important to recognize that the fan laws only apply to fans and must not be used to calculate performance of other system components, such as drive belts, motors, or variable-frequency drives. More information about fan law deviations related to Reynolds number, Mach number, and bearing and drive losses can be found in Annex E of ASHRAE *Standard* 51-2016, Phelan et al. (1979), and Sardar (2001).

Fan Law 1 shows the effect of changing size, speed, or density on volume airflow rate, pressure, and power. **Fan Law 2** shows the effect of changing size, pressure, or density on volume airflow rate, speed, and power. **Fan Law 3** shows the effect of changing size, volume airflow rate, or density on speed, pressure, and power.

As indicated by the fan laws, fan performance is affected by gas density. Unless otherwise identified, fan performance data are based on dry air at standard conditions: 101.325 kPa and 20°C (1.20 kg/m^3). In actual applications, the fan may be required to handle air or gas at some other density. Changes in density may be caused by temperature, humidity, composition of the gas, or altitude. With constant size and speed, power and pressure vary in accordance with the ratio of gas density to standard air density.

Figure 4 shows application of the fan laws for a change in fan speed N for the same fan (i.e., $D_1 = D_2$). The computed P_{tf} curve is derived from the base curve. For example, point E ($N_1 = 650$) is computed from point D ($N_2 = 600$) as follows:

At point D,

$$Q_2 = 3 \text{ m}^3/\text{s and } P_{tf_2} = 1125 \text{ Pa}$$

Using Fan Law 1a at point E,

$$Q_1 = 3(650/600) = 3.25 \text{ m}^3/\text{s}$$

Using Fan Law 1b ($\rho_1 = \rho_2$),

$$P_{tf_1} = 1125(650/600)^2 = 1320 \text{ Pa}$$

The total pressure curve P_{tf_1} at $N = 650$ rpm may be generated by computing additional points from data on the base curve, such as point G from point F.

If equivalent points of rating are joined, as shown by the dashed lines in Figure 4, they form parabolas, which are defined by the relationship expressed in Equation (2).

Each point on the base P_{tf} curve determines only one point on the computed curve. For example, point H cannot be calculated from either point D or point F. Point H is, however, related to some point between these two points on the base curve, and only that point can be used to locate point H. Furthermore, point D cannot be used to calculate point F on the base curve. The entire base curve must be defined by test.

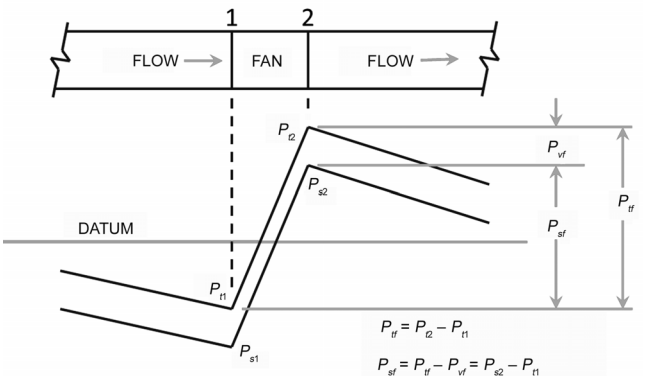

Fig. 5 Pressure Changes for Fan with Equal-Sized Ducted Inlet and Outlet Systems

6. FAN AND SYSTEM PRESSURE RELATIONSHIPS

Air traveling through a fan and air distribution system contains both static energy and kinetic energy. At any plane in the flow direction, these energies are represented by static pressure P_s and average velocity pressure P_v, respectively. Energy conversion occurs within the fan and distribution system, and is indicated by changes in static pressure to velocity pressure, and vice versa. Total pressure P_t at any plane, representing the total energy, is the sum of the static and velocity pressures. Although static and velocity pressures can increase of decrease with changes in cross-sectional area, total pressure always decreases in the direction of flow (except in the fan, where energy is added and total system pressure increases).

System pressure loss ΔP is the sum of all individual total pressure losses imposed by the air distribution system elements on both the inlet and outlet sides of the fan. Chapter 21 of the 2021 *ASHRAE Handbook—Fundamentals* provides further information about airflow versus pressure relationships in air distribution systems. System pressure loss is not simply the sum of the static pressure losses in individual distribution system elements (e.g., ducts, coils, filters), except in special cases where air velocities are the same throughout all of the distribution system elements.

ASHRAE *Standard* 51-2016 describes laboratory methods of test to determine fan aerodynamic performance data, such as fan pressure versus airflow characteristics. The terminology used to describe fan pressures P_{tf}, P_{sf}, and P_{vf} and the applicability of those terms must be clearly understood. **Fan total pressure P_{tf}** is the difference between the total pressures at the fan outlet and inlet ($P_{t2} - P_{t1}$). In contrast, **fan static pressure P_{sf}** is the difference between the fan total pressure and the fan velocity pressure ($P_{tf} - P_{vf}$). Therefore, it is also the difference between the static pressure at the fan outlet and the total pressure at the fan inlet ($P_{s2} - P_{t1}$). Except in special cases, fan static pressure P_{sf} is not the measured difference between static pressures at the fan inlet and outlet planes ($P_{s2} - P_{s1}$).

Figures 5 to 7 depict pressure changes throughout various fan and system configurations. The datum line shown in these figures refers to zero pressure for a typical system. Figure 5 shows a fan with ducted inlet and outlet systems, and Figure 6 shows a fan with a ducted outlet system but no connected inlet system. An inlet bell may be required to achieve published fan performance in the absence of an inlet duct. In this case, published fan performance effectively extends from plane 0 to plane 2, and fan static pressure is equal to the static pressure rise across the fan and inlet bell. Finally, Figure 7 shows a fan with a ducted inlet system but no outlet system.

Fan selection (covered in detail in the section on Selection) involves, in part, matching the fan pressure capability with system pressure loss at a design condition (often at the maximum required airflow). For fan systems having ducted outlets (Figures 5 and 6), fan total pressure P_{tf} should be used for fan selection. For a fan without an outlet duct (Figure 7), however, fan static pressure P_{sf} should be used instead. In the latter case, the fan velocity pressure at the discharge dissipates immediately and cannot contribute to overcoming system resistance. Therefore, the fan static pressure P_{sf}, which is the static pressure at the fan outlet P_{s2} minus the total pressure at the fan inlet P_t1, is matched to the system pressure loss.

All systems shown in Figures 5 to 7 have inlet or outlet ducts that match the fan connections in size. Often, however, the duct size is not identical to the fan outlet or inlet, thus introducing a further complication. To illustrate pressure changes in this case, Figure 8 shows a diverging outlet cone, which is a common type of fan connection. Static pressure in the cone increases in the direction of airflow (**static regain**). The regain occurs because the cross-sectional area increases through the cone and the average velocity decreases correspondingly. The total pressure decreases slightly because the conversion from average velocity pressure to static pressure involves losses. As with the other two previous ducted-outlet systems, fan total pressure P_{tf} should be used for fan selection, and static pressure across the fan ($P_{s2} - P_{s1}$) does not equal the fan static pressure P_{sf}.

7. AIR TEMPERATURE RISE ACROSS FANS

In certain applications, it may be desirable to calculate the air temperature rise across the fan. For low pressure rises (<2.5 kPa), estimate the air temperature rise by

$$\Delta T = \frac{\Delta P}{\rho c_p \eta} \quad (1)$$

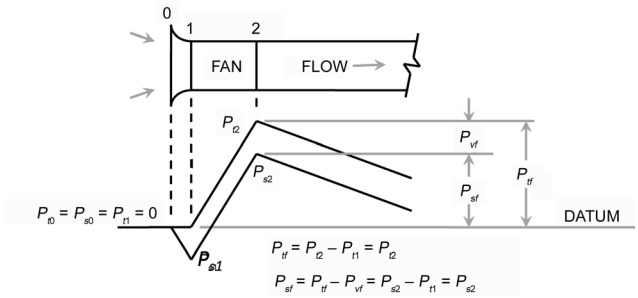

Fig. 6 Pressure Changes for Fan with Outlet System Only

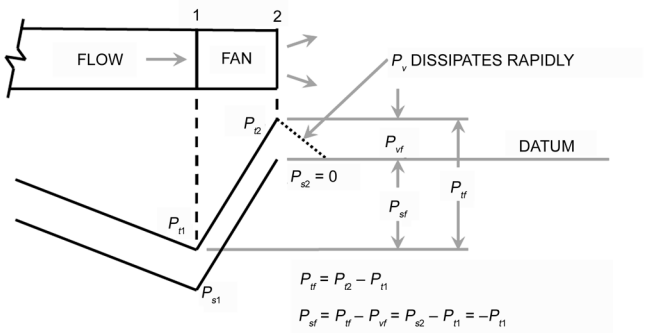

Fig. 7 Pressure Changes for Fan with Ducted Inlet System Only

where

ΔT = air temperature rise across fan, K
ΔP = pressure rise across fan, Pa
ρ = air density, kg/m^3
c_p = specific heat of air = 1005 J/(kg·K)
η = efficiency, decimal

If the motor is not in the airstream, efficiency is the fan total efficiency. If the motor and transmission (e.g., drive belt, if used) are in the airstream, the efficiency is instead the product of the motor, transmission, and fan efficiencies. It is important to recognize that fan, transmission, and motor efficiencies are not necessarily constant, and in many cases vary with the fraction of full-load operation.

Also, heat rejected by variable-frequency drives (if used, and usually not located in the airstream) and the fraction of motor and transmission heat not transferred to the airstream should be accounted for as building loads instead.

8. DUCT SYSTEM CHARACTERISTICS

Figure 9 shows a simplified duct system with three 90° elbows. These elbows represent the resistance offered by the ductwork and account for duct friction losses and fitting losses. A given airflow through a system requires a definite total pressure in the system. If the rate of airflow changes, the resulting total pressure required will vary (Equation [2], which is true for systems with no coils or filters [e.g., return or exhaust air systems]). HVAC systems such as these generally follow this law very closely.

$$(\Delta P_2 / \Delta P_1) = (Q_2 / Q_1)^2 \quad (2)$$

In some systems, particularly constant- or variable-volume air systems that include coils and filters and that may also control pres-

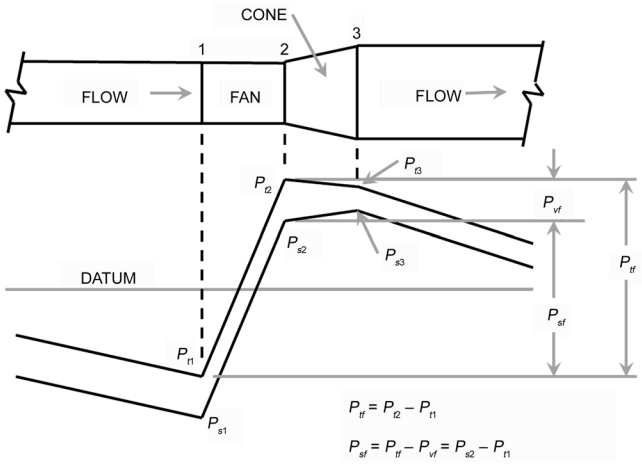

Fig. 8 Pressure Changes for Fan with Diverging Cone at Outlet

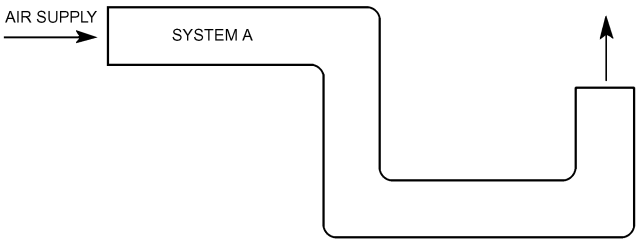

Fig. 9 Simple Duct System with Resistance to Flow Represented by Three 90° Elbows

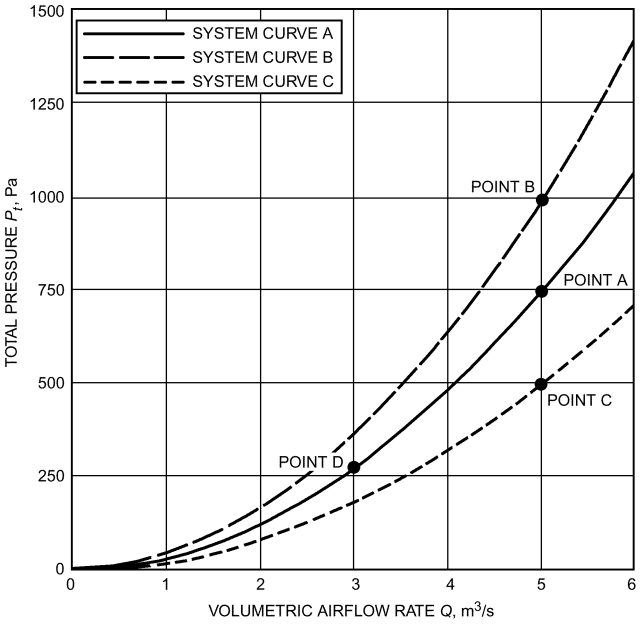

Fig. 10 Example System Total Pressure Loss ΔP Curves

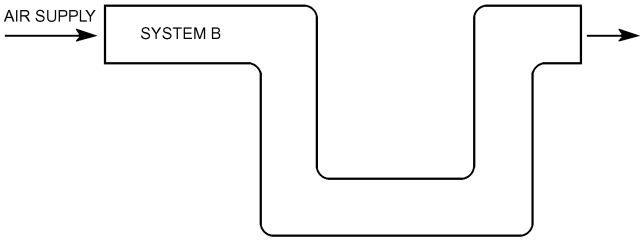

Fig. 11 Resistance Added to Duct System of Figure 9

sures at some points, the system resistance curves can deviate widely from Equation (2), even if many of the system elements are described by this equation. Sherman and Wray (2010) provide more details about these types of systems, including the effects of system leakage.

Equation (2) can plot this simple system's pressure loss ΔP curve from one known operating condition (see Figure 4). The fixed system must operate at some point on this simple quadratic system curve as the volume flow rate changes. For example, in Figure 10, at point A of system curve A, when the flow rate through a duct system such as that shown in Figure 9 is 5 m^3/s, the total pressure loss is 750 Pa. If these values are substituted in Equation (2) for ΔP_1 and Q_1, other points along the system curve (Figure 10) can be determined.

For 3 m^3/s (Point D in Figure 10):

$$\Delta P_2 = 750(3/5)^2 = 270 \text{ Pa}$$

If the system is changed so total pressure at the design flow rate is increased, the system will no longer operate on the previous system curve, and a new system curve will be defined.

For example, in Figure 11, an elbow added to the duct system shown in Figure 9 increases the total pressure loss of the system. If the total pressure loss at 5 m^3/s is increased by 250 Pa, the system total pressure loss at this point is now 1000 Pa, as shown by point B in Figure 10.

If the system in Figure 9 is changed by removing one of the elbows (Figure 12), the resulting system total pressure loss decreases, and the new system curve is curve C of Figure 10. For

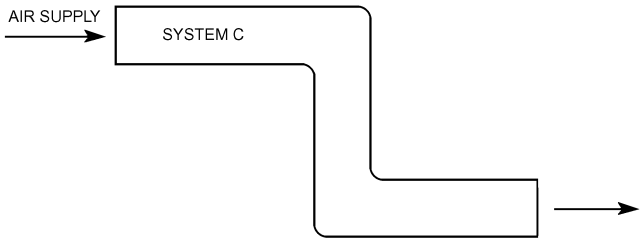

Fig. 12 Resistance Removed from Duct System of Figure 9

curve C, a total pressure loss of 250 Pa has been assumed when 5 m^3/s flows through the system; thus, the point of operation is at 500 Pa, as shown by point C.

The three system curves in Figure 10 follow the relationship expressed in Equation (2). These curves result from changes in the system itself and do not change the fan performance. During duct design, such system total pressure changes may occur because of alternative duct routing, differences in duct sizes, allowance for future duct extensions, or the design safety factor being applied to the system.

In an actual operating constant-air-volume system without coils or air filters, these three system curves can represent three system characteristic lines caused by three different positions of a throttling control damper. Curve C is the most open position, and curve B is the most closed. A control damper forms a continuous series of these system curves as it moves from wide open to completely closed and covers a much wider range of operation than is shown here. Note that pressure-independent throttling of VAV box dampers does not result in different system curves (Sherman and Wray 2010).

9. SYSTEM EFFECTS

A fan is normally tested under one of several standardized laboratory conditions (e.g., wide-open inlet and a long, straight duct attached to the outlet), which result in uniform flow into the fan and efficient static pressure recovery on the fan outlet. When a fan is installed in an application, laboratory conditions are usually not preserved. Typically, inlet and outlet conditions in installations are not the same as in the testing environment, because the fan discharges to a plenum, the discharge or intake side of the fan is too close to a transition (change in area and direction of flow) or wall, or any other interference in the flow field. This difference affects the actual fan performance.

The adverse influences of system connections on fan performance are commonly called **system effects**. To select and apply the fan properly, the system effects must be considered and the pressure requirements of the fan, as calculated by duct design procedures, must be increased accordingly. More importantly, because of the huge potential pressure (and thus energy) losses associated with system effects, great care should be taken in actual air system design and installation to eliminate or minimize system effects.

The magnitudes of system effects are typically characterized by **system effect factors**, which are values (usually in terms of pressure) suggested to compensate for the system effects. ASHRAE's (2012) *Duct Fitting Database* provides information on converting system effect factors into loss coefficients so that they can be combined with other duct losses. AMCA *Publication* 201 provides further information on determining system effect factors for various conditions. These calculated system effect factors are only an approximation, however. Fans of different types, and even fans of the same type but supplied by different manufacturers, do not necessarily react to a system in the same way. Therefore, judgment based on experience must be applied to air system design.

To provide improved knowledge and additional test data on system effects, ASHRAE completed a series of research projects to study the inlet system effects on both air and sound for different types of fans. Conclusions from these research projects include the following:

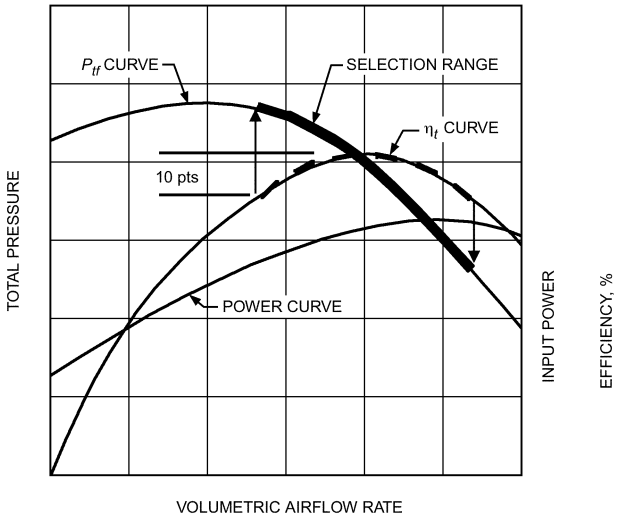
- Substantial system effects will be induced if the distance between the fan inlet and the cabinet wall is less than 0.5 times the impeller diameter; hence, this layout should be avoided as much as possible in actual system design and installation.
- System effects on sound caused by poor inlet conditions are very pronounced but also difficult to quantify.

More details are provided by Darvennes et al. (2008), Stevens and Schubert (2010), and Swim (1997). ASHRAE research projects RP-1216 and RP-1420 (Guedel et al. 2011, 2014) also provide further information on inlet and discharge installation effects on airfoil centrifugal fans.

10. SELECTION

After the system pressure loss curve of the air distribution system has been defined, a fan can be selected to meet the system requirements (Graham 1966, 1972). Fan manufacturers present performance data in either graphics (curves) (Figure 13), tabular form (multirating tables), or selection software. Multirating tables usually provide only performance data within the recommended operating range. The optimum selection range or peak efficiency point is identified in various ways by different manufacturers.

One of the most important selection criteria for fans is energy use. In recent years, fan energy consumption has been addressed by several energy codes and regulations. For example, a building code or regulation may require fans in most applications to meet a minimum **fan energy index (FEI)**. The FEI is a metric used to characterize fan energy usage for fans inclusive of motors and drives. It is defined in AMCA *Standards* 208 and 214 and is being included in ISO *Standard* 12759-6. The FEI is the ratio of the electrical input power of a reference fan to the electrical input power of the actual fan for which the FEI is calculated, both at the same duty point (which is characterized by the value of airflow and fan pressure). The FEI can be calculated for each point on a fan curve. The FEI may be reported with the manufacturer's performance data or electronic selection tools. If not, consult the fan manufacturer.



Curve shows performance of a fixed fan size running at a fixed speed.

Fig. 13 Fan Performance Curve

Other codes and regulation also apply to the extended fan system. For example, the European EU *Directive* 327/2011: *Ecodesign—Fans* requires the extended fan system to meet a minimum efficiency metric that is similar to **fan motor efficiency grade (FMEG).** The FMEG is a wire-to-air efficiency metric and is defined in ISO *Standard* 12759:2010 (soon to be ISO *Standard* 12759-4, under development). Determination of FMEG is based on overall fan system peak efficiency, electrical input power, efficiency category, and fan type.

In addition to codes and regulations as related to the extended fan system, some apply only to the stand-alone fan (without drive components) such as the **fan efficiency grade (FEG)**. The FEG is a metric used to characterize fan energy efficiency and is defined in AMCA *Standard* 205-19 and ISO *Standard* 12759:2010 (soon to be ISO *Standard* 12759-3, under development). Fans that comply with a minimum FEG requirement must be selected so that the difference between peak total efficiency and total efficiency at the selection point is within a prescribed value (e.g., 15%, as shown in Figure 13).

Fans that do not meet the minimum requirements of a code or regulation cannot be considered for selection. The FEI, FMEG, and FEG are separate, distinct metrics for describing fan efficiency and energy usage. They can be used to establish compliance with applicable codes or regulations, but not as a means to make fan selections or to quantify actual fan performance in a given application.

Performance data as tabulated in typical manufacturers' fan performance tables or as shown by fan performance maps are based on arbitrary increments of flow rate and pressure. In the tables, adjacent data, either horizontally or vertically, represent different points of operation (i.e., different points of rating) on the fan performance curve. These points of rating depend solely on the fan's characteristics; they cannot be obtained from each other by the fan laws. However, points of operation listed in fan performance tables are usually close together, so intermediate points may be interpolated arithmetically with adequate accuracy for fan selection.

Selecting a fan for a particular air distribution system requires that the fan pressure capability matches with the system pressure loss at a design condition. For a fan system *with* a ducted outlet, the fan total pressure should be used for fan selection. On the other hand, for a fan system *without* an outlet duct, the fan static pressure should be used instead. Since the system pressure loss is the sum of all individual total pressure losses imposed by the air distribution system elements on both the inlet and outlet sides of the fan, the total system must be evaluated and airflow requirements, system resistances, system air leakage, and system effect factors at the fan inlet and outlet must be known (see Chapter 21 of the 2021 *ASHRAE Handbook—Fundamentals* and Chapter 19 of this volume). Fan speed and power requirements are then calculated, using multirating tables or single or multispeed performance curves or graphs.

Fan manufacturers provide catalogs or electronic tools for making fan selections. Fan performance data (e.g., airflow rate, pressure rise, input power) are typically presented over a recommended range of fan operating conditions. When the fan is selected within this recommended range, airflow over the aerodynamic surfaces, such as the inlet cone and impeller blades, smoothly follows the surfaces in a way that results in good aerodynamic efficiency. However, when the fan operates outside of this recommended range, airflow may be unable to follow these surfaces and it breaks away, or separates, resulting in a number of undesirable effects. This condition, generally known as **stall**, is characterized by extensive regions of separated flow, increased noise, and highly unsteady behavior in the key flow variables (airflow rate, static pressure rise, and input power). The latter effect is known as **surge**. Fans operating under these conditions are subject to mechanical damage because of the large unsteady forces involved.

Different fan types exhibit stall and surge to varying degrees. Care must be taken when selecting a fan to ensure that operation

does not extend beyond the recommended boundaries provided by the fan manufacturer. Fan manufacturers provide a recommended selection range for each fan to avoid stall and flow pulsations. For further information about stall, refer to Eurovent (2007).

The selected point of operation (Figure 14) must represent a desirable point on the fan curve, to attain maximum efficiency and resistance to stall and pulsation. In systems where more than one point of operation is encountered, look at the range of performance and evaluate how the selected fan reacts within this complete range. This analysis is particularly necessary for variable-air-volume (VAV) systems, where not only the fan undergoes a performance change, but the entire system deviates from the relationships defined in Equation (2). In these cases, it is necessary to look at actual losses in the system at performance extremes and throughout the part-load operating range (where the system operates most of the time).

Special attention is needed to select the proper motor and any related drive components (e.g., belts, variable-speed drives). The motor and other component ratings must be sufficient to allow operation at all anticipated points of operation. Fans with overloading power characteristics and fans operating at elevated temperatures present areas of concern. Variable-air-volume systems may require special consideration if operated before system balancing. Techniques for assessing the effects of fan system component characteristics (i.e., fan, belt, motor, variable-frequency drive) on efficiency, power, and energy use throughout the operating range of a VAV system are described in DOE (2022).

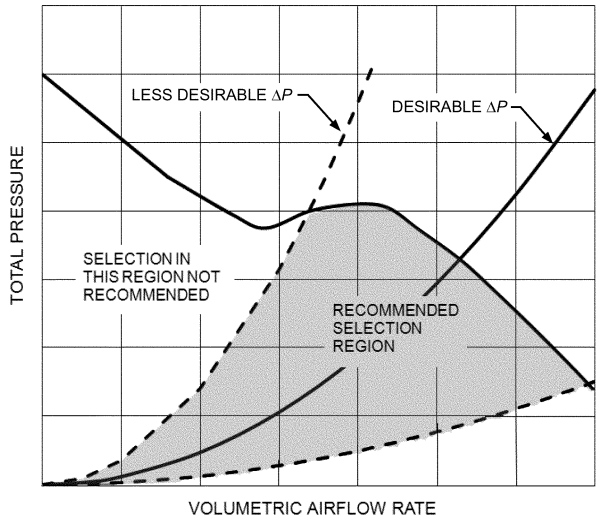


Fig. 14 Desirable Combination of P_{tf} and ΔP Curves

11. PARALLEL FAN OPERATION

When two identical fans with **stable** performance characteristics throughout the range of their individual performance curves operate in parallel, ideally their combined performance curve can be created by doubling the airflow of a single fan at any pressure level. Examples of such fans include backward-inclined centrifugal fans and axial-flow fans operated with a low pitch blade angle. Figure 15A illustrates a combined performance curve of two fans with stable operating characteristics.

When two fans with **unstable** performance characteristics (i.e., a pressure reduction to the left of the peak pressure point) operate in parallel, an unstable flow condition may occur if the fans operate too close to the peak pressure point of the combined performance curve. Figure 15B illustrates the combined performance curve of two fans operating in parallel.

Curve A-A of Figure 15B represents the pressure characteristic of a single fan. Curve C-C is the combined performance of two fans operating in parallel. All operating points to the right of point CD, the peak pressure point, are the sum of two times the airflow values for a single fan at the same pressure. The points are along the stable operating range of each fan. All systems with a resistance curve intersecting the combined performance curve to the right of point CD, such as resistance curve D-D, have stable flow characteristics.

Points to the left of point CD are the sum of all airflow values possible at the same pressure level of the fans. The points are along the unstable operating range of each fan. The double-loop shape (∞) seen in Figure 15B to the left of the peak pressure of two-fan operation is formed by summing the multiple airflows possible at a single pressure level. Systems with a resistance curve intersecting the performance curve in this region, to the left of point CD (e.g., resistance curve E-E), have unstable flow characteristics. Unstable flow is shown by the intersection of the system resistance curve at multiple points on the combined fan performance curve, points CE and CE'. The fans oscillate between these two points with random changes in airflow, noise, and vibration levels.

Avoid operating at unstable conditions. Always select fans to operate in their stable range, well to the right of the peak pressure point subject to the guidance in the section on Selection. If possible, plot the combined fan performance curve, including the double loop, and select the fan operating point along the stable portion of the performance curve to the right of the double loop.

When three or more identical fans are installed in parallel, the resulting airflow is the individual fan performance multiplied by the

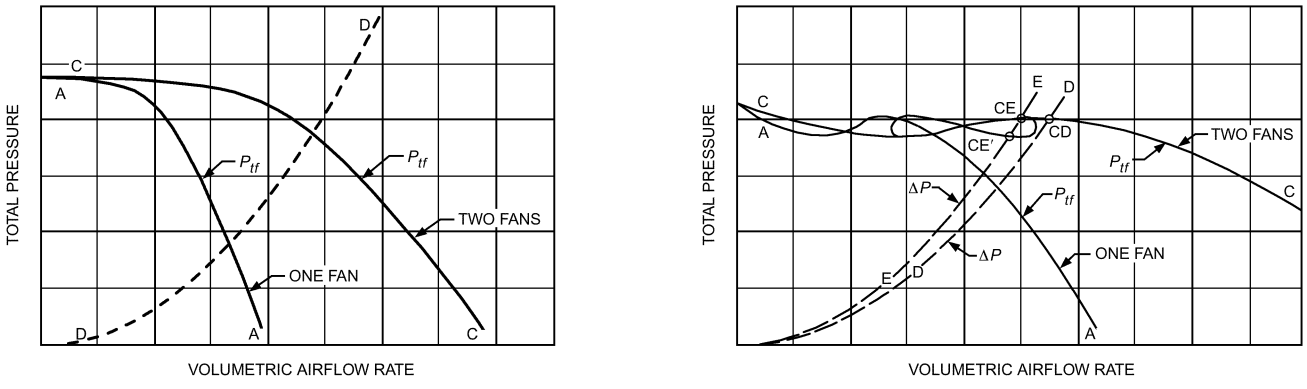

Fig. 15 Two (A) Stable and (B) Unstable Fans in Parallel Operation

number of fans in the system, for properly selected and installed fans. The designer must ensure that the operating point of each fan is well to the right of the peak to avoid oscillation of any one of the fans. Also, fan configuration (e.g., inlet and outlet duct orientation, distance between fans relative to impeller diameter) plays a major part in how well the system performs. Though parallel fan performance is easily estimated, actual performance may vary due to installation.

12. SERIES FAN OPERATION

Two identical fans operating in series theoretically double the pressure rise without changing airflow (Figure 16). Actual performance of the two fans operating in series will be less than the theoretical, because losses occur in the transition between the two fans and the second fan operates less efficiently. Lack of sufficient spacing and/or straightening of flow between the fans further reduces performance. At fan pressures below 7.5 kPa, air compressibility can be neglected. Above that limit, calculation of the operating point, fan material selection, and fan design should consider temperature rise caused by friction and compressible gases.

13. NOISE

Fan noise is a function of the fan design, volume flow rate Q, total fan pressure P_{tf}, and efficiency η_t. After the proper type of fan for a given application has been determined (keeping in mind the system effects), the best size selection of that fan is commonly based on efficiency, because the most efficient operating range for a specific line of fans is normally the quietest. Low outlet velocity does not necessarily ensure quiet operation, so selections made on this basis alone are not appropriate. Also, noise comparisons of different types of fans, or fans offered by different manufacturers, made on the basis of rotational or tip speed are not valid. The only valid basis for comparison are the actual sound power levels generated by the different types of fans when they are all producing the required volume airflow rate and total pressure. Obtain octave-band sound power level data from the fan manufacturer for the specific fan being considered.

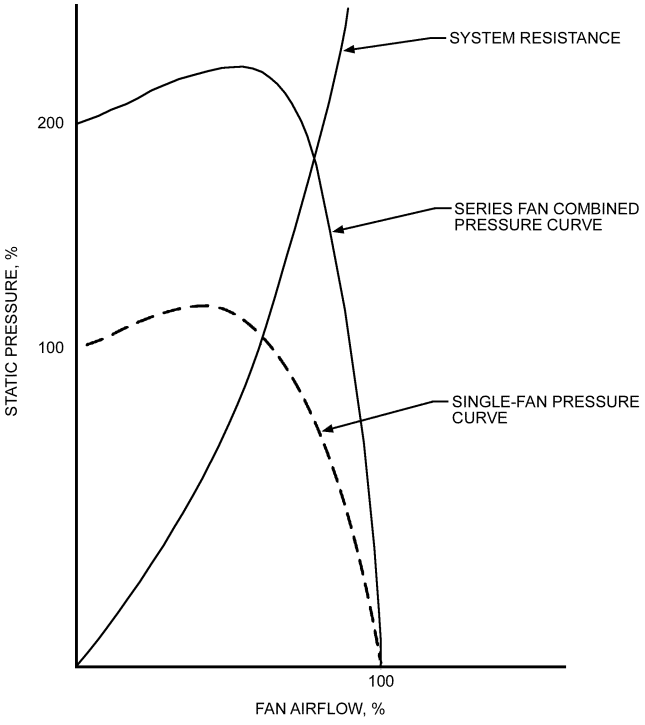

Fig. 16 Theoretical Characteristic Curve of Two Fans Operating in Series

Sound power levels L_w can be determined using several different laboratory methods, such as a reverberant room comparing the sound generated by the fan to the sound generated by a reference source of known sound power; using an anechoic room; or using sound intensity measurements. The reverberant room measuring technique is described in AMCA *Standard* 300; the enveloping surface method, which uses an anechoic room, is described in ISO *Standard* 13347-3; and the sound intensity method is described in AMCA *Standard* 320. These standards do not fully evaluate the pure tones generated by some fans; these tones can be quite objectionable when they radiate into occupied spaces. On critical installations, make special allowance by providing extra sound attenuation in the octave band containing the tone.

Discussions of sound and sound control may be found in Chapter 8 of the 2021 *ASHRAE Handbook—Fundamentals* and Chapter 49 of the 2023 *ASHRAE Handbook—HVAC Applications*.

14. VIBRATION

Fan vibration is the structural response of a fan to excitations caused by impeller imbalance, unsteady aerodynamic forces, and drive torque pulsations. The magnitude and extent of the structural response, or vibration level, is determined by the stiffness of the fan components, drive alignment, and bearing properties, among other factors.

Excessive vibration levels can lead to premature failure of the fan, produce high noise levels, and transmit undesirable forces into the support structure. Although fan vibration can never be entirely eliminated, acceptable levels can be achieved through proper fan design, manufacture, and application.

Acceptable vibration levels have been established from a long history of practical fan experience. AMCA *Standard* 204 defines recommended fan balance and vibration levels based on the fan application and fan drive power. The fan balance and vibration (BV) category, shown in Table 3, determines acceptable levels for fan balance quality and vibration levels.

Fan balance quality, or balance grade (e.g., G 6.3), is used to establish the maximum residual imbalance specification for a given fan speed and size. Balance grades for each of the BV categories are shown in Table 4.

Acceptable vibration levels, as measured in mm/s, are shown in Table 5. These levels are generally obtained using an accelerometer placed in the vicinity of the fan or motor. A newly commissioned fan would be expected to meet the start-up values given in the table. If alarm levels are reached during operation, appropriate steps should be taken to identify, contain, and correct the source of the vibration. The fan should be taken out of service if vibration levels exceed the shutdown values. Operation at these levels can lead to premature failure of the fan.

Acceptable vibration performance at the fan design conditions can be achieved by following these recommendations. However, with the widespread use of variable-speed control, fans may still produce excessive vibration levels at certain *critical* speeds that correspond to natural frequencies of the fan and/or fan support structure. These critical speeds should be avoided, or eliminated through proper design of the fan components.

The vibration level of a fan changes with fan operating condition and time. Therefore, it is important to monitor, or periodically check, the fan vibration level to ensure safe and reliable operation.

Vibration Isolation

During fan operation, vibration is transmitted to the support structure and building. This can lead to objectionable noise in occu-

Table 3 Fan Application Categories for Balance and Vibration

Application	Examples	Driver Power Limits, kW	Fan Balance and Vibration (BV) Application Category
Residential	Ceiling fans, attic fans, window AC	≤0.15	BV-1
		>0.15	BV-2
HVAC and agricultural	Building ventilation and air conditioning; commercial systems	≤3.7	BV-2
		>3.7	BV-3
Industrial processes, power generation, etc.	Baghouse, scrubber, mine, conveying, boilers, combustion air, pollution control, wind tunnels	≤298	BV-3
		>298	BV-4
Transportation and marine	Locomotives, trucks, automobiles	≤15	BV-3
		>15	BV-4
Transit/tunnel	Subway emergency ventilation, tunnel fans, garage ventilation	≤75	BV-3
		>75	BV-4
	Tunnel jet fans	All	BV-4
Petrochemical process	Hazardous gases, process fans	≤37	BV-3
		>37	BV-4

pied spaces, or to undesirable vibration in other components of the HVAC system (e.g., the ductwork). Vibration isolation (e.g., coil springs, rubber-in-shear) can be used to attenuate the vibration reaching the building. More information on vibration and application of vibration isolation can be found in Chapter 8 of the 2021 *ASHRAE Handbook—Fundamentals* and Chapter 49 of the 2023 *ASHRAE Handbook—HVAC Applications*.

15. ARRANGEMENT AND INSTALLATION

Direction of rotation is determined from the drive side of the fan. On single-inlet centrifugal f ans, the drive side is usually considered the side opposite the fan inlet. The AMCA *Standard* 99 series defines standard nomenclature for fan arrangements.

For a duct connected to a fan outlet or inlet, a flexible connection should be used to minimize vibration transmission. Provide access to the fan impeller for periodic removal of any accumulations tending to unbalance the rotor. When operating against high resistance or when low noise levels are required, it is preferable to locate the fan in a room away from occupied areas or acoustically treated to prevent sound transmission. The lighter-mass building construction common today makes it desirable to mount fans and driving motors on resilient bases designed to prevent vibration transmission through floors to the building structure. Conduits, pipes, and other rigid members should not be attached to fans. Noise that results from obstructions, abrupt turns, grilles, and other items not connected with the fan may be present. Treatments for such problems, as well as the design of sound and vibration absorbers, are discussed in Chapter 49 of the 2023 *ASHRAE Handbook—HVAC Applications*.

16. FAN CONTROL

Many fan applications require the air volume to vary in response to ventilation requirements. Control strategy selection is based on several considerations, such as frequency of airflow changes, effects on fan energy consumption, and first cost of control device(s).

Airflow control can be achieved by changing the system characteristic or the fan characteristic. Methods that change the system characteristic have low first cost, but generally consume more energy compared to methods that affect the fan characteristic.

System characteristic can be altered by installing dampers or orifice plates. This approach reduces airflow by increasing the system restriction. In general, the resulting input power is higher than that of a comparable fan correctly selected for the new airflow operating point. Dampers are usually the lowest-first-cost method of achieving airflow control and are sometimes used in cases where continuous control is needed, although other, more energy-efficient means are available.

Inlet vanes are a form of damper control that offer better energy efficiency. Inlet vanes are typically a series of triangular vanes located in the inlet of a fan. The vanes are controlled through a linkage mechanism, similar to a damper, with one important difference: the vanes are oriented such that incoming flow is turned to provide a preswirl into the fan impeller. In many cases, this can improve fan performance and offset the energy penalty of the vanes. Figure 17 illustrates the change in fan performance with inlet vane control. Curves A, B, C, D, and E are the pressure and power curves for various vane settings between wide open (A) and nearly closed (E).

Changing the fan characteristic (P_{tf} curve) for airflow control can reduce power consumption. One option is to vary the fan's rotational speed to produce the desired performance. If the change is infrequent, the speed of belt-driven fans may be adjusted by changing the drive pulley combination. More frequent changes using belt drive can be accomplished with adjustable sheaves that are manually, electrically, or hydraulically actuated. An alternative method for speed control, and the only option for direct-driven fans, is to

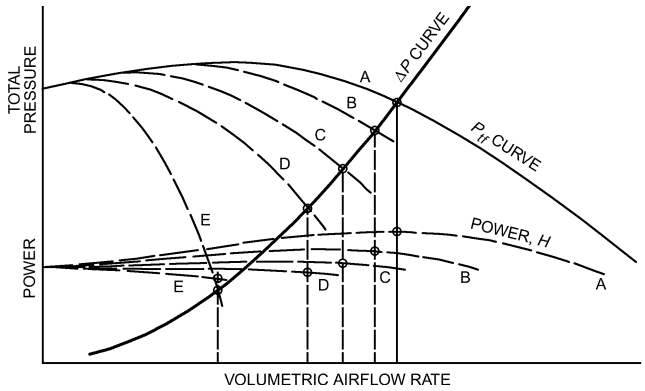

Fig. 17 Effect of Inlet Vane Control on Backward-Curved Centrifugal Fan Performance

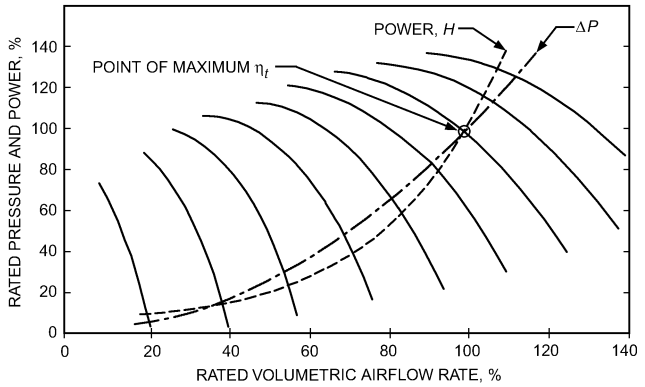

Fig. 18 Effect of Controlled Blade Pitch on Vaneaxial Fan Performance

vary the motor speed with a variable-speed control, such as a variable-frequency drive (VFD) or similar electronic device. Electronic motor speed control is often the best option from an energy consumption standpoint. When using variable-speed controls based on duct static pressure control, the fan characteristic can still be calculated with the fan laws.

An alternative to speed control is to change the fan geometry (especially blade setting angles) to optimize aerodynamic efficiency. This approach is more common in axial fans than with centrifugal fans.

Tubeaxial and vaneaxial fans are available with adjustable-pitch blades to allow balancing the airflow system, or to make infrequent adjustments. Vaneaxial fans can also be produced with controllable-pitch blades (i.e., pitch that can be varied while the fan is in operation) for frequent or continuous adjustment. Varying pitch angle retains high efficiencies over a wide range of conditions. The performance shown in Figure 18 is from a typical vaneaxial fan with variable-pitch blades. From the standpoint of noise, variable speed is somewhat better than variable blade pitch. However, both control methods give high operating efficiency and generate less noise than inlet vanes or dampers.

Table 6 summarizes control strategies and their relative energy consumption and first cost.

Further information on fan control as it relates to specific HVAC distribution systems may be found in Chapter 45 of this volume and in Chapter 48 of the 2023 *ASHRAE Handbook—HVAC Applications*. Additional information about estimating energy consumption during part-load operation is listed in the Fans, Pumps, and Distribution Systems section of Chapter 19 of the 2021 *ASHRAE Handbook—Fundamentals*. More detailed information about economic analyses is listed in Chapter 38 of the 2023 *ASHRAE Handbook—HVAC Applications*.

Table 6 Summary of Control Strategies

Control Type	Control Method	Energy Consumption	First Cost
System characteristic	Orifice plates	High	Very low
	Dampers	High	Low
	Inlet vanes	Moderate	Medium
Fan characteristic	Variable sheaves	Moderate	High
	Motor speed (belt)	Moderate	High
	Motor speed (direct)	Low	High
	Variable pitch (axial)	Low	Very High

17. FAN INLET CONE INSTRUMENTED FOR AIRFLOW MEASUREMENT

A fan inlet cone has a flared inlet and a narrow throat for efficiently receiving and guiding airflow into a rotating fan impeller. An instrumented fan inlet cone uses pressure taps to measure static pressures at both the inlet and near the throat diameter. The difference between these static pressures, adjusted for the empirically determined characteristics of the inlet cone, is used as an indication of the fan airflow mainly for control purposes (Figure 19).

The technique is based on the Bernoulli and continuity equations, which allow calculation of flow through a converging nozzle based on measurement of the static pressure drop across the nozzle.

Airflow is estimated by the formula

$$Q = k\sqrt{\frac{\Delta P}{\rho}} \quad (3)$$

where

Q = airflow rate, m^3/s
k = inlet cone calibration factor, m^2
ΔP = differential pressure across inlet cone, Pa
ρ = actual air density, kg/m^3

If the fan inlet is entirely unobstructed, then single pressure taps at the cone's inlet and throat will suffice. Otherwise, two piezometer rings, each typically consisting of four conduit-connected pressure taps, should be used for pneumatic averaging. The inlet cone calibration factor should be established experimentally by test.

18. FAN TERMINOLOGY

Air. Term used as abbreviation for "air or other gases"; a mixture of atmospheric gases. Commonly used to denote any gaseous medium measured, moved, or controlled, and that may include solid or liquid particulate.

Airflow. A flow of air or an air current, specifically one that passes through a dimensionally defined plane.

Airflow rate. *See* **Volume airflow rate.**

Air system. An assembly of connected components such as ducts, coils, filters, conditioning devices, dampers, louvers, and fans for the purpose of moving air from one place to another.

Average air velocity. Volume airflow at a plane divided by the cross-sectional area of that plane.

Balance quality grade. Recommended limits for residual unbalance of a rotor, based on the intended application. The value represents the product of the unbalance multiplied by the angular velocity and divided by the mass of the rotor.

Balancing. The process of adding or removing mass in a plane or planes on a rotor to move the center of gravity towards the axis of rotation.

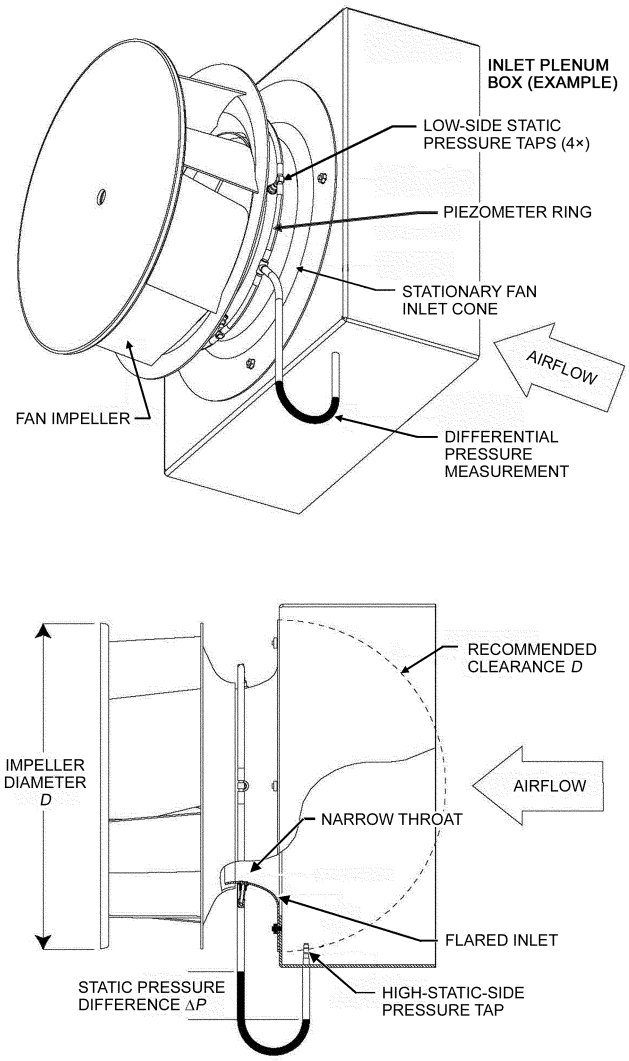

Fig. 19 Illustration of Instrumented Fan Inlet Cone
Source: Reprinted from AMCA *Publication* 600-16, Application Manual for Airflow Measurement Stations, with written permission from Air Movement and Control Association International, Inc.

Balancing speed. That rotational speed, expressed in revolutions per minute (rpm), at which a rotor is balanced.

Blade. The flow element of an impeller that, by its shape and motion, generates airflow inside a fan, transforming impeller rotational energy to kinetic energy of airflow.

Blade pass frequency (BPF). The frequency of a tone generated by the fan's blades, given by f(Hz) = (number of blades × fan revolutions per minute)/60.

Compressibility. The characteristic of air whereby its density is a function of pressure.

Compressibility coefficient. The ratio of mean airflow rate through the fan to the airflow rate at fan air density; the ratio of the fan total pressure that would be developed with an incompressible fluid to the fan total pressure that is developed with a compressible fluid (e.g., air, the test gas).

Critical speed. Rotational speed of a fan corresponding to the lowest natural frequency of the rotating fan impeller and shaft assembly when mounted on rigid supports without benefit of damping.

Dynamic similarity. A relationship between airflow systems requiring that the ratios of all corresponding forces in the two fans be equal. This includes ratios of forces due to elasticity, viscosity, gravity, surface tension, inertia, and pressure to show equivalence between two similar fans. The variables compared are fan Reynolds number, compressibility, gas specific heat ratio and tip speed Mach number at a point of operation.

Efficiency. Ratio of energy in the air provided by a dynamic application to the energy supplied to the system at a specific point of operation.

Fan. A device that uses a power-driven rotating impeller or impellers to move air or gas. The internal energy increase imparted by a fan to air or a gas is limited to 25 kJ/kg. This limit is approximately equivalent to a pressure of 30 kPa.

Fan air density. The density of air corresponding to the total pressure and total temperature at a fan inlet.

Fan air power. Product of the inlet flow rate, fan total pressure, and compressibility coefficient.

Fan airflow rate. The volumetric airflow rate at fan air density at the fan inlet or outlet.

Fan application category. Grouping used to describe fan applications, their appropriate balance quality grades, and recommended vibration levels.

Fan assembly. An assembly that consists of those items typically packaged together as "a complete fan," including, as applicable, rotor, bearings, belts, housing, motor, sheaves, and mounting base/structure.

Fan drives. Any device used to power the fan, including the motor, mechanical transmission (e.g., belt drive, coupling), and motor/control system (e.g., variable-frequency controller, electronic commutator).

Fan efficiency grade. The efficiency grade of a fan without consideration of the drives, as defined in AMCA *Standard* 205.

Fan electrical input power. The electrical power required to operate a fan, including any motor controllers, at a given duty point.

Fan energy index. The ratio of electric input power of a reference fan to the electric input power of the actual fan as calculated per AMCA *Standard* 214.

Fan housing. A stationary enclosure for an impeller. This enclosure has an inlet and an outlet and is designed to direct the flow of air through the impeller and towards the outlet.

Fan impeller. The assembled rotating component of a fan, designed to increase the energy level of the airstream.

Fan impeller power. The power delivered to a fan impeller, specifically the fan shaft power minus fan shaft losses (e.g. bearings, seals).

Fan inlet. The plane perpendicular to an airstream where the airflow first meets the inlet cone or the inlet box furnished by the fan manufacturer.

Fan inlet area. The gross inside area measured at the planes of inlet connections. For converging inlets without connection elements, it is considered to be the area where a plane perpendicular to the airstream first meets the inlet of the fan.

Fan input power. The mechanical power required to drive a fan.

Fan outlet. The plane perpendicular to the airstream at the outlet opening of the fan or the manufacturer-supplied evasé or diffuser.

Fan outlet area. The gross inside area measured at the plane of the outlet opening.

Fan outlet velocity. Average velocity of air emerging from an outlet measured in the plane of the outlet.

Fan peak efficiency. Maximum fan total or static efficiency with the fan speed and air density being fixed.

Fan performance characteristics. The total or static pressure and the volume airflow rate generated by a fan and its power consumption at any given point of operation.

Fan output power. The power delivered to the air. It is proportional to the product of the fan airflow rate, the fan total pressure and the compressibility coefficient. Sometimes called the fan's *air power*.

Fan Reynolds number (Re). A dimensionless parameter for judging dynamic similarity of flow in geometrically similar fans, relating inertia to viscous forces.

Fan rotor. A body capable of rotation, generally with journals that are supported by bearings.

Fan shaft. The spindle on which a fan impeller is mounted.

Fan shaft power. Mechanical power supplied to the fan shaft. *Note*: power loss in the fan shaft bearings is considered as a fan internal loss.

Fan sound power level. The ratio of sound power emitted by a fan to a reference value of 1.0×10^{-12} W. Sound power levels are normally presented in decibels.

Fan speed. Rotational speed of the impeller, typically measured in revolutions per minute (rpm).

Fan static efficiency. Fan total efficiency multiplied by the ratio of static pressure to total pressure at a given point of operation.

Fan static pressure. The difference between the fan total pressure and the fan velocity pressure. Therefore, it is the difference between static pressure at the fan outlet and total pressure at the fan inlet.

Fan static pressure rise. At a given point of fan operation, the increase in static pressure between fan inlet and fan outlet.

Fan total efficiency. At a given point of fan operation, a ratio equal to the fan power output divided by the power input to the fan.

Fan total pressure. At a given point of fan operation, the difference between total pressure at fan outlet and fan inlet.

Fan velocity pressure. The pressure corresponding to the average air velocity and density at the fan outlet.

Free air delivery. That point of operation where a fan operates against zero static gauge pressure.

Geometric similarity (geometric proportionality). A relationship requiring that the ratios of all corresponding dimensions for two fans be equal. This includes ratios of thickness, clearance, and roughness, as well as all the other linear dimensions of the airflow passages. All corresponding angles must be equal.

Guide vanes. Vanes located at the impeller or cabinet inlet or discharge to reduce swirl and to enhance static pressure regain from the airflow.

Housing. A stationary enclosure for an impeller, having an inlet and an outlet and designed to direct flow of air through the impeller and towards the outlet. The housing may also affect the energy transformation of the airstream.

Hub. The center portion of an impeller, which is connected to a shaft.

Impeller. *See* **Fan impeller.**

Impeller power. *See* **Fan impeller power.**

Kinematic similarity. A relationship between airflow systems requiring that the ratios of all corresponding velocities be equal for two fans to be considered similar. The directions and points of application of all corresponding vectors must be equal.

Kinematic viscosity. Absolute viscosity divided by mass density.

Mach number. Ratio of fluid velocity to the speed of sound in the same fluid.

Motor input power. Electrical power supplied to the terminals of an electric motor.

Motor output power. Power delivered from the output shaft of the motor.

Natural frequency. The frequency at which a system oscillates with a maximum amplitude in the absence of external forces.

Octave band. The interval between any two frequencies having a ratio of two.

Optimum Efficiency. *See* **Fan peak efficiency.**

Operating speed. Rotational speed, measured in revolutions per minute (rpm), at which a rotor operates.

Outlet area. *See* **Fan outlet area.**

Outlet velocity. The average velocity of air emerging from an outlet, measured in the plane of the outlet. Calculated by dividing the airflow rate by the outlet area.

Point of operation. The point on a performance curve corresponding to a particular airflow rate, pressure, power consumption, and efficiency.

Point of rating. A specified point of operation based on certain standard on a performance characteristic curve.

Propeller. An impeller that moves the air in an axial direction without creating radial flow.

Reynolds number (Re). A dimensionless number representing the ratio of internal forces to viscous forces at a particular point of a fluid in motion.

Shaft. A component used to support a rotating part, such as a fan impeller, and to transmit torque to the supported component.

Shut off. That point of operation on the fan performance curve where the airflow rate is zero.

Sound. An auditory sensation produced by the variation of pressure through an elastic medium.

Sound intensity level. The sound power level per unit area.

Sound power level. The value, expressed in decibels (dB), of ten times the logarithm (base 10) of the ratio of the sound power W to the reference sound power $W_{ref}(10^{-12})$ W.

Sound pressure level. The acoustic pressure at a point in space where a microphone or a listener's ear is situated. One decibel (dB) of sound pressure is defined as 20 times the logarithm (base 10) of the sound pressure fluctuation with reference to 20 mPa.

Standard air. Air at 20°C, 50% rh, and 101.325 kPa having approximately these properties:

- Density of 1.2 kg/m^3
- Specific heat ratio of 1.4
- Viscosity of 1.819×10^{-5} Pa·s
- Absolute pressure of 101.325 kPa

Static pressure. The pressure that exists by degree of compression only. If expressed as gauge pressure, it may be positive or negative.

Static regain. The amount of static pressure gained by conversion of velocity pressure to static pressure. This conversion takes place as air passes gradually from a small area to a larger area by means of a diffuser or an evasé.

System effect factor (SEF). A decrease in fan performance capability, observed as a pressure loss that results from the effect of fan inlet restrictions/obstructions, fan outlet restrictions or other conditions influencing the performance of the fan when it is installed in a system.

System pressure losses. The sum of the static pressure losses due to friction, shock, dissipation of velocity pressure at the system discharge, and static pressure differences between the entry and discharge openings of an air system.

Thrust. The reaction force due to the momentum change of the mass flow through the device.

Tip speed. The peripheral velocity of the fan impeller tips.

Total pressure. The air pressure that exists by virtue of the degree of compression and rate of motion of flowing air. It is equal to the algebraic sum of the velocity pressure and the static pressure at a point.

Trim balance. The process that makes minor unbalance corrections, which may become necessary as a result of the fan assembly or installation.

Unbalance. A condition of a rotor in which its rotation results in centrifugal forces being applied to the rotor's supporting bearings. Unbalance is usually measured by the product of the mass

of the rotor times the distance between its center of gravity and its center of rotation in a plane.

Vane (inlet). A flat or curved surface that can be rotated about an axis to direct airflow.

Velocity (dynamic) pressure. The pressure that exists by virtue of rate of motion only. Mathematically defined as [(density)(velocity)^2]/2.

Velocity profile. A distribution of velocities across a plane of the moving fluid.

Volume airflow rate. The volume of air that passes through a given area in a unit time.

19. SYMBOLS

A = fan outlet area, m^2
c_p = specific heat in Equation (1), J/(kg·K)
D = fan size or impeller diameter
d = area of inner cylinder
F_t = thrust of fan, N
H_o = power output of fan: based on fan volume flow rate and fan total pressure, W
H_i = power input to fan: measured by power delivered to fan shaft, W
k = inlet cone calibration factor in Equation (3), m^2
N = rotational speed, revolutions per minute
Q = volume airflow rate moved by fan at fan inlet conditions, m^3/s
P_{tf} = fan total pressure: fan total pressure at outlet minus fan total pressure at inlet, Pa
P_{vf} = fan velocity pressure: pressure corresponding to average velocity determined from volume airflow rate and fan outlet area, Pa
P_{sf} = fan static pressure: fan total pressure diminished by fan velocity pressure, Pa. Fan static pressure is also the difference between static pressure at outlet and total pressure at inlet.
P_{sx} = static pressure at given point, Pa
P_{vx} = velocity pressure at given point, Pa
P_{tx} = total pressure at given point, Pa
ΔP = pressure change, Pa
ΔT = temperature change, K
V = fan inlet or outlet velocity, m/s
η_s = static efficiency of fan: total efficiency of fan multiplied by ratio of fan static pressure to fan total pressure; $\eta_s = \eta_t(P_{sf}/P_{tf})$
η_t = total efficiency of fan; ratio of power output to power input; $\eta_t = H_o/H_i$
ρ = gas (air) density, kg/m^3

CHAPTER 22

HUMIDIFIERS

Environmental Conditions 1
Enclosure Characteristics 4
Energy and Water Considerations 5
Equipment 7
Controls 15
Application Considerations 17

IN the selection and application of humidifiers, the designer considers (1) the environmental conditions of the occupancy or process and (2) the characteristics of the building enclosure. Because these may not always be compatible, compromise is sometimes necessary, particularly in the case of existing buildings.

1. ENVIRONMENTAL CONDITIONS

A particular occupancy or process may dictate a specific relative humidity, a required range of relative humidity, or certain limiting maximum or minimum values. The following classifications explain the effects of relative humidity and provide guidance on the requirements for most applications.

Health, Comfort, and Indoor Environmental Quality

There is a growing body of compelling evidence for a strong link between indoor relative humidity and occupant health, comfort, and indoor environmental quality.

Thermal Comfort, Eyes, and Skin. Derby et al. (2017) find (through a literature review [1985 to 2015]) that the impact of low humidity on comfort manifests as eye irritation, skin dryness, and static electricity.

Low humidity does not affect thermal comfort as long as temperature is suitable (Derby et al. 2017). Higher temperature is generally considered necessary to offset decreased relative humidity (see ASHRAE Standard 55).

Low relative humidity increases evaporation from the membranes of the nose and throat, drying the mucous membranes in the respiratory system; it also dries the skin and hair. Sunwoo et al. (2006) find higher eye evaporation rates or blink frequencies at lower humidities, but because tests were conducted on the time scale of minute to hours, long-term effects on comfort and visual acuity are unknown. In general, an ultra-low humidity environment (~2.5% rh) was found to be too dry and reduced worker comfort (Chou et al. 2005, 2007). In laboratory studies, low humidity increased transepidural water loss (TEWL) and skin discomfort (Wyon et al. 2006). However, in different studies within offices, humidification both yielded and did not yield a reduction in skin dryness. Very low humidity also increased the likelihood of static buildup. Nordström et al. (1994) document a significant decrease in electrostatic discharge complaints when relative humidity increases from 25 to 40%.

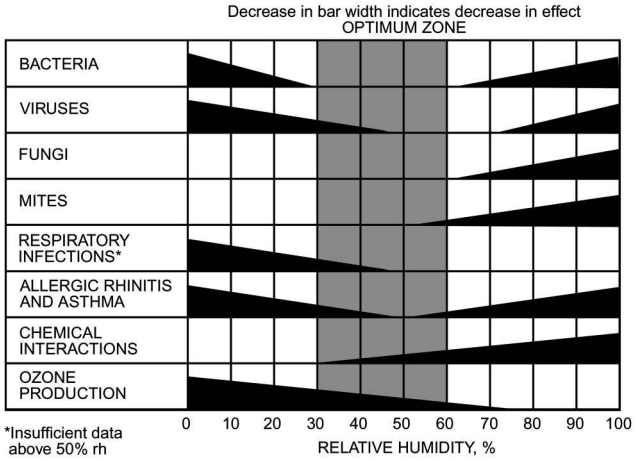

Fig. 1 Optimum Humidity Range for Human Comfort and Health

(Adapted from Sterling et al. 1985)

Indoor Environmental Quality (IEQ). Derby et al. (2017) determines that the effects of humidity on indoor environmental quality (IEQ) are modest. Results on the effects of relative humidity on volatile organic compound (VOC) emissions from building materials are inconclusive and depend on type of material and type of VOC. Emissions from materials may or may not vary with changes in temperature and humidity. In general, increases in temperature and humidity decrease the perceived quality or acceptability of the air. (Fang et al. 1998, 1999)

During one study, Fang et al. reported an increase of fatigue, headache, and difficulty thinking at lower levels of temperature and humidity. However, in another study, Norbäck et al. (1990) saw no correlation between room temperature and humidity and symptoms. Additionally, Fiedler et al. (2005) exposed women to brief (three-hour) mixtures of VOCs with and without ozone, and no significant subjective or objective health effects were reported as a result of the short VOC exposure.

Health. ASHRAE research project RP-1630 (Derby et al. 2017) findings indicate that low humidity (especially in cold air) triggers asthma (Bundgaard et al. 1982; Kaminsky et al. 1995), though the studies do not address specific lower humidity limits. Data included in house dust mite (HDM) literature by Arlian et al. support the conclusion that higher humidity levels encourage dust mite growth and subsequent HDM allergen production, and that controlling indoor relative humidity below approximately 50% can be an effective means of reducing house dust mite allergens. When considering the effects of low humidity on asthma, one must consider the interactions of allergies, ventilation, and viruses, as asthmatics are extremely susceptible to upper and lower respiratory tract infections.

The increased incidence of respiratory complaints during winter is often linked to low relative humidity. Epidemiological studies have found lower rates of respiratory illness reported among occupants of buildings with midrange relative humidity than among occupants of buildings with low humidity.

Extremes of humidity are the most detrimental to human comfort, productivity, and health. Figure 1 shows that the range between 30 and 60% rh (at normal room temperatures) provides the best conditions for human occupancy (adapted from Sterling et al. 1985). In this range, both the growth of bacteria and biological organisms and the speed at which chemical interactions occur are minimized. The trends of Figure 1 are, in general, correct, though the increasing widths of the bars designated "decrease in effect" are approximate at

The preparation of this chapter is assigned to TC 5.11, Humidifying Equipment.

best. (Derby et al. 2017). Figure 1 has been adapted from its original published form. In the original work, an optimal range of 40 to 60% rh, was recommended. However, this has been expanded to include the 30 to 40% range, recognizing that higher humidity levels may not be feasible in cold climates.

Derby et al. (2017) make several observations across the comfort, IEQ, and health categories. Human subjects in this research were nearly always adults, and of these, a significant percentage of studies used university students, so it is unknown if the same conclusions apply to children, adolescents, and the elderly. Across the categories, ventilation was noted as a confounding factor, and this is a topic for future investigation. Time was noted as an important factor as well; most studies were conducted for a few hours, and long-term effects of low humidity are unknown.

Prevention and Treatment of Disease

The effect of relative humidity on occupant comfort has been considered a secondary concern compared to sensible temperatures. This oversight is partly because humans have no skin sensors for dryness. The role of relative humidity in occupant health, a more important consideration than comfort, has pushed management of indoor water vapor to the forefront. Relative humidity has a significant effect on the control of airborne infection.

One of the clearest examples of the importance of maintaining indoor rh between 40 and 60% for comes from a study of a hospital in the midwestern US. Over the course of one year, ten patient rooms were monitored for temperature, CO_2 levels, outdoor air fractions, lighting, visitor and clinician traffic, absolute and relative humidity, room pressurization, and RAC. These environmental parameters, measured every 5 to 30 minutes, were then statistically correlated with newly acquired healthcare-associated infections (HAIs) in approximately 300 patients residing in these rooms. Of all the room measurements, low relative humidity correlated the most significantly with increased HAIs (Taylor and Hugentobler 2016). In this study, as patient room relative humidity increased from 32 to 42%, the number of HAIs fell dramatically.

Reimann et al. (2018) expand on the prior works by testing the hypothesis that raising the absolute humidity above seasonal values would have an impact on influenza virus survival and transmission. The researchers added humidifiers to several classrooms within a Minneapolis school and controlled the room humidity in the range of 40 to 60% (as recommended by Sterling et al. 1985). These rooms were compared with control classrooms where no humidity control was present and the air became considerably drier during the cold winter months. Air and object samples were tested to determine the presence of influenza and its ability to infect cells. Additionally, occupant surveys determined the number of influenza-like infections within the classroom. Results of this study showed a significant reduction in the number of influenza A virus samples in rooms with humidification. Furthermore, influenza-like infections occurred 2.3 times more regularly in the control (not humidified) rooms. While the authors recommend further research, they do note that the humidification could serve as a solution for reducing influenza or other viral outbreaks.

Another study in a longterm care facility monitored patient infections and indoor conditions over a four-year period. (Taylor and Tasi 2018). The most significant parameter associated with increased patient infections, especially respiratory and gastrointestinal (GI) infections, was low indoor relative humidity. As shown in Figure 2, patient health was most optimal at indoor rh 40 to 60%.

Derby et al. (2017) draw several general conclusions regarding humidification effects on bacteria, viruses, and fungi. Influenza virus survival exhibits a canonical dip between 40 and 80% rh across many studies, and for nearly all cases, virus survival declined the longer the length of exposure. It has been hypothesized that changes of pH within the aerosol, induced by evaporation, may trigger conformational changes of the surface glycoproteins of enveloped viruses, leading to a decrease in viral infectivity (Yang and Marr 2012).

Kudo et al. 2019 examined the mechanisms through which mid-range 40 to 60% rh affects the body. This landmark study provides insights for the seasonality of the influenza virus epidemics, whereby inhalation of dry air compromises the host's ability to restrict influenza virus infection. The study shows that exposure of mice to low humidity conditions of 20% rh renders them more susceptible to influenza disease through impaired mucociliary clearance, decreased first line-of-defense against viral invasion of the respiratory tract, more lung damage from inflammation after viral disease, and defective tissue repair. Conversely, 50% rh was protective to the infected mice and associated with almost twice the survival rate, as shown in Figure 3.

While previous studies have clearly shown that environmental conditions such as dry air affect transmission of the flu virus, this is the first to show the mechanism through which humidification

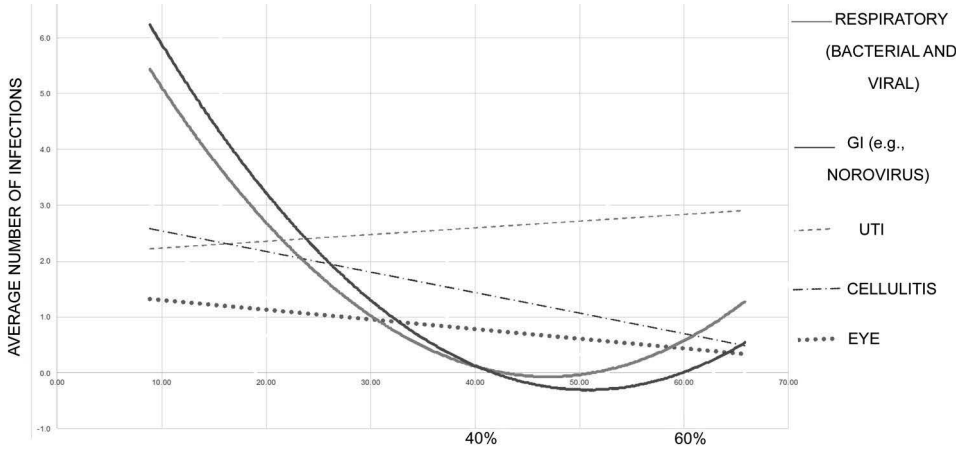

Fig. 2 Patient Infections at Indoor Relative Humidities

(Patient respiratory and gastrointestinal infections from viral and bacterial pathogens were lowest at indoor rh of 40 to 60%). (Taylor and Tasi 2018)

decreases illness and mortality in an animal model that applies to humans.

These recent works build on previous work showing that at 50% rh, the mortality rate of certain organisms is highest, and the influenza virus loses much of its virulence. The mortality rate of these organisms decreases both above and below this value. High humidity can support the growth of pathogenic or allergenic organisms. As shown in Figure 4, humidity levels around 50% can be lethal to the *Pneumococcus* bacterium (Brundrett 1990). Similar effects can be seen in other microorganisms that cause serious health issues. Consequently, relative humidity in habitable spaces should be maintained between 30 and 60%.

Relative humidity also has a major role in the effects of different bacteria. Figure 5 shows the mortality of mice exposed to influenza under varying degrees of relative humidity (Brundrett 1990).

During the COVID-19 pandemic much research was conducted on behavior of the SARS-COV-2 virus and opportunities to mitigate risks. Parhizkar et al. 2022 conducted a study with students at the University of Oregon who had been diagnosed with COVID-19. These students spent 3 days living in a specialized chamber where ventilation, filtration, and humidity was varied to determine the effect on infectious particles. This study found that higher humidity levels resulted in lower aerosol loadings in the air, and higher surface viral loadings due to increased particle deposition rates. This deposition effect was originally described in Noti et al (2013); infectious particles emitted into dry environments rapidly lost moisture mass to the air and became lighter enabling them to remain aloft and travel further. In higher humidity environments the moisture mass is retained, resulting in heavier particles, which settle out of the breathing zone more rapidly. Parhizkar et al. concluded that humidity was an important part of risk mitigation interventions within the building stating "*the findings indicate that building operation practices such as ventilation, filtration, and humidification substantially reduce the environmental aerosol viral load and therefore inhalation does, and should be prioritized to improve building health and safety.*"

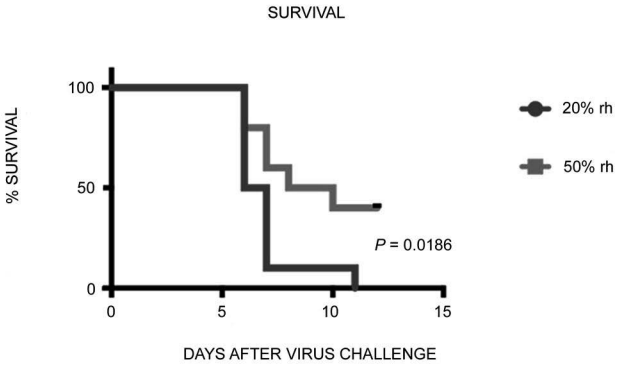

Fig. 3 Mice Survival Rates at 20 and 50% rh

(Mice maintained at 20 and 50% rh were infected with influenza A virus. Survival rates shown here.)
(Kudo et al. 2019)

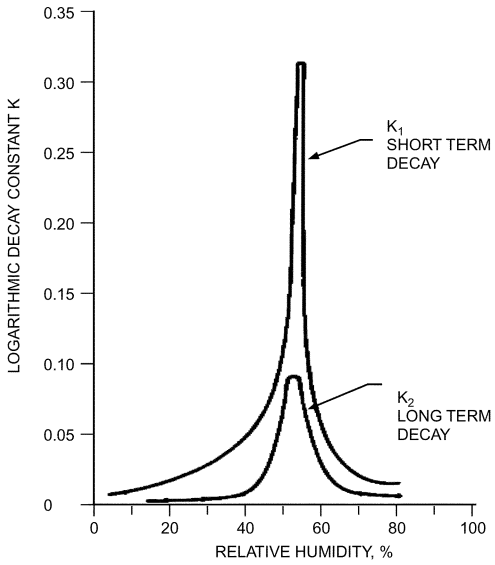

Fig. 4 Mortality of *Pneumococcus* Bacterium

Maximum mortality for airborne *Pneumococci* comes when relative humidity is held at 55% rh. (Adapted from Brundrett [1990], *Criteria for Moisture Control*. Copyright Elsevier © 1990.)

Electronic Equipment

Electronic data processing equipment requires controlled relative humidity. High relative humidity may cause condensation in the equipment, whereas low relative humidity may promote static electricity. Also, rapid changes in relative humidity should be avoided because of their effect on bar code readers, magnetic tapes, disks, and data processing equipment. Generally, computer systems have a recommended design and operating range of 35 to 55% rh. However, the manufacturer's recommendations should be adhered to for specific equipment operation.

Process Control and Materials Storage

The relative humidity required by a process is usually specific and related to one or more of several factors:

- Control of moisture content, regain or release
- Rate of chemical or biochemical reactions
- Rate of crystallization
- Product accuracy or uniformity

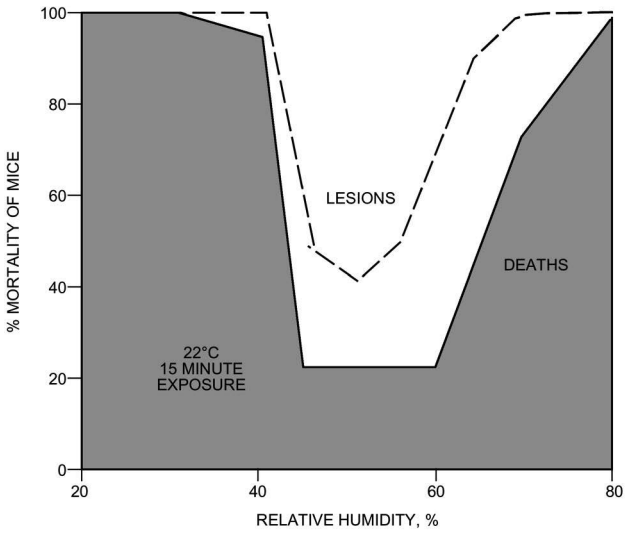

Fig. 5 Mortality in Mice Exposed to Aerosolized Influenza

Note that numbers of deaths and lung lesions were minimized when humidity was held between 40 and 60% rh.
(Adapted from Brundrett [1990], *Criteria for Moisture Control*. Copyright Elsevier © 1990.)

- Corrosion
- Static electricity

Typical conditions of temperature and relative humidity for storage of certain commodities and manufacturing and processing of others may be found in Chapter 15 of the 2023 *ASHRAE Handbook—HVAC Applications*.

Low humidity in winter may cause drying and shrinking of furniture, wood floors, and interior trim. Winter humidification should be considered to maintain relative humidity closer to that experienced during manufacture or installation.

For storing hygroscopic materials, maintaining constant humidity is often as important as, or even more important than, the humidity level itself. This is particularly true of artwork and museum artifacts, which are sensitive to rapid changes in humidity and temperature.The design of the structure should always be considered. Temperature control is important because of the danger of condensation on products through a transient lowering of temperature.

Static Electricity

Electrostatic charges are generated when materials of high electrical resistance move against each other. The accumulation of such charges may have a variety of results: (1) unpleasant sparks caused by friction between two materials (e.g., stocking feet and carpet fibers); (2) difficulty in handling sheets of paper, fibers, and fabric; (3) objectionable dust clinging to oppositely charged objects (e.g., negatively charged metal nails or screws securing gypsum board to wooden studding in the exterior walls of a building that attract positively charged dust particles); (4) destruction of data stored on magnetic disks and tapes that require specifically controlled environments; and (5) hazardous situations if explosive gases are present, as in hospitals, research laboratories, or industrial clean rooms.

Increasing the relative humidity of the environment reduces the accumulation of electrostatic charges, but the optimum level of humidity depends to some extent on the materials involved. Based on the study by Paasi et al. (2001), electrostatic discharge (ESD) for several materials is a concern below 30% rh. Figure 6 illustrates the voltage that can be accumulated in the human body at different humidity levels. Relative humidity of 45% reduces or eliminates electrostatic effects in many materials, but wool and some synthetic materials may require a higher relative humidity.

Hospital operating rooms, where explosive mixtures of anesthetics are used, constitute a special and critical case. A relative humidity of at least 50% is usually required, with special grounding arrangements and restrictions on the types of clothing worn by occupants. Conditions of 22°C and 55% rh are usually recommended for comfort and safety.

Sound Wave Transmission

Air absorption of sound waves, which results in the loss of sound strength, is worst at 15 to 20% rh, and the loss increases as the frequency rises (Harris 1963). There is a marked reduction in sound absorption at 40% rh; above 50%, the effect of air absorption is negligible. Air absorption of sound does not significantly affect speech but may merit consideration in large halls or auditoriums where optimum acoustic conditions are required for musical performances.

Miscellaneous

Laboratories and test chambers, in which precise control of relative humidity over a wide range is desired, require special attention. Because of the interrelation between temperature and relative humidity, precise humidity control requires equally precise temperature control.

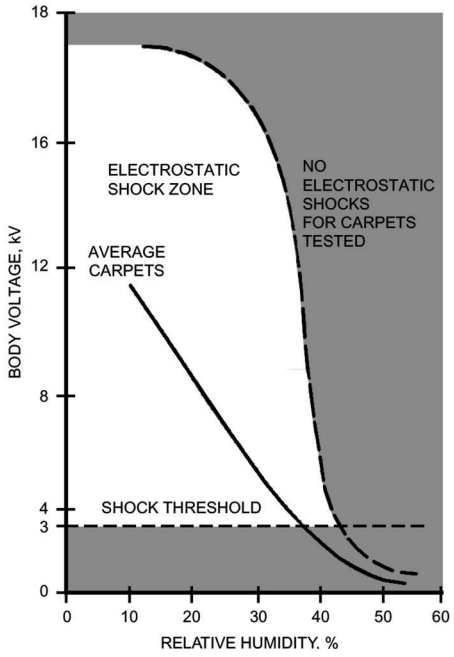

Fig. 6 Effect of Relative Humidity on Static Electricity from Carpets

Below 40% rh, perceptible shocks are more likely. (Adapted from Brundrett [1990], *Criteria for Moisture Control*. Copyright Elsevier © 1990.)

2. ENCLOSURE CHARACTERISTICS

Vapor Retarders

The maximum relative humidity level to which a building may be humidified in winter depends on the ability of its walls, roof, and other elements to prevent or tolerate condensation. Condensed moisture or frost on surfaces exposed to the building interior (visible condensation) can deteriorate the surface finish, cause mold growth and subsequent indirect moisture damage and nuisance, and reduce visibility through windows. If the walls and roof have not been specifically designed and properly protected with vapor retarders on the warm side to prevent the entry of moist air or vapor from the indoors, concealed condensation within these constructions is likely to occur, even at fairly low interior humidity, and cause serious deterioration.

Visible Condensation

Condensation forms on an interior surface when its temperature is below the dew-point temperature of the air in contact with it. The maximum relative humidity that may be maintained without condensation is thus influenced by the thermal properties of the enclosure and the interior and exterior environment.

Average surface temperatures may be calculated by the methods outlined in Chapter 25 of the 2021 *ASHRAE Handbook—Fundamentals* for most insulated constructions. However, local cold spots result from high-conductivity paths such as through-the-wall framing, projected floor slabs, and metal window frames that have no thermal breaks. The vertical temperature gradient in the air space and surface convection along windows and sections with a high thermal conductivity result in lower air and surface temperatures at the sill or floor. Drapes and blinds closed over windows lower surface temperature further, while heating units under windows raise the temperature significantly.

In most buildings, windows present the lowest surface temperature and the best guide to permissible humidity levels for no

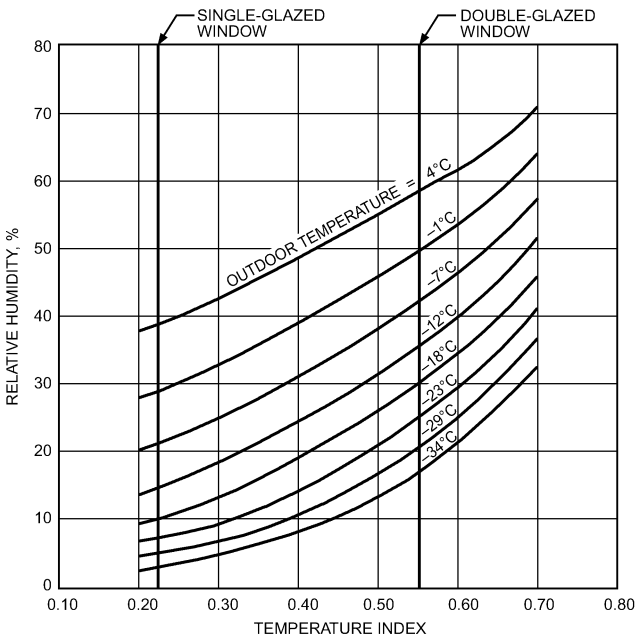

Fig. 7 Limiting Relative Humidity for No Window Condensation

condensation. While calculations based on overall thermal coefficients provide reasonably accurate temperature predictions at midheight, actual minimum surface temperatures are best determined by test. Wilson and Brown (1964) related the characteristics of windows with a **temperature index**, defined as $(t - t_o)/(t_i - t_o)$, where t is the indoor window surface temperature, t_i is the indoor air temperature, and t_o is the outdoor air temperature.

The results of limited tests on actual windows indicate that the temperature index at the bottom of a double, residential-type window with a full thermal break is between 0.55 and 0.57, with natural convection on the warm side. Sealed, double-glazed units exhibit an index from 0.33 to 0.48 at the junction of glass and sash, depending on sash design. The index is likely to rise to 0.53 or greater only 25 mm above the junction.

With continuous under-window heating, the minimum index for a double window with a full break may be as high as 0.60 to 0.70. Under similar conditions, the index of a window with a poor thermal break may be increased by a similar increment.

Figure 7shows the relationship between temperature index and the relative humidity and temperature conditions at which condensation occurs. The limiting relative humidities for various outdoor temperatures intersect vertical lines representing particular temperature indexes. A temperature index of 0.55 was selected to represent an average for double-glazed, residential windows; 0.22 represents an average for single-glazed windows. Table 1 shows the limiting relative humidities for both types of windows at various outdoor air temperatures.

Concealed Condensation

Vapor retarders are imperative in certain applications because the humidity level a building is able to maintain without serious concealed condensation may be much lower than that indicated by visible condensation. Migration of water vapor through the inner envelope by diffusion or air leakage brings the vapor into contact with surfaces at temperatures below its dew point. During building design, the desired interior humidity may be determined by the building enclosure's ability to handle internal moisture. This is particularly important when planning for building humidification in colder climates.

Table 1 Maximum Relative Humidity in a Space for No Condensation on Windows

Outdoor Temperature, °C	Limiting Relative Humidity, %	
	Single Glazing	Double Glazing
5	41	60
0	31	52
–5	23	45
–10	17	39
–15	12	33
–20	9	28
–25	6	24
–30	4	20
–35	3	17

Note: Natural convection, indoor air at 23.3°C.

3. ENERGY AND WATER CONSIDERATIONS

When calculating energy requirements for a humidification system, the effect of dry air on any material supplying it with moisture should be considered. The release of liquid in a hygroscopic material to a vapor state is an evaporative process that requires energy. The source of energy is heat contained in the air. Heat lost from the air to evaporate moisture equals the heat necessary to produce an equal amount of moisture vapor with an efficient humidifier. If proper humidity levels are not maintained, moisture migration from hygroscopic materials can have destructive effects.

The true energy required for a humidification system must be calculated from the actual humidity level in the building, not from the theoretical level.

A study of residential heating and cooling systems showed a correlation between infiltration and indoor relative humidity, indicating a significant energy saving from increasing the indoor relative humidity, which reduced infiltration of outdoor air by up to 50% during the heating season (Luck and Nelson 1977). This reduction is apparently due to sealing of window cracks by frost formation.

To assess accurately the total energy required to provide a desired level of humidity, all elements relating to the generation of humidity and the maintenance of the final air condition must be considered. This is particularly true when comparing different humidifiers. For example, the cost of boiler steam should include generation and distribution losses; costs for an evaporative humidifier include electrical energy for motors or compressors, water conditioning, and addition of reheat (when the evaporative cooling effect is not required).

Load Calculations

The humidification load depends primarily on the rate of natural infiltration of the space to be humidified or the amount of outdoor air introduced by mechanical means. Other sources of moisture gain or loss should also be considered. The **humidification load** H can be calculated by the following equations:

For ventilation systems having natural infiltration,

$$H = \rho VR(W_i - W_o) - S + L \quad (1)$$

For mechanical ventilation systems having a fixed quantity of outdoor air,

$$H = 3.6\rho Q_o(W_i - W_o) - S + L \quad (2)$$

For mechanical systems having a variable quantity of outdoor air,

$$H = 3.6\rho Q_t(W_i - W_o)\left(\frac{t_i - t_m}{t_i - t_o}\right) - S + L \quad (3)$$

where

H = humidification load, kg of water/h
V = volume of space to be humidified, m^3
R = infiltration rate, air changes per hour
Q_o = volumetric flow rate of outdoor air, L/s
Q_t = total volumetric flow rate of air (outdoor air plus return air), L/s
t_i = design indoor air temperature, °C
t_m = design mixed air temperature, °C
t_o = design outdoor air temperature, °C
W_i = humidity ratio at indoor design conditions, kg of water/kg of dry air
W_o = humidity ratio at outdoor design conditions, kg of water/kg of dry air
S = contribution of internal moisture sources, kg of water/h
L = other moisture losses, kg of water/h
ρ = density of air at sea level, 1.20 kg/m^3

Design Conditions

Interior design conditions are dictated by the occupancy or the process, as discussed in the preceding sections on Enclosure Characteristics and on Environmental Conditions. Outdoor relative humidity can be assumed to be 70 to 80% at temperatures below 0°C or 50% at temperatures above 0°C for winter conditions in most areas. Additional data on outdoor design data may be obtained from Chapter 14 of the 2021 *ASHRAE Handbook—Fundamentals.* Absolute humidity values can be obtained either from Chapter 1 of the 2021 *ASHRAE Handbook—Fundamentals* or from an ASHRAE psychrometric chart.

For systems handling fixed outdoor air quantities, load calculations are based on outdoor design conditions. Equation (1) should be used for natural infiltration, and Equation (2) for mechanical ventilation.

For economizers that achieve a fixed mixed air temperature by varying outdoor air, special considerations are needed to determine the maximum humidification load. This load occurs at an outdoor air temperature other than the lowest design temperature because it is a function of the amount of outdoor air introduced and the existing moisture content of the air. Equation (3) should be solved for various outdoor air temperatures to determine the maximum humidification load. It is also important to analyze the energy use of the humidifier (especially for electric humidifiers) when calculating the economizer setting in order to ensure that the energy saved by "free cooling" is greater than the energy consumed by the humidifier.

In residential load calculations, the actual outdoor design conditions of the locale are usually taken as –6.7°C and 70% rh, while indoor conditions are taken as 21.1°C and 35% rh. These values yield an absolute humidity difference ($W_i - W_o$) of 0.0040 kg per kilogram of dry air for use in Equation (1). However, the relative humidity may need to be less than 35% to avoid condensation at low outdoor temperatures (see Table 1).

Ventilation Rate

Ventilation of the humidified space may be caused by natural infiltration alone or natural infiltration in combination with intentional mechanical ventilation. Natural infiltration varies according to the indoor-outdoor temperature difference, wind velocity, and tightness of construction, as discussed in Chapter 16 of the 2021 *ASHRAE Handbook—Fundamentals*. The rate of mechanical ventilation may be determined from building design specifications or estimated from fan performance data (see ASHRAE *Standard* 62.1).

In load calculations, water vapor removed from the air during cooling by air-conditioning or refrigeration equipment must be considered. This moisture may have to be replaced by humidification equipment to maintain the desired relative humidity in some industrial projects where the moisture generated by the process may be greater than that required for ventilation and heating.

Estimates of infiltration rate are made in calculating heating and cooling loads for buildings; these values also apply to humidification load calculations. For residences where such data are not available, it may be assumed that a tight house has an infiltration rate of 0.5 air changes per hour (ach); an average house, 1 ach; and a loose house, as many as 1.5 ach. A tight house is assumed to be well insulated and to have vapor retarders, tight storm doors, windows with weather stripping, and a dampered fireplace. An average house is insulated and has vapor retarders, loose storm doors and windows, and a dampered fireplace. A loose house is generally one constructed before 1930 with little or no insulation, no storm doors, no insulated windows, no weather stripping, no vapor retarders, and often a fireplace without an effective damper. For building construction, refer to local codes and building specifications.

Additional Moisture Losses

Hygroscopic materials, which have a lower moisture content than materials in the humidified space, absorb moisture and place an additional load on the humidification system. An estimate of this load depends on the absorption rate of the particular material selected. Table 2 in Chapter 15 of the 2023 *ASHRAE Handbook—HVAC Applications* lists the equilibrium moisture content of hygroscopic materials at various relative humidities.

In cases where a certain humidity must be maintained regardless of condensation on exterior windows and walls, the dehumidifying effect of these surfaces constitutes a load that may need to be considered, if only on a transient basis. The loss of water vapor by diffusion through enclosing walls to the outdoors or to areas at a lower vapor pressure may also be involved in some applications. The properties of materials and flow equations given in Chapter 26 of the 2021 *ASHRAE Handbook—Fundamentals* can be applied in such cases. Normally, this diffusion constitutes a small load, unless openings exist between the humidified space and adjacent rooms at lower humidities.

Internal Moisture Gains

The introduction of a hygroscopic material can cause moisture gains to the space if the moisture content of the material is above that of the space. Similarly, moisture may diffuse through walls separating the space from areas of higher vapor pressure or move by convection through openings in these walls (Brown et al. 1963).

Moisture contributed by human occupancy depends on the number of occupants and their degree of physical activity. As a guide for residential applications, the average rate of moisture production for a family of four has been taken as 320 g/h. Unvented heating devices produce about 1 kg of vapor for each kilogram of fuel burned. These values may no longer apply because of changes in equipment as well as in living habits.

Industrial processes constitute additional moisture sources. Single-color offset printing presses, for example, give off 200 g of water per hour. Information on process contributions can best be obtained from the manufacturer of the specific equipment.

Supply Water for Humidifiers

There are three major categories of supply water: potable (untreated) water, softened potable water, and demineralized (deionized [DI] or reverse osmosis [RO]) water. Either the application or the humidifier may require a certain water type; consult the humidifier manufacturer's literature.

In areas with water having a high mineral content, precipitated solids may be a problem: they can clog nozzles, tubes, evaporative elements, and controls. In addition, solids allowed to enter the air-

stream via mist leave a fine layer of white dust over furniture, floors, and carpets.

Many humidifiers may bleed off or actively replace some or all of the water passing through the equipment to reduce the concentration of salts in the recirculating water. This allows for less frequent maintenance at the cost of increased water usage.

Dust, scaling, biological organisms, and corrosion are all potential problems associated with water in humidifiers. Stagnant water can provide a fertile breeding ground for algae and bacteria, which have been linked to odor and respiratory ailments. Bacterial slime reacts with sulfates in the water to produce hydrogen sulfide and its characteristic bad odor. Regular maintenance and periodic disinfecting with approved microbicides may be required (Puckorius et al. 1995). This has not been a problem with residential equipment; however, regular maintenance is good practice because biocides are generally used only with atomizing humidifiers.

Scaling

Industrial pan humidifiers, when supplied with water that is naturally low in hardness, require little maintenance, provided a surface skimmer bleedoff is used.

Water softening is an effective means of eliminating mineral precipitation in a pan-type humidifier. However, the concentration of sodium left in a pan as a result of water evaporation must be held below the point of precipitation by flushing and diluting the tank with new softened water. The frequency and duration of dilution depend on the water hardness and the rate of evaporation. Dilution is usually accomplished automatically by a timer-operated drain valve and a water makeup valve.

Demineralized or reverse osmosis (RO) water may also be used. The construction materials of the humidifier and the piping must withstand the corrosive effects of this water. Commercial demineralizers or RO equipment removes hardness and other total dissolved solids completely from the humidifier makeup water. They are more expensive than water softeners, but no humidifier purging is required. Sizing is based on the maximum required water flow to the humidifier and the amount of total dissolved solids in the makeup water.

Potential Bacterial Growth

Certain microorganisms are occasionally present in poorly maintained humidifiers. To deter the propagation and spread of these detrimental microorganisms, periodic cleaning of the humidifier and draining of the reservoir (particularly at the end of the humidification season) are required. Research by Unz et al. (1993) on several types of plenum-mounted (evaporative and steam) residential humidifiers showed no evidence of organism transmission originating from the humidifier. Ruud et al. (1993) also determined that humidifiers (evaporative and steam) did not add bacteria or particles to the heated airstream. Misting type systems, such as ultrasonic, fogging nozzles, and other systems that atomize water present a higher risk for distributing bacteria into the air if their reservoirs become contaminated. When using these types of products, care must be taken to heed the manufacturers cleaning and hygiene instructions to ensure safe operation of the system.

4. EQUIPMENT

Humidifiers can be broken into two basic categories, depending on when the energy is added for converting the water from a liquid to a gas in the humidification process. Each process results in different air temperatures during the humidification process, as seen in Figure 8. Table 2 shows the types of humidifiers in each category. See Chapter 1 of the 2021 *ASHRAE Handbook—Fundamentals* for more information on the humidification process.

Isothermal units use external energy to produce a steam vapor, and the humidification process results in a near-constant air temperature. All of the energy for producing the steam is added by the humidifier unit, before it enters the airstream. Isothermal units are typically called steam units by those in the industry, and fall into a couple of different groups of equipment as detailed in the paragraphs below. Because isothermal units produce only steam vapor, they are considered non-aerosol-generating humidifiers.

Adiabatic units allow direct contact between the water and airstream, and the humidification process results in a lower air temperature. All of the energy for the transformation, from liquid to gas, is provided by the airstream. Adiabatic units are typically called atomizers or evaporative systems, and fall into a couple of different groups of equipment: atomizing units are considered aerosol-generating, because they introduce water droplets directly into the airstream, whereas isothermal units are considered non-aerosol-generating, because the process only involves air absorbing the moisture as it passes over a pan or wetted device.

In Figure 8, during humidification, the isothermal system results in the air transformation of B to D. For the adiabatic system, the air transformation is shown as step C to D. For either process, the preheating steps of A to B or A to C are external to the humidification system, and are part of the air-handling system. Step B to C is equal to the energy that is required to convert the water from a liquid to a gas during the adiabatic process.

Humidifiers can generally be classified as either residential or industrial, although residential humidifiers can be used for small industrial applications, and small industrial units can be used in large homes. Equipment designed for use in central air systems also differs from that for space humidification, although some units are adaptable to both.

Air washers and direct evaporative coolers may be used as humidifiers; they are sometimes selected for additional functions such as air cooling or air cleaning, as discussed in Chapter 41.

The capacities of residential humidifiers are generally based on litres per day of operation; capacities of industrial and commercial humidifiers are based on kilograms per hour of operation. Published evaporation rates established by equipment manufacturers through test criteria may be inconsistent. Rates and test methods should be evaluated when selecting equipment. The Air-Conditioning, Heating and Refrigeration Institute (AHRI) developed *Standard* 610 for residential central system humidifiers, *Standard* 620 for self-con-

tained residential units, and *Standard* 640 for commercial and industrial humidifiers. Association of Home Appliance Manufacturers (AHAM) *Standard* HU-1 addresses self-contained residential units.

Residential Humidifiers for Central Air Systems

Residential humidifiers designed for central air systems depend on airflow in the heating system for evaporation and distribution. General principles and description of equipment are as follows:

Pan Humidifiers. Capacity varies with temperature, humidity, and airflow. Vapor is introduced into the air by evaporation.

- **Basic pan.** A shallow pan is installed within the furnace plenum. Household water is supplied to the pan through a control device.
- **Electrically heated pan.** Similar to the basic unit, this type adds an electric heater to increase water temperature and evaporation rate.
- **Pan with wicking plates.** Similar to the basic unit, this type includes fitted water-absorbent plates. The increased area of the plates provides greater surface area for evaporation to take place (Figure 9A).

Wetted-Element Humidifiers. Capacity varies with air temperature, water temperature, humidity, and airflow volume. Vapor is introduced into the air by evaporation. Air circulates over or through an open-textured, wetted medium. The evaporating surface may be a fixed pad wetted by either sprays or water flowing by gravity, or a paddle-wheel, drum, or belt rotating through a water reservoir. The various types are differentiated by the way air flows through them:

- **Fan type.** A small fan or blower draws air from the furnace plenum, through the wetted pad, and back to the plenum. A fixed pad (Figure 9B) or a rotating drum-type pad (Figure 9C) may be used.
- **Bypass type.** These units do not have their own fan, but rather are mounted on the supply or return plenum of the furnace with an air connection to the opposite plenum (Figure 9D). The difference in static pressure created by the furnace blower circulates air through the unit.
- **In-duct type.** These units are designed for installation within the furnace plenum or ductwork with a drum element rotated by either the air movement in the duct or a small electric motor.

Atomizing Humidifiers. The capacity of an atomizing humidifier does not depend on the air conditions. However, it is important not to oversaturate the air and allow liquid water to form in the duct. The air's ability to absorb moisture depends on the temperature, flow rate, and moisture content of the air moving through the system. Small particles of water are formed and introduced into the airstream in one of the following ways:

- A **spinning disk or cone** throws a water stream centrifugally to the rim of the disk and onto deflector plates or a comb, where it is turned into a fine fog (Figure 9E).
- Spray nozzles rely on **water pressure** to produce a fine spray.
- Spray nozzles use **compressed air** to create a fine mist.
- **Ultrasonic vibrations** are used as the atomizing force, to produce a fine mist or fog.

Self-Contained Electrode Steam Humidifiers (Figure 9G). These units operate by passing an electric current directly into ordinary tap water, thereby creating heat energy to boil the water, and produce steam vapor. The humidifier usually contains a plastic bottle (see Figure 10E) that is supplied with water through a solenoid valve. Periodic and partial drains maintain a desirable solids concentration and the correct electrical flow. Units are available for steam distribution into the duct with a steam nozzle or wand, or into a room with a booster fan.

Residential Humidifiers for Nonducted Applications

Many portable or room humidifiers are used in residences heated by nonducted hydronic or electric systems, or where the occupant is prevented from making a permanent installation. These humidifiers may be equipped with humidity controllers.

Portable units evaporate water by any of the previously described means, such as heated pan, fixed or moving wetted element, or atomizing spinning disk. They may be tabletop-sized or a larger, furniture-style appliance (Figure 9F). A multispeed motor on the fan or blower may be used to adjust output. Portable humidifiers usually require periodic filling from a bucket or filling hose.

Some portable units are offered with an auxiliary package for semipermanent water supply. This package includes a manual shutoff valve, a float valve, copper or other tubing with fittings, and so forth. Lack of drainage provision for water overflow may result in water damage.

Some units may be recessed into the wall between studs, mounted on wall surfaces, or installed below floor level. These units are permanently installed in the structure and use forced-air circulation. They may have an electric element for reheat when desired. Other types for use with hydronic systems involve a simple pan or pan plate, either installed within a hot-water convector or using the steam from a steam radiator.

Industrial and Commercial Humidifiers for Central Air Systems

Humidifiers must be installed where the air can absorb the vapor; the temperature of the air being humidified must exceed the dew point of the space being humidified. When fresh or mixed air is humidified, the air may need to be preheated to allow absorption to take place.

Heated Pan Humidifiers. These units offer a broad range of capacities and may be heated by a heat exchanger supplied with either steam or hot water (Figure 10A). They may be installed directly under the duct, or they may be installed remotely and feed vapor through a hose. In either case, a distribution manifold should be used.

Steam heat exchangers are commonly used in heated-pan humidifiers, with steam pressures ranging from 35 to 105 kPa (gage). Hot-water heat exchangers are also used in pan humidifiers; a water temperature below 115°C is not practical.

All pan-type humidifiers should have water regulation and some form of drain or flush system. When raw water is used, periodic cleaning is required to remove the buildup of minerals. (Using softened or demineralized water can greatly extend time between cleanings.) Care should also be taken to ensure that all water is drained off when the system is not in use to avoid the possibility of bacterial growth in the stagnant water.

Direct Steam Injection Humidifiers. These units cover a wide range of designs and capacities. Steam is water vapor under pressure and at high temperature, so the process of humidification can be simplified by adding steam directly into the air. This method is an isothermal process because the temperature of the air remains almost

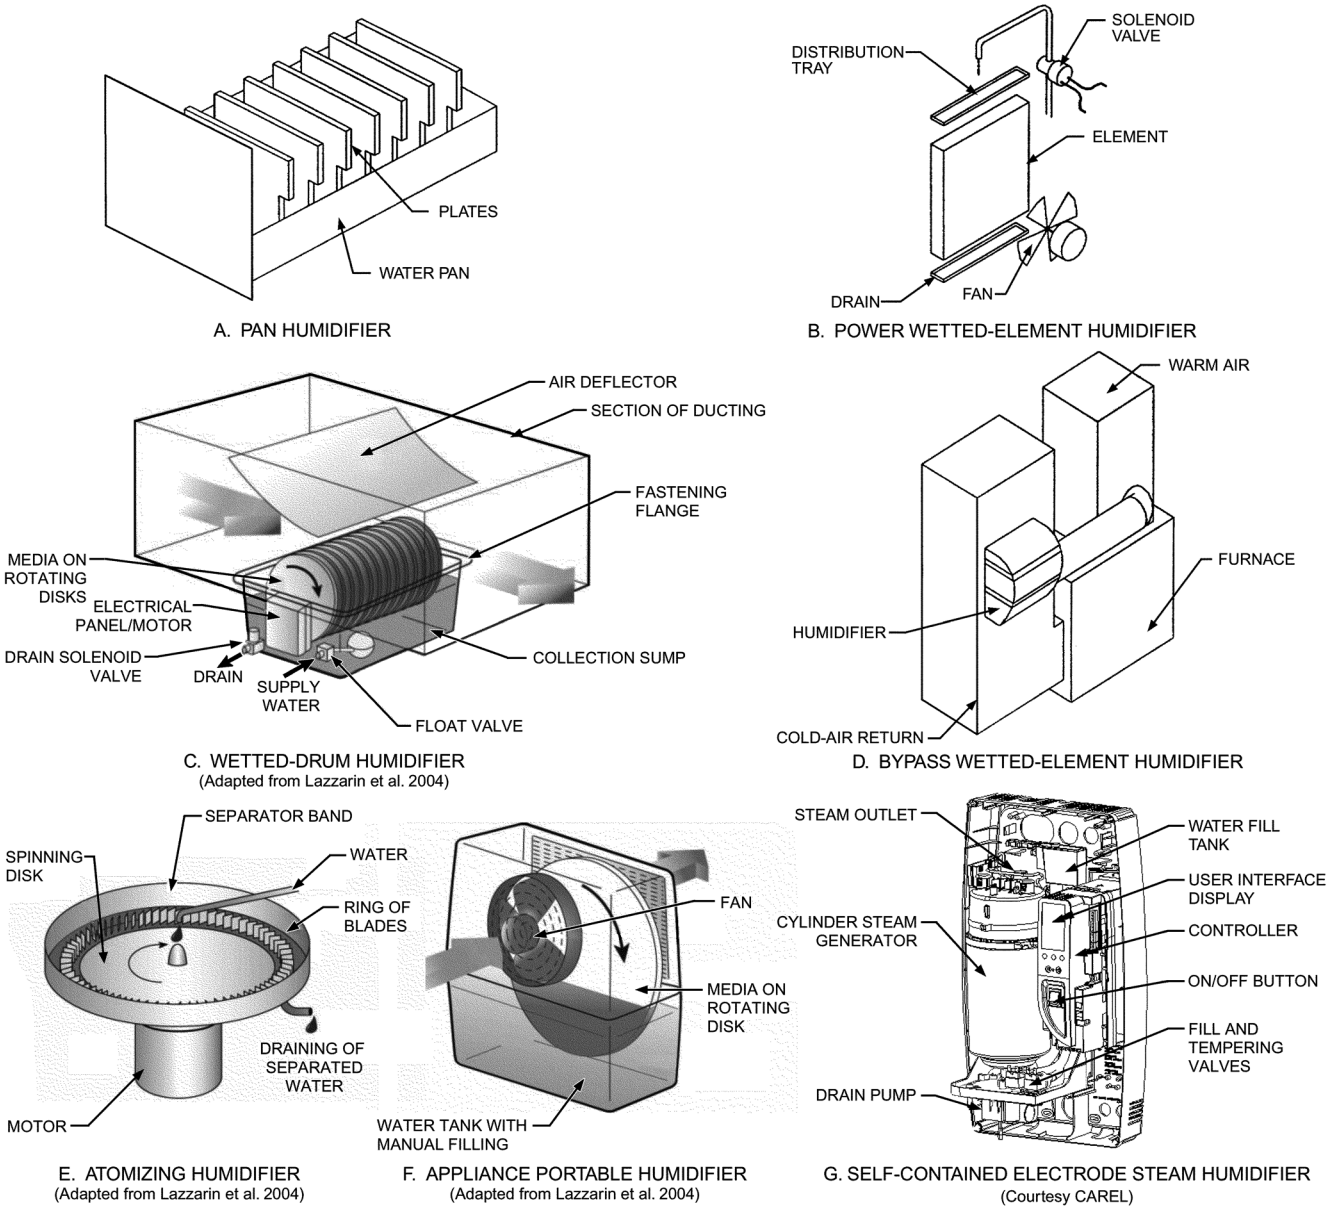

Fig. 9 Residential Humidifiers

constant as the moisture is added. For this type of humidification system, the steam source is usually a central steam boiler at low pressure. When steam is supplied from a source at a constant supply pressure, humidification responds quickly to system demand. A control valve may be modulating or two-position in response to a humidity sensor/controller. Steam can be introduced into the airstream through one of the following devices:

- Single or multiple **steam-jacketed manifolds** (Figure 10B), depending on the size of the duct or plenum. The steam jacket is designed to reevaporate any condensate droplets before they are discharged from the manifold.
- **Nonjacketed manifold** or **panel-type distribution systems** (Figure 10C), with or without injection nozzles for distributing steam across the face of the duct or plenum.

Units must be installed where the air can absorb the discharged vapor before it comes into contact with components in the airstream, such as coils, dampers, or turning vanes. Otherwise, condensation can occur in the duct. Absorption distance varies according to the design of the humidifier distribution device and the air conditions within the duct. For proper psychrometric calculations, refer to Chapter 1 of the 2021 *ASHRAE Handbook—Fundamentals.* Because these humidifiers inject steam from a central boiler source directly into the space or distribution duct, boiler treatment chemicals discharged into the air system may compromise indoor air quality. Check chemicals for safety, and carefully avoid contamination from the water or steam supplies.

Self-Contained Steam Humidifiers. These units convert ordinary city tap water to steam by electrical or gas energy using either electrodes, resistance heater elements, infrared lamps, or gas combustion. Steam is generated at atmospheric pressure and discharged

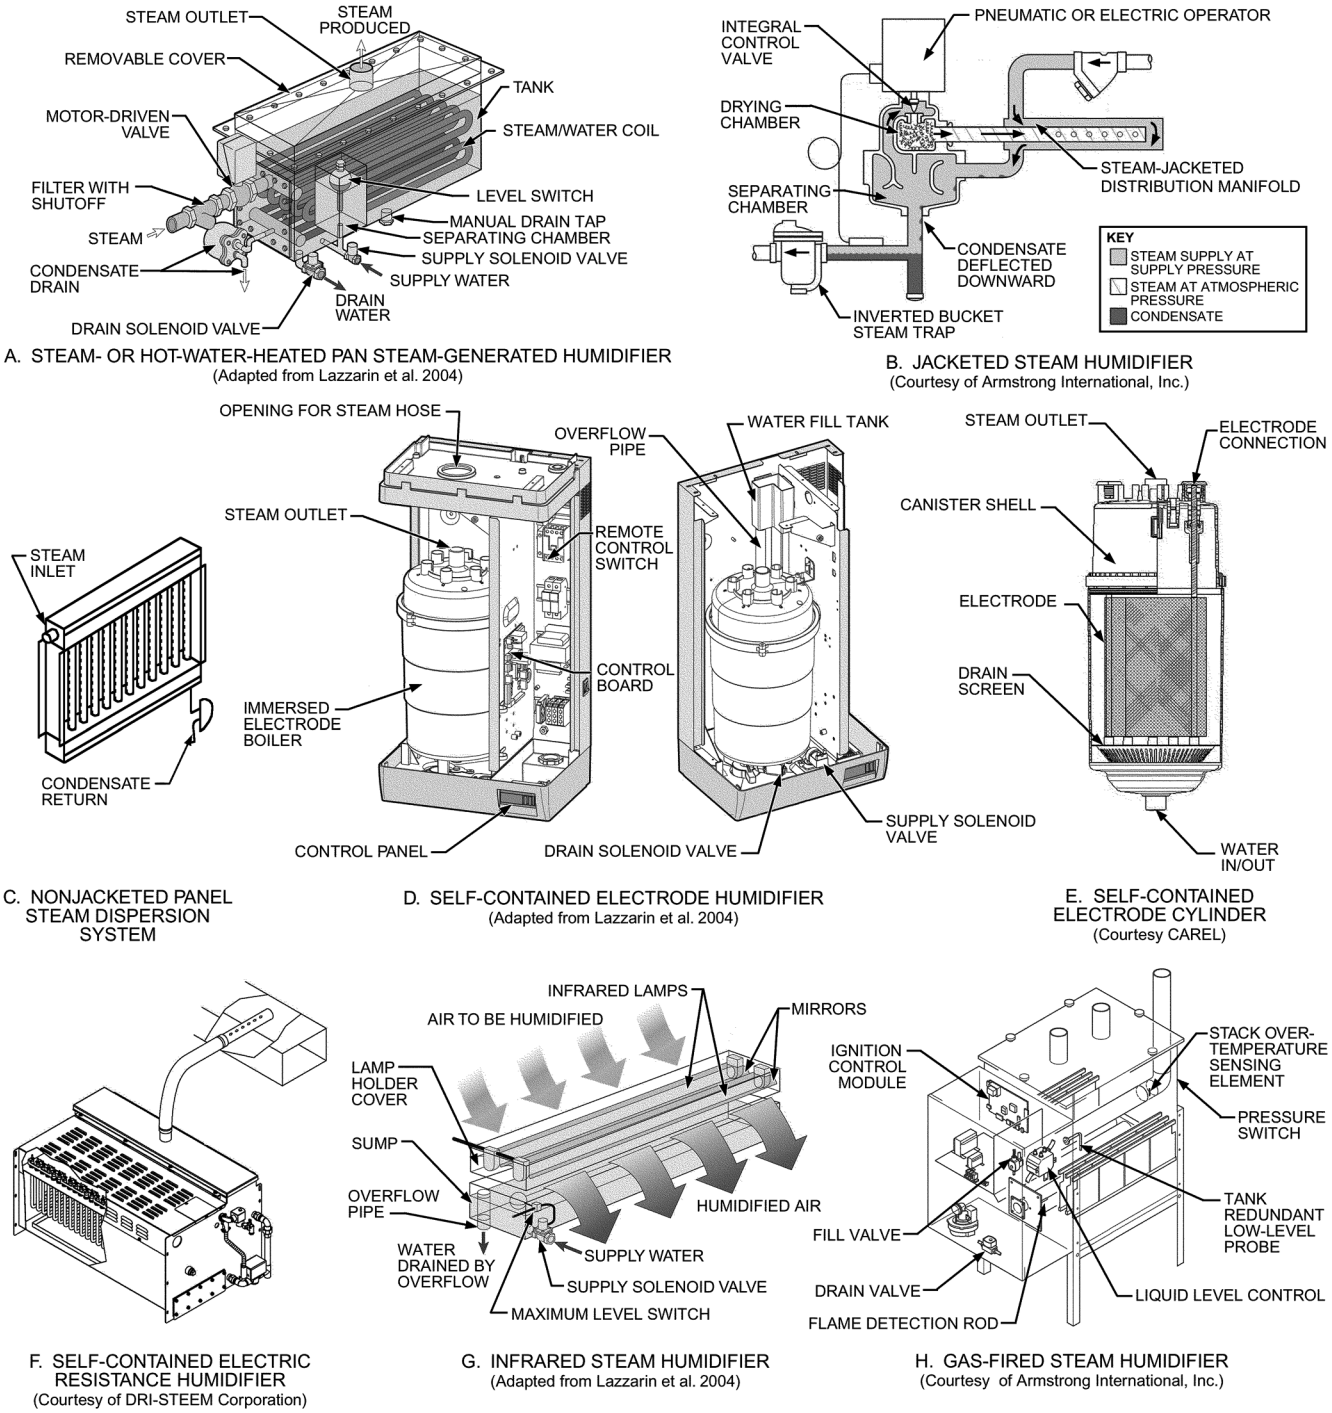

Fig. 10 Industrial Isothermal (Steam) Humidifiers

into the duct system through dispersion manifolds; if the humidifier is a freestanding unit, the steam is discharged directly into the air space or mixed in the airstream. Some units allow use of softened or demineralized water, which greatly extends the time between cleanings.

- **Electrode humidifiers** (Figure 10D) operate by passing an electric current directly into ordinary tap water, thereby creating heat energy to boil the water and produce steam vapor. The humidifier usually contains a plastic bottle (Figure 10E), either throwaway or cleanable, that is supplied with water through a solenoid valve. Periodic and partial drains maintain a desirable solids concentration and the correct electrical flow. Manufacturers offer humidifiers with several different features, so their data should be consulted.
- **Resistance humidifiers** (Figure 10F) use one or more electrical elements that heat water directly to produce steam. The water can be contained in a stainless or coated steel shell. The element and

shell should be accessible for cleaning out mineral deposits. High and low water levels should be controlled with either probes or float devices, and a blowdown drain system should be incorporated, particularly for off-operation periods.

- **Infrared humidifiers** (Figure 10G) use one or more quartz lamps to produce infrared energy that is reflected off mirrors and into a tank of water. The boiling water produces steam, which is then removed by air flowing over the surface of the tank. The water level and dilution drains are controlled by either solenoid valves, or an overflow system.
- **Gas-fired humidifiers** (Figure 10H) use one or more forced air combustion burners and heat exchangers to heat water to produce steam. The water is typically contained in a stainless steel tank, and the heat exchangers can be made from stainless steel or aluminum. The heat exchanger and tank should be accessible for cleaning out mineral deposits. High and low water levels should be controlled with either probes or float devices, and a blowdown drain system should be incorporated, particularly for off-operation periods.

Steam Distributors. Humidifiers that produce steam require a steam distributor to introduce the steam into an airstream or conditioned space. Correct selection and installation of both the steam distributors and the steam lines from the humidifier are essential for proper performance of the humidification system.

There are three common steam distributor types:

- **Individual-tube** distributors consist of one or more perforated tubes that are inserted into a section of ductwork. Steam from the humidifier escapes through holes in the tubes while condensate is collected and drained. Tubes are generally designed to span the width of the duct, and can be used individually or in groups to achieve a certain performance level.
- **Short absorption manifolds** (Figure 10C) are used in ducted or air handler applications and consist of multiple perforated distributor tubes connected to a central header. The multiple tubes spread the steam across as much of the airstream as possible, thus reducing the time and distance needed for the steam to be absorbed. However, the additional distributor tubes result in increased condensate loss and heat transfer to the airstream compared with a single-tube distributor. To minimize this effect, many short absorption manifolds are available with insulation.
- **Room fan** distributors (Figure 11) are used for direct room humidification without relying on a central HVAC system. Fan distributors can be built directly onto a humidifier or remotely mounted to distribute steam in a desired location. These distributors have the advantage of allowing the humidifier to operate independently of the ventilation system; however, they can result in a visible steam plume in the room. This plume may require some distance to fully absorb, so fans must be positioned with adequate clearance from occupants, walls, ceilings, and equipment. In addition, fan distributors also generate some noise from the motor and air movement in the fan. Both sound and absorption clearance are important considerations when placing these devices, particularly in quiet office environments.

Individual-Tube and Short Absorption Manifold Considerations. Both individual-tube and short absorption manifold distributors require tubes placed directly in an airstream. Increasing the number of tubes tends to shorten steam absorption distance, because the steam is more evenly distributed across the cross section of the airstream; however, it also increases the exposed area for heat transfer and thus also increases airstream heat gain and condensate losses in the distributor. It is best practice to minimize the number of tubes used while still maintaining absorption within the available distance. This approach reduces condensate losses and airstream heat gain while also reducing installation cost. To further reduce losses and improve efficiency, many manufacturers offer insulated distributors.

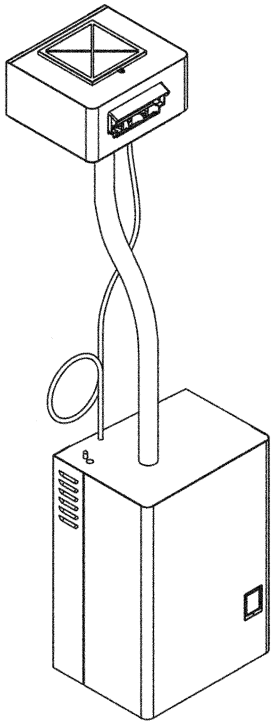

Fig. 11 Room Fan Distributor

Tubes and short absorption manifolds should both be located in a straight section of ductwork with laminar airflow. Avoid placing these distributors immediately after bends or in areas where turbulent airflow can be expected. Eddies and recirculation currents in these locations can cause the steam to be drawn into duct walls and condense.

Although not strictly required, it is good practice to include a drain pan in the distributor section to protect against possible leaks or condensation from the distributor.

Duct-mounted sensors and controls should be placed far enough away from the distributor for the moisture to mix adequately with the airstream. As a rule of thumb, high-limit controls and humidity sensors should be installed downstream at a minimum distance of five times the expected absorption distance.

Atmospheric Steam Lines. The steam lines that connect the humidifier to the steam distributors are another important part of the humidification system. Steam lines must be correctly sized, properly routed, made of correct material, have adequate drainage, and be insulated.

Sizing. Follow manufacturer guidelines when selecting an overall diameter. Lines that are too narrow create restriction that is difficult for the humidifier to overcome and can reduce system efficiencies. Lines that are too large have very low steam flow velocities and can cause high condensate losses. As a starting point, consider matching the diameter of the steam line to the outlet of the humidifier and maintaining this diameter through to the distributor.

Routing. Most stand-alone isothermal humidifiers generate atmospheric steam [i.e., steam at a very low pressure (1.5 to 4.5 kPa)]. As such, steam flow in these lines cannot travel long distances. Consider the following when routing steam lines:

- Keep atmospheric steam lines as short as possible

- Avoid long horizontal runs
- Maintain at a minimum slope of 15% for upward lines
- Maintain a minimum slope of 4% for downward lines
- Ensure lines are adequately supported to avoid unintentional low points
- Minimize the number of elbow and tee fittings

Materials. Material selection is an important aspect of steam line design. Common materials for atmospheric steam lines include copper tubing, stainless steel tubing, and hose. Compared to tubing, **piping** is costlier to install, has thicker walls, and has higher containment ratings that are not necessary for atmospheric steam. **Steam hose** is typically made of a flexible rubber or polymer material. Restrict steam hoses to short runs of 3 m or less, because the materials can soften and sag over time. Ensuring adequate support of steam hose is important to avoid low points where condensate can collect and block steam flow.

Plastic tubing and black iron piping are generally not recommended as materials for atmospheric steam lines. Certain types of plastic tubing can emit odors or become brittle from repeated heating cycles. Similarly, black iron pipe can emit odors from oils used during the manufacturing process and is prone to corrosion.

Draining. Condensate forms inside steam lines from heat losses and from cool lines on start-up. To minimize the risks of choking steam flow or discharging condensate from the distributor, this condensate should be removed through drains along the steam lines. It is best practice to place a drain and trap immediately before the distributor to collect and drain condensate before it can enter the distributor. Additionally, drains and traps should be placed every 4.5 m on steam line runs, and at any low points in the line. Low points often occur as the steam line is routed under beams, ductwork, or other piping.

A condensate drain should consist of a full-sized tee placed in the steam line, and a pressure trap. At a minimum, the trap must be sized to resist the maximum expected duct static pressure.

Condensate drained from steam lines can be recovered back to the humidifier, returned to a water treatment system, stored for irrigation and toilet usage, or directed to drain as directed by local codes. Steam line condensate is hot, often near 100°C, and should be cooled before draining. Commonly, a high-temperature condensate pump or a condensate cooling tank is used for this purpose.

Insulating. Heat transfer from steam lines can cause steam to condense back to liquid water. Losses in steam lines can reduce the overall system efficiency and reduce the amount of steam being distributed to the space. In the worst cases, significant line losses can prevent the humidifier from maintaining the desired humidity in the space. Therefore, atmospheric steam lines should be insulated with a suitable insulation for the chosen material.

Atomizing Humidifiers. Water treatment should be considered if mineral fallout from hard water is a problem. Optional filters may be required to remove mineral dust from humidified air (Figure12A). Depending on the application and the water condition, atomizing humidifiers may require a reverse osmosis (RO) or a deionized (DI) water treatment system to remove the minerals. It is also important to note that wetted parts should be able to resist the corrosive effects of DI and RO water. Atomizing humidifiers introduce fine droplets or a fog, directly into the airstream. A mist elimination system is suggested for all atomizing-type humidifiers.

There are four main categories of atomizing humidifiers:

- **Ultrasonic humidifiers** (Figure 12B) use a piezoelectric transducer submerged in demineralized water. The transducer converts a high-frequency mechanical electric signal into a high-frequency oscillation. A momentary vacuum is created during the negative oscillation, causing the water to cavitate into vapor at low pressure. The positive oscillation produces a high-compression wave that drives the water particle from the surface to be quickly absorbed into the airstream. Because these types typically use demineralized water, no filter medium is required downstream. The ultrasonic humidifier is also manufactured as a freestanding unit.
- **Centrifugal humidifiers** (Figure 12C) use a high-speed disk that slings water to its rim, where it is thrown onto plates or a comb to produce a fine mist. The mist is introduced to the airstream, where it is evaporated.
- **Pressurized-water humidifiers** (Figure 12D) use a volumetric pump to generate water at pressures between 210 and 1265 kPa. This high-pressure water is then transferred to a duct, air handler, or ambient space by distribution piping, and discharged through special nozzles. The nozzles use swirl jet or impaction features (Figures 12E and 12F) to produce billions of very small droplets that spontaneously evaporate, humidifying and cooling the air.
  - A **duct** or **air handler pressurized-water system** typically consists of a pumping station, control sensor, distribution piping, a nozzle grid array with control solenoid valves, a mist eliminator section, and a limit sensor downstream of the mist eliminator.
  - An **ambient pressurized-water system** typically consists of a pumping station, control sensor, distribution piping, and a manifold circuit (with or without air blowers) containing spray nozzles.
- **Compressed-air nozzle humidifiers** (Figure 12A) use a system of air and water control unit, distribution piping and nozzles. The control sections manage the flow of air and water going to the nozzles. The nozzles can operate in two ways:
  - Compressed air and water are combined inside the nozzle and discharged onto a resonator to create a fine fog at the nozzle tip (Figure 12G).
  - Compressed air is passed through an annular orifice at the nozzle tip, and water is passed through a center orifice. The air creates a slight vortex at the tip, where the water breaks up into a fine fog on contact with the high-velocity compressed air.

Wetted-Media Humidifiers. **Rigid-media humidifiers** (Figure 12H) use a porous core and the process of evaporation. Water is circulated over the media while air is blown through the openings. These humidifiers are adiabatic, cooling the air as it is humidified. Rigid-media cores are often used for the dual purpose of winter humidification and summer cooling. They depend on airflow for evaporation: the rate of evaporation varies with air temperature, humidity, and velocity.

The rigid media should be located downstream of any heating or cooling coils. For close humidity control, the element can be broken down into several (usually two to four) banks having separate water supplies. Individual pumps or solenoids controlling water flow to each bank are activated as humidification is required.

Rigid-media humidifiers have inherent filtration and scrubbing properties because of the water-washing effect in the filter-like channels. Only pure water is evaporated; therefore, contaminants collected from the air and water must be flushed from the system. A continuous bleed or regular pan flushing is recommended to minimize accumulation of contaminants in the pan and on the media. A cycles-of-concentration method can be used to minimize scale build-up and water discharge.

Hybrid Humidifiers. Hybrids (Figure 12I) combine a nozzle-type humidifier and a rigid-media humidifier. They are used in ducted or air handler applications. Nozzles, which typically operate at low pressure, are placed upstream of a rigid-media core and spray water into the airstream toward media. Droplets that do not evaporate are captured on the media and evaporated or drained off. The media functions as both a mist eliminator and an evaporator. Hybrid

Fig. 12 Industrial Adiabatic (Atomizing and Evaporative) Humidifiers

humidifiers normally use either RO or DI water to prevent mineral precipitation from fouling the media.

Evaporative Cooling. Atomizing and wetted media humidifiers discharge water at ambient temperature. The water absorbs heat from the surrounding air to evaporate the fog, mist, or spray at a rate of 2500 kJ per kilogram of water. This evaporative cooling effect (see Chapter 41) should be considered in the design of the system and if reheat is required to achieve the final air temperature. The ability of the surrounding air to efficiently absorb the fog, mist, or spray depends on its temperature, velocity, and moisture content.

Selecting Humidifiers

Each type of humidifier has its own strengths and best applications (Table 3).

Table 3 Humidifier Advantages and Limitations

	Advantages	Limitations	Ancillary Equipment
Adiabatic			
Centrifugal	Simple Provides evaporative cooling to surrounding air	Difficult to apply to air-handling systems Limited capacity Possible plugging issues	N/A
Compressed air and water	Adjusts to changes in demand High turndown of output Customizable to air-handling systems Available in a wide range of capacities	Requires sufficient volume of compressed air Requires purified water Longer evaporation distances Requires sufficient preheat of air supply May generate noise	Air compressor Reverse-osmosis water treatment system Three-way drain valve Mist eliminator Controls and control panel
High-pressure atomizers	Same benefits as compressed air and water Benefits of atomization without cost of compressed air Provides evaporative cooling to surrounding air	Requires potable or better water source Requires sufficient preheat of air supply Longer evaporation distances	Reverse-osmosis water treatment system Mist eliminator Controls
Low-pressure atomizers	Benefits of atomization without cost of compressed air Potential energy benefit of evaporative cooling Lower energy consumption than high-pressure atomizers High evaporation efficiencies if used with a postevaporator Typically shorter evaporation distances than high-pressure atomizers Longer life on pumps because of lower operating pressures	Must stage discharge Requires purified water Requires sufficient preheat of air supply Requires service to prevent bacterial contamination	Optional reverse-osmosis water treatment system or water softener Mist eliminator or post evaporator Controls
Ultrasonic	Adjusts to changes in demand, modulates output High turndown of output Customizable to air-handling systems Provides evaporative cooling to surrounding air	Uses deionized (DI) water Requires sufficient preheat of air supply Longer evaporation distances Needs to have an accurate reservoir liquid level Limited output from each piezo crystal Requires frequent disinfection to reduce risk of microbial dispersion	Deionized water treatment system Mist eliminator Controls
Wetted-media evaporative	Available in a wide range of capacities Provides evaporative cooling to surrounding air Low energy consumption	Slow response to reduced demand Requires biocide Nonpurified water can lead to a build-up of impurities Water collection pan must be purged periodically	Controls Recirculation pumps
Direct-Injection Steam			
Steam cup	Simple design	Limited performance features Limits in control of steam output Limitations in allowable steam capacity Unrefined sound silencing Can disperse boiler chemicals into air	N/A
Steam jacketed manifold	Reliable performance Available in a wide range of capacities Adjusts to changes in demand Separates steam from condensate Sound silencing capability Low maintenance requirements Available with high turndown or valve rangeability Lifts condensate within stream pressure constraints Control valve can be adjusted electrically or pneumatically	Requires availability of a steam boiler Longer nonwetting distance than steam panel-type Can disperse boiler chemicals into air	Steam trap Wye-type strainer Temperature switch Controls
Steam panel	Reliable performance Available in a wide range of capacities Adjusts to changes in demand Separates steam from condensate Sound silencing capability Low maintenance requirements Available with high turndown or valve rangeability Short nonwetting distances Control valve can be adjusted electrically or pneumatically Performs without steam jacket or manifolds Can be insulated for energy savings	Requires availability of a steam boiler Can disperse boiler chemicals into air Difficulty lifting condensate from steam traps	Wye-type strainer Controls Condensate pump Manufacturer supplied and installed panel insulation

Table 3 Humidifier Advantages and Limitations (*Continued*)

	Advantages	Limitations	Ancillary Equipment
Heated Tank			
Electric (electrode type)	Compact size Provides a modulated output to a variable demand signal Available with cleanable or disposable tanks Available with self diagnostics Typically wall mounted	Water minerals precipitate out, remaining in tank Cannot use extremely low-conductivity water or purified water Performance can be adversely affected by long steam distribution pipe runs Softened water may not be usable	Fill cup extension kits for high-back-pressure applications Optional tank drain temperature-tempering device Controls Steam dispersion tube or steam dispersion panel for shorter nonwetting distance, or steam blower to disperse steam Steam hose with clamps for steam dispersion
Electric (resistive type)	Can use any type of fill water: tap, softened, RO/DI Some provide modulated output through SCR/SSR control Available with self diagnostics Can be wall, floor, or rooftop mounted	Water minerals precipitate out, remaining in tank Typically larger and heavier than electrode units	Optional tank drain temperature-tempering device Controls Steam dispersion tube or steam dispersion panel for shorter nonwetting distance, or steam blower to disperse steam Steam hose with clamps for steam dispersion Roof curb for outdoor mounting
Infrared steam humidifiers	Simple and compact design	Infrared bulbs are sensitive and fracture Limited output capacity Control accuracy Radiant energy is converted to heat rather than evaporating water	N/A
Gas-fired steam humidifiers	Can use any type of fill water: tap, softened, RO/DI Low energy costs Offers models with steam capacity greater than electric units Available with self diagnostics	Water minerals precipitate out, remaining in tank unless using RO/DI water Limitations in placement because of venting requirement	Steam dispersion tube or steam dispersion panel for shorter nonwetting distance, or steam blower to disperse steam Optional tank drain temperature-tempering device Controls Sealed combustion option for dedicated combustion air Roof curb for outdoor mounting
Steam-to-steam	Available with self diagnostics Additive-free steam High-capacity units available Can be floor or rooftop mounted	Water minerals precipitate out, remaining in tank Condensate pump required to lift condensate discharged from steam trap	Control panel, control valve, steam trap, and strainer Steam dispersion tube, steam dispersion panel for shorter nonwetting distance, or blower for dispersing steam Roof curb for outdoor mounting Optional tank drain water-tempering device
Hot water humidifiers	Available with self diagnostics Additive-free steam High-capacity units available	Water minerals precipitate out, remaining in tank Minimum temperature of liquid heat source is 115°C	Controls Optional tank drain temperature-tempering device Control panel, control valve, steam trap, and strainer Steam dispersion tube, steam dispersion panel for shorter nonwetting distance, or blower for dispersing steam

5. CONTROLS

It is critical to consider how any humidification system will be properly controlled. Many aspects of the area to be humidified and how it interacts with other areas of the building must also be considered.

Water vapor concentrations equalize rapidly, moving from an area of high water vapor content to one of lower vapor content. If the space being humidified adjoins a space that does not have humidity control, the areas must be isolated or the combined area will be humidified. Similarly, if a humidified space is connected to a ventilation system that also serves nonhumidified spaces, the water vapor will equalize throughout the total area served by the ventilation system, which could require considerably increasing the humidification system size. Also, if a space is to be controlled to a lower humidity level than adjacent spaces or the environment, infiltration of moisture from the other spaces is likely as the water vapor concentration attempts to equalize.

Outdoor weather conditions can significantly affect the indoor relative humidity is a space. Cold outdoor air holds lower amounts of water vapor compared to warmer indoor air, and can lower the indoor humidity when introduced to the space. Similarly, when outdoor conditions are hot and humid, the higher water vapor content of the outdoor air will equalize with the lower water vapor in the indoor space.

Therefore, proper humidity controls must be installed to manage the humidification or dehumidification system serving a controlled space.

Several different types of controls are available to serve the requirements of the project. Controls commonly provide an on/off or a modulating signal, such as 0-10 VDC or 4-20 mA, as the humidity changes from the set point. Most humidistats can be used to activate either humidification or dehumidification systems.

Mechanical Controls

Mechanical sensors depend on a change in the length or size of the sensor as a function of relative humidity. Many humidity-sensitive materials are available, such as nylon, human hair, wood, and animal membranes that change length with humidity changes. The most commonly used sensors are synthetic polymers or human hair. They can be attached to a mechanical linkage to control the mechanical, electrical, or pneumatic switching element of a valve or motor. This design is suitable for most human comfort applications, but it may lack the necessary accuracy for industrial applications.

A humidity controller is normally designed to control at a set point selected by the user. Some controllers have a setback feature that lowers the relative humidity set point as outdoor temperature drops to reduce condensation within the structure.

Electronic Controls

Electrical sensors change electrical resistance as the humidity changes. They typically consist of two conductive materials separated by a humidity-sensitive, hygroscopic insulating material (polyvinyl acetate, polyvinyl alcohol, or a solution of certain salts). Small changes are detected as air passes over the sensing surface. Capacitive sensors use a dielectric material that changes its dielectric constant with relative humidity. The dielectric material is sandwiched between special conducting materials that allow a fast response to changes in relative humidity.

Electronic control is common in laboratory or process applications requiring precise humidity control. It is also used to vary fan speed on portable humidifiers to regulate humidity in the space more closely and to reduce noise and draft to a minimum.

Electronic controls are now widely used for residential applications because of low-cost, accurate, and stable sensors that can be used with inexpensive microprocessors. They may incorporate methods of determining outdoor temperature so that relative humidity can be automatically reset to some predetermined algorithm intended to maximize human comfort and minimize any condensation problems (Pasch et al. 1996).

Along with a main humidity controller, the system may require other sensing devices:

- **High-limit sensors** may be required to ensure that duct humidity levels remain below the saturation or dew-point level. Sometimes cooler air is required to offset sensible heat gains. In these cases, the air temperature may drop below the dew point. Operating the humidifier under these conditions causes condensation in the duct or fogging in the room. High-limit sensors may be combined with a temperature sensor in certain designs. The high-limit humidistat should be installed approximately 3 m from the humidifier section. This distance is necessary to allow for the moisture to be fully absorbed; high limits installed closer to the humidifier risk being damaged by moisture or cycling rapidly, causing short cycling of the entire humidification system. High-limit humidistats are commonly set to a maximum of 85 to 90% rh, and should be wired to close when the relative humidity falls below the set point and open when the relative humidity exceeds the set point.
- **Airflow sensors** should be used in place of a fan interlock. They sense airflow and disable the humidifier when insufficient airflow is present in the duct. An airflow switch is typically a sail or pressure switch that opens the control circuit of the humidifier when the airflow decreases or fails, and shuts the humidifier off. During system commissioning, confirm that this switch operates properly.
- **Steam sensors** are used to keep the control valve on direct-injection humidifiers closed when steam is not present at the humidifier. A pneumatic or electric temperature-sensing switch is fitted between the separator and the steam trap to sense the temperature of the condensate and steam. When the switch senses steam temperature, it allows the control valve to function normally.

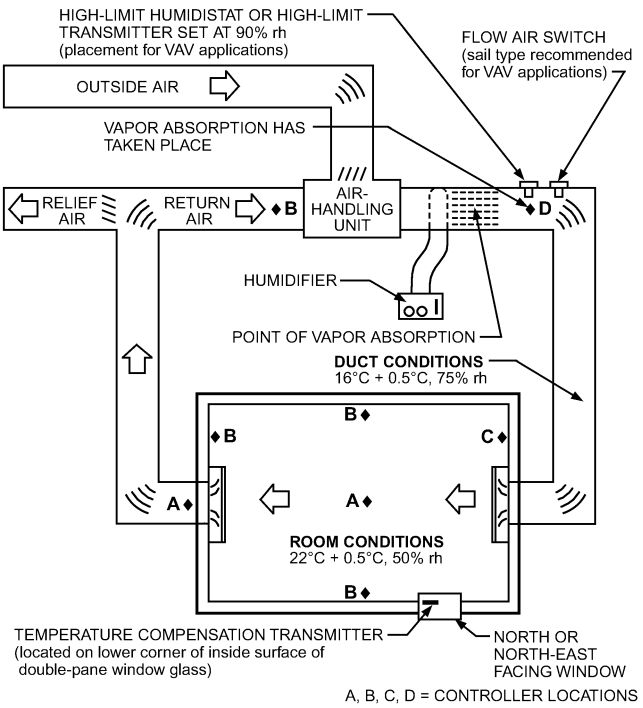

Fig. 13 Recommended Humidity Controller Location

Further information on humidity sensors can be found in Chapter 37 of the 2021 *ASHRAE Handbook—Fundamentals*.

Control Location

In centrally humidified structures, the humidity controller is most commonly mounted in a controlled space. Another method is to mount the controller in the return air duct of an air-handling system to sense average relative humidity. Figure 13 shows general recommended locations for the humidistat for a centrally air-conditioned room.

The manufacturer's instructions regarding the use of the controller on counterflow furnaces should be followed because reverse airflow when the fan is off can substantially shift the humidity control point in a home. The sensor should be located where it will not be affected by (1) air that exits the bypass duct of a bypass humidifier or (2) drafts or local heat or moisture sources.

Management Systems

In many applications, humidifiers can be integrated with the building management system (BMS). These types of systems can be set up with simple analog interaction with the humidifier, or by various communication protocols.

For analog-type systems, the management system can enable/disable the unit, send proportional signals for direct humidity control, or

redirect humidity sensor signals. These types of systems use various analog and digital outputs and inputs to command the humidifiers to operate, and at what level, as well as receive alarm states.

Communication protocols can be used as well to interact with and control humidification equipment. Common protocols include BACnet®, LonWorks®, Modbus®, TCP/IP, and SNMP. In some cases, these protocols can fully control the humidifier, replacing the need for any analog wiring, or can monitor the status and operation of the unit, or a combination of both. Some equipment providers can also supply a user interface system that offers online access to the status and operation modes of the units. See ASHRAE *Standard* 135 for more information.

6. APPLICATION CONSIDERATIONS

Humidity Control with Direct Space Humidification

Often, humidifiers are installed directly in the space they are humidifying, using humidity controllers (humidistats) for control, either installed directly within the space or mounted in the duct system of the ventilation unit serving the area. It is critical that space humidistats be located where they can sense the actual temperature and humidity of the controlled space. Normally, this requires that they are located at the working level of the facility on an interior wall or column. Humidistats should not be installed in the following areas:

- On exterior walls
- In drafts created by the HVAC system or interior machinery
- On surfaces affected or heated by sunlight, traffic, heat from machinery, lights, or other devices
- Near skids of materials stored in hot or cold warehouses
- Near rest rooms, washing facilities, or areas where moisture or heat is produced

In these areas, local changes in temperature or moisture cause the sensed relative humidity level to differ from the space as a whole.

It is good practice to install a high-limit humidistat to protect the space from possible excessive humidity in case the controlling humidistat fails or is damaged. Normally, this high-limit humidistat is an on/off type with a set point of 5 to 10% above the desired space conditions. It is then wired to open the control circuit of the humidifier and turn the humidifier off in case the control humidistat fails to properly shut the system off.

Humidity Control with Duct-Mounted Humidification

Humidifiers are commonly installed in ductwork or an air-handling unit (AHU) to control the temperature and humidity in the space or building as a whole. For these systems, best practice is to include the following controls:

- Space humidity controller
- Duct high-limit humidity controller
- Duct air proving switch for each humidifier

The space humidity controller can mount either directly within the conditioned space or in the return duct leaving the conditioned space. If using the return duct method, ensure that the humidistat senses conditions representative of the space as opposed to elevated temperatures or humidity levels resulting from machinery, stratification at the ceiling, or other process in the space.

When installing humidifiers in the AHU or supply duct, consider the psychrometrics of the airstream where the humidifiers are located. Warm air can absorb more water vapor than cold air, and the temperature and volume of air flowing through the ventilation system must be able to absorb the moisture being added to the airstream without becoming saturated. If the supply air is significantly cooler than the space design, the supply air may not be able to transport the required amount of moisture to satisfy the humidification load. For example, space design conditions of 24°C and 50% rh require 0.00944 kg of moisture per kilogram of air. Supply air at 13°C can only hold 0.00937 kg of moisture per kilogram of air and will be fully saturated under these conditions. The excess moisture that cannot be absorbed will likely become deposited in the duct or AHU, where it can cause bacterial growth, odors, or corrosion.

When using steam for humidification, the characteristics of the steam distributor should be considered. Adequate distance must be allotted for the steam to fully absorb to prevent unintended condensation on coils and other surfaces in the ventilation system. It is important to keep in mind that hot steam distributor tubes often contribute a small amount of heat to the airstream, which can increase the supply air temperature.

When using adiabatic humidification, consider the energy required to evaporate the water being discharge into the airstream. Evaporating a kilogram of water extracts 2500 kJ/kg from the airstream. As a result, the airstream leaving the adiabatic humidifier will be significantly cooler than the airstream entering the humidifier. Air preheating may be required to offset this cooling effect.

Humidity Control in Variable-Air-Volume Systems

Control in variable-air-volume (VAV) systems is much more demanding than in constant-volume systems. VAV systems, common in large, central-station applications, control space temperature by varying the volume rather than the temperature of the supply air. Continual airflow variations to follow load changes in the building can create wide and rapid swings in space humidity. Because of the fast-changing nature and cooler supply air temperatures (13°C or lower) of most VAV systems, special modulating humidity controls should be applied.

Best results are obtained by using both space and duct modulating humidity sensors with an integrating device, which in turn modulates the output of the humidifier. This allows the duct sensor to respond quickly to a rapid rise in duct humidity caused when airflow to the space decreases as temperature conditions are satisfied. The duct sensor at times overrides the space humidistat by reducing the humidifier output to correspond to decreasing air volumes. This type of system, commonly referred to as **anticipating control**, allows the humidifier to track the dynamics of the system and provide uniform control. Because of the operating duct static pressures of a VAV system, using an **airflow proving device** is recommended to detect air movement.

Commissioning Systems

Each individual humidifier should have a dedicated space control, high-limit humidistat, and air proving switch. All should be calibrated and checked for accurate control capabilities when commissioning the system and periodically as recommended by the control manufacturer. Properly commissioning the humidification system according to the manufacturer's instructions is essential for long-term reliability, sustainability, performance, and ultimately owner satisfaction with the system.

CHAPTER 23

AIR-COOLING AND DEHUMIDIFYING COILS

Uses for Coils 23.1
Coil Construction and Arrangement 23.1
Coil Selection 23.5
Airflow Resistance 23.6
Heat Transfer 23.7
Performance of Sensible Cooling Coils 23.7
Performance of Dehumidifying Coils 23.9
Determining Refrigeration Load 23.14
Maintenance 23.15
Symbols 23.16

MOST equipment used today for cooling and dehumidifying an airstream under forced convection incorporates a coil section that contains one or more cooling coils assembled in a coil bank arrangement. Such coil sections are used extensively as components in room terminal units; larger factory-assembled, self-contained air conditioners; central station air handlers; and field built-up systems. Applications of each coil type are limited to the field within which the coil is rated. Other limitations are imposed by code requirements, proper choice of materials for the fluids used, the configuration of the air handler, and economic analysis of the possible alternatives for each installation.

1. USES FOR COILS

Coils are used for air cooling with or without accompanying dehumidification. Examples of cooling applications without dehumidification are (1) precooling coils that use well water or other relatively high-temperature water to reduce load on the refrigerating equipment and (2) chilled-water coils that remove sensible heat from chemical moisture-absorption apparatus. The heat pipe coil is also used as a supplementary heat exchanger for preconditioning in air-side sensible cooling (see Chapter 26). Most coil sections provide air sensible cooling and dehumidification simultaneously.

The assembly usually includes a means of cleaning air to protect the coil from dirt accumulation and to keep dust and foreign matter out of the conditioned space. Although cooling and dehumidification are their principal functions, cooling coils can also be wetted with water or a hygroscopic liquid to aid in air cleaning, odor absorption, or frost prevention. Coils are also evaporatively cooled with a water spray to improve efficiency or capacity. Chapter 41 has more information on indirect evaporative cooling. For general comfort conditioning, cooling, and dehumidifying, the **extended-surface (finned) cooling coil** design is the most popular and practical.

2. COIL CONSTRUCTION AND ARRANGEMENT

In finned coils, the external surface of the tubes is primary, and the fin surface is secondary. The primary surface generally consists of rows of round tubes or pipes that may be staggered or placed in line with respect to the airflow. Flattened tubes or tubes with other nonround internal passageways are sometimes used. The inside surface of the tubes is usually smooth and plain, but some coil designs have various forms of internal fins or turbulence promoters (either fabricated or extruded) to enhance performance. The individual tube passes in a coil are usually interconnected by return bends (or hairpin bend tubes) to form the serpentine arrangement of multipass tube circuits. Coils are usually available with different circuit arrangements and combinations offering varying numbers of parallel water flow passes within the tube core (Figure 1).

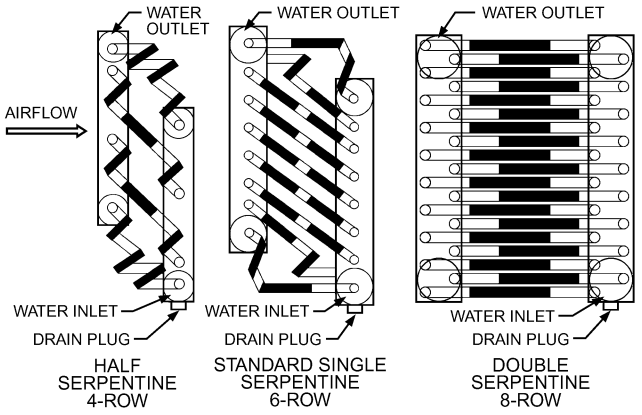

Fig. 1 Typical Water Circuit Arrangements

Cooling coils for water, aqueous glycol, brine, or halocarbon refrigerants usually have aluminum fins on copper tubes, although copper fins on copper tubes and aluminum fins on aluminum tubes (excluding water) are also used. Adhesives are sometimes used to bond header connections, return bends, and fin-tube joints, particularly for aluminum-to-aluminum joints. Certain special-application coils feature an all-aluminum extruded tube-and-fin surface.

Common core tube outside diameters are 8, 10, 12.5, 16, 20, and 25 mm, with fins spaced 1.4 to 6.4 mm apart. Tube spacing ranges from 15 to 75 mm on equilateral (staggered) or rectangular (in-line) centers, depending on the width of individual fins and on other performance considerations. Fins should be spaced according to the job to be performed, with special attention given to air friction; possibility of lint accumulation; and frost accumulation, especially at lower temperatures.

Tube wall thickness and the required use of alloys other than copper are determined mainly by the coil's working pressure and safety factor for hydrostatic burst (pressure). Maximum allowable working pressure (MAWP) for a coil is derived according to ASME's *Boiler and Pressure Vessel Code*, Section VIII, Division 1 and Section II (ASTM material properties and stress tables). Pressure vessel safety standards compliance and certifications of coil construction may be required by regional and local codes before field installation. Fin type and header construction also play a large part in determining wall thickness and material. Local job site codes and applicable nationally recognized safety standards should be consulted in coil design and application.

This type of air-cooling coil normally has a shiny aluminum airside surface. For special applications, the fin surface may be copper or have a brown or blue-green dip-process coating. These coatings protect the fin from oxidation that occurs when common airborne corrosive contaminants are diluted on a wet (dehumidifying) surface. Corrosion protection is increasingly important as indoor air quality (IAQ) guidelines call for higher percentages of outdoor air. Baked-on or anodized coating improves the expected service life

The preparation of this chapter is assigned to TC 8.4, Air-to-Refrigerant Heat Transfer Equipment.

compared to plain aluminum fins under similar conditions. Uncoated fins on non-dehumidifying, dry cooling coils are generally not affected by normal ambient airborne chemicals, except, to some extent, in a saline atmosphere. Once the coil is installed, little can be done to improve air-side protection.

Incoming airstream stratification across the coil face reduces coil performance. Proper air distribution is defined as having a measured airflow anywhere on the coil face that does not vary more than 20%. Moisture carryover at the coil's air leaving side or uneven air filter loading are indications of uneven airflow through the coil. Normal corrective procedure is to install inlet air straighteners, or an air blender if several airstreams converge at the coil inlet face. Additionally, condensate water should never be allowed to saturate the duct liner or stand in the drain pan (trough). The coil frame (particularly its bottom sheet metal member) should not be allowed to sit in a pool of water, to prevent rusting.

Water and Aqueous Glycol Coils

Good performance of water-type coils requires both eliminating all air and water traps in the water circuit and the proper distribution of water. Unless properly vented, air may accumulate in the coil tube circuits, reducing thermal performance and possibly causing noise or vibration in the piping system. Air vent and drain connections are usually provided on coil water headers, but this does not eliminate the need to install, operate, and maintain the coil tube core in a level position. Individual coil vents and drain plugs are often incorporated on the headers (Figure 1). Water traps in tubing of a properly leveled coil are usually caused by (1) improper nondraining circuit design and/or (2) center-of-coil downward sag. Such a situation may cause tube failure (e.g., freeze-up in cold climates, tube erosion because of untreated mineralized water).

Depending on performance requirements, fluid velocity inside the tube usually ranges from approximately 0.3 to 2.4 m/s for water and 0.15 to 1.8 m/s for glycol. When turbulators or grooved tubes are used, in-tube velocities should not exceed 1.2 m/s. The design fluid pressure drop across the coils varies from about 15 to 150 kPa. For nuclear HVAC applications, ASME *Standard* AG-1 requires a minimum tube velocity of 0.6 m/s. AHRI *Standard* 410 requires a minimum of 0.3 m/s or a Reynolds number of 3100 or greater. This yields more predictable performance.

In certain cases, the water may contain considerable sand and other foreign matter (e.g., precooling coils using well water, or where minerals in the cooling water deposit on and foul the tube surface). It is best to filter out such sediment. Some coil manufacturers offer removable water header plates or a removable plug for each tube that allows the tube to be cleaned, ensuring continuing rated performance while the cooling units are in service. Where build-up of scale deposits or fouling of the water-side surface is expected, a scale factor is sometimes included when calculating thermal performance of the coils. Cupronickel, red brass, bronze, and other tube alloys help protect against corrosion and erosion deterioration caused primarily by internal fluid flow abrasive sediment. The core tubes of properly designed and installed coils should feature circuits that (1) have equally developed line length, (2) are self-draining by gravity during the coil's off cycle, (3) have the minimum pressure drop to aid water distribution from the supply header without requiring excessive pumping pressure, and (4) have equal feed and return by the supply and return header. Design for proper in-tube water velocity determines the circuitry style required. Multirow coils are usually circuited to the cross-counterflow arrangement and oriented for top-outlet/bottom-feed connection.

Direct-Expansion Coils

Coils for halocarbon refrigerants present more complex cooling fluid distribution problems than do water or brine coils. The coil should cool effectively and uniformly throughout, with even refrigerant distribution. Halocarbon coils are used on two types of refrigerated systems: flooded and direct-expansion.

A flooded system is used mainly when a small temperature difference between the air and refrigerant is desired. Chapter 2 of the 2022 *ASHRAE Handbook—Refrigeration* describes flooded systems in more detail.

For direct-expansion systems, two of the most commonly used refrigerant liquid metering arrangements are the capillary tube assembly (or restrictor orifice) and the thermostatic expansion valve (TXV) device. The **capillary tube** is applied in factory-assembled, self-contained air conditioners up to approximately 35 kW capacity, but is most widely used on smaller-capacity models such as window or room units. In this system, the bore and length of a capillary tube are sized so that at full load, under design conditions, just enough liquid refrigerant to be evaporated completely is metered from the condenser to the evaporator coil. Although this type of metering arrangement does not operate over a wide range of conditions as efficiently as a TXV system, its performance is targeted for a specific design condition.

A **thermostatic expansion valve** system is commonly used for all direct-expansion coil applications described in this chapter, particularly field-assembled coil sections and those used in central air-handling units and larger, factory-assembled hermetic air conditioners. This system depends on the TXV to automatically regulate the rate of refrigerant liquid flow to the coil in direct proportion to the evaporation rate of refrigerant liquid in the coil, thereby maintaining optimum performance over a wide range of conditions. Superheat at the coil suction outlet is continually maintained within the usual predetermined limits of 3 to 6 K. Because the TXV responds to the superheat at the coil outlet, superheat within the coil is produced with the least possible sacrifice of active evaporating surface.

The length of each coil's refrigerant circuits, from the TXV's distributor feed tubes through the suction header, should be equal. The length of each circuit should be optimized to provide good heat transfer, good oil return, and a complementary pressure drop across the circuit. The coil should be installed level, and coil circuitry should be designed to self-drain by gravity toward the suction header connection. This is especially important on systems with unloaders or variable-speed-drive compressor(s). When non-self-drain circuitry is used, the circuit and suction connection should be designed for a minimum tube velocity sufficient to avoid compressor lube oil trapping in the coil.

To ensure reasonably uniform refrigerant distribution in multicircuit coils, a distributor is placed between the TXV and coil inlets to divide refrigerant equally among the coil circuits. The refrigerant distributor must be effective in distributing both liquid and vapor because refrigerant entering the coil is usually a mixture of the two, although mainly liquid by mass. Distributors can be placed either vertically or horizontally; however, the vertical down position usually distributes refrigerant between coil circuits better than the horizontal for varying load conditions.

Individual coil circuit connections from the refrigerant distributor to the coil inlet are made of small-diameter tubing; the connections are all the same length and diameter so that the same flow occurs between each refrigerant distributor tube and each coil circuit. To approximate uniform refrigerant distribution, refrigerant should flow to each refrigerant distributor circuit in proportion to the load on that coil. The heat load must be distributed equally to each refrigerant circuit for optimum coil performance. If the coil load cannot be distributed uniformly, the coil should be recircuited and connected with more than one TXV to feed the circuits (individual suction may also help). In this way, refrigerant distribution is reduced in proportion to the number of distributors to have less effect on overall coil performance when design must accommodate some unequal circuit loading. Unequal circuit loading may also be caused by uneven air velocity across the coil's face, uneven entering air temperature,

improper coil circuiting, oversized orifice in distributor, or the TXV's not being directly connected (close-coupled) to the distributor.

Control of Coils

Cooling capacity of water coils is controlled by varying either water flow or airflow. Water flow can be controlled by a three-way mixing, modulating, and/or throttling valve. For airflow control, face and bypass dampers are used. When cooling demand decreases, the coil face damper starts to close, and the bypass damper opens. In some cases, airflow is varied by controlling fan capacity with speed controls, inlet vanes, or discharge dampers.

Chapter 47 of the 2023 *ASHRAE Handbook—HVAC Applications* addresses air-cooling coil control to meet system or space requirements and factors to consider when sizing automatic valves for water coils. Selection and application of refrigerant flow control devices (e.g., thermostatic expansion valves, capillary tube types, constant-pressure expansion valves, evaporator pressure regulators, suction-pressure regulators, solenoid valves) as used with direct-expansion coils are discussed in Chapter 11 of the 2022 *ASHRAE Handbook—Refrigeration*.

For factory-assembled, self-contained packaged systems or field-assembled systems using direct-expansion coils equipped with TXVs, a single valve is sometimes used for each coil; in other cases, two or more valves are used. The thermostatic expansion valve controls the refrigerant flow rate through the coil circuits so refrigerant vapor at the coil outlet is superheated properly. Superheat is obtained with suitable coil design and proper valve selection. Unlike water flow control valves, standard pressure/temperature thermostatic expansion valves alone do not control the refrigeration system's capacity or the temperature of the leaving air, nor do they maintain ambient conditions in specific spaces. However, some electronically controlled TXVs have these attributes.

To match refrigeration load requirements for the conditioned space to the cooling capacity of the coil(s), a thermostat located in the conditioned space(s) or in the return air temporarily interrupts refrigerant flow to the direct-expansion cooling coils by stopping the compressor(s) and/or closing the solenoid liquid-line valve(s). Other solenoids unload compressors by suction control. For jobs with only a single zone of conditioned space, the compressor's on/off control is frequently used to modulate coil capacity. Selection and application of evaporator pressure regulators and similar regulators that are temperature-operated and respond to the temperature of conditioned air are covered in Chapter 11 of the 2022 *ASHRAE Handbook—Refrigeration*.

Applications with multiple zones of conditioned space often use solenoid liquid-line valves to vary coil capacity. These valves should be used where thermostatic expansion valves feed certain types (or sections) of evaporator coils that may, according to load variations, require a temporary but positive interruption of refrigerant flow. This applies particularly to multiple evaporator coils in a unit where one or more must be shut off temporarily to regulate its zone capacity. In such cases, a solenoid valve should be installed directly upstream of the thermostatic expansion valve(s). If more than one expansion valve feeds a particular zone coil, they may all be controlled by a single solenoid valve.

For a coil controlled by multiple refrigerant expansion valves, there are three arrangements: (1) face control, in which the coil is divided across its face; (2) row control; and (3) interlaced circuitry (Figure 2).

Face control, which is the most widely used because of its simplicity, equally loads all refrigerant circuits in the coil. Face control has the disadvantage of allowing condensate reevaporation on the coil portion not in operation and bypassing air into the conditioned space during partial-load conditions, when some of the TXVs are off. However, while the bottom portion of the coil is cooling, some of the advantages of single-zone humidity control can be achieved with air bypasses through the inactive top portion.

Row control, seldom available as standard equipment, eliminates air bypassing during partial-load operation and minimizes condensate reevaporation. Close attention is required for accurate calculation of row-depth capacity, circuit design, and TXV sizing.

Interlaced circuit control uses the whole face area and depth of coil when some expansion valves are shut off. Without a corresponding drop in airflow, modulating refrigerant flow to an interlaced coil increases coil surface temperature, thereby necessitating compressor protection (e.g., suction pressure regulators or compressor multiplexing).

Flow Arrangement

In air conditioning, the relation of the fluid flow arrangement in the coil tubes to coil depth greatly influences performance of the heat transfer surface. Generally, air-cooling and dehumidifying coils are multirow and circuited for **counterflow** arrangement. Inlet air is applied at right angles to the coil's tube face (coil height), which is also at the coil's outlet header location. Air exits at the opposite face (side) of the coil where the corresponding inlet header is located. Counterflow can produce the highest possible heat exchange in the shortest possible (coil row) depth because it has the closest temperature relationships between tube fluid and air at each (air) side of the coil; the temperature of the entering air more closely approaches the temperature of the leaving fluid than the temperature of the leaving air approaches the temperature of the entry fluid. The potential of realizing the highest possible mean temperature difference is thus arranged for optimum performance.

Most direct-expansion coils also follow this general scheme of thermal counterflow, but proper superheat control may require a hybrid combination of parallel flow and counterflow. (Air flows in the same direction as the refrigerant in parallel-flow operation.) Often, the optimum design for large coils is parallel flow in the coil's initial (entry) boiling region followed by counterflow in the superheat (exit) region. Such a hybrid arrangement is commonly used for process applications that require a low temperature difference (low TD).

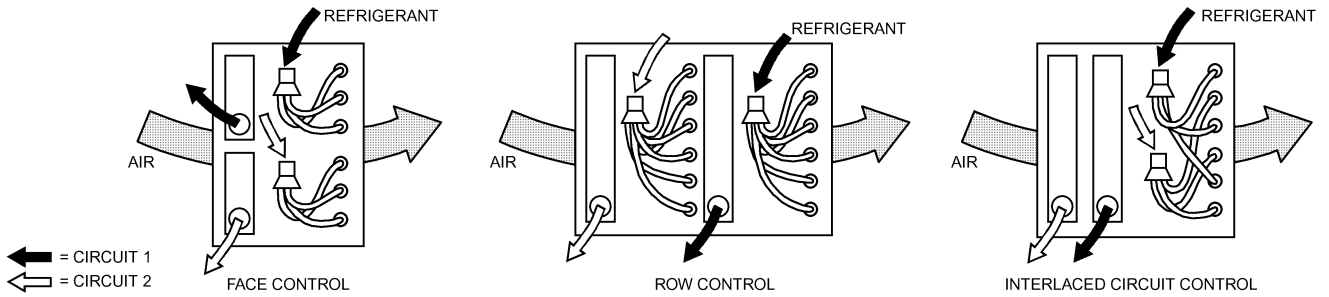

Fig. 2 Arrangements for Coils with Multiple Thermostatic Expansion Valves

Coil hand refers to either the right hand (RH) or left hand (LH) for counterflow arrangement of a multirow counterflow coil. There is no convention for what constitutes LH or RH, so manufacturers usually establish a convention for their own coils. Most manufacturers designate the location of the inlet water header or refrigerant distributor as the coil hand reference point. Figure 3 shows the more widely accepted coil hand designation for multirow water or refrigerant coils.

Applications

Figure 4 shows a typical arrangement of coils in a field built-up central station system. All air should be filtered to prevent dirt, insects, and foreign matter from accumulating on the coils. The cooling coil (and humidifier, when used) should include a drain pan under each coil to catch condensate formed during cooling (and excess water from the humidifier). The drain connection should be downstream of the coils, be of ample size, have accessible cleanouts, and discharge to an indirect waste or storm sewer. The drain also requires a deep-seal trap so that no sewer gas can enter the system. Precautions must be taken if there is a possibility that the drain might freeze. The drain pan, unit casing, and water piping should be insulated to prevent sweating.

Factory-assembled central station air handlers incorporate most of the design features outlined for field built-up systems. These packaged units can generally accommodate various sizes, types, and row depths of cooling and heating coils to meet most job requirements. This usually eliminates the need for field built-up central systems, except on very large jobs.

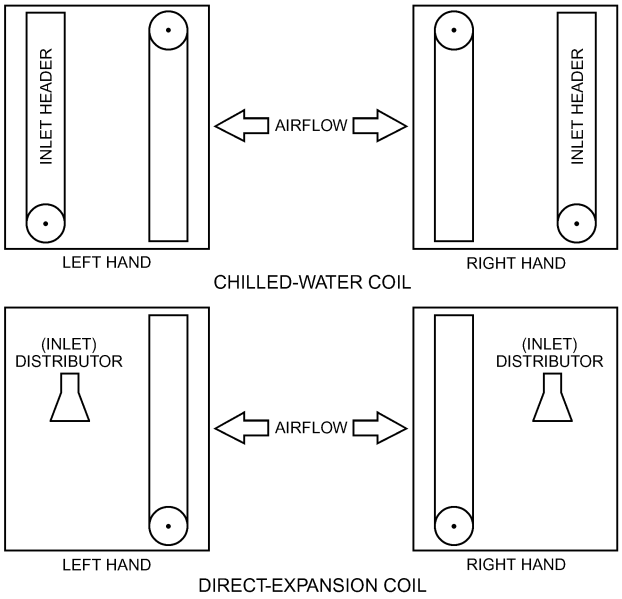

Fig. 3 Typical Coil Hand Designation

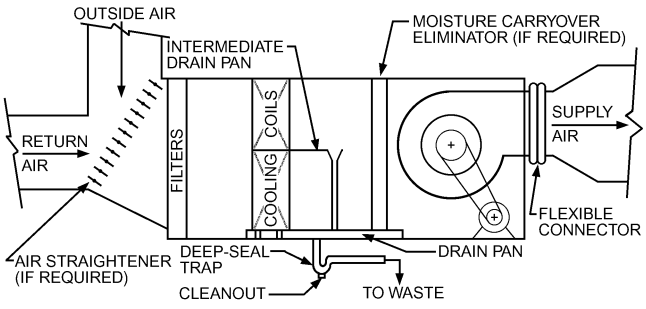

Fig. 4 Typical Arrangement of Cooling Coil Assembly in Built-Up or Packaged Central Station Air Handler

The coil's design features (fin spacing, tube spacing, face height, type of fins), together with the amount of moisture on the coil and the degree of surface cleanliness, determine the air velocity at which condensed moisture blows off the coil. Generally, condensate water begins to be blown off a plate fin coil face at air velocities above 3 m/s. Water blowoff from coils into air ductwork external to the air-conditioning unit should be prevented. However, water blowoff is not usually a problem if coil fin heights are limited to 1140 mm and the unit is set up to catch and dispose of condensate. When a number of coils are stacked one above another, condensate is carried into the airstream as it drips from one coil to the next. A downstream eliminator section could prevent this, but an intermediate drain pan and/or condensate trough (Figure 5) to collect the condensate and conduct it directly to the main drain pan is preferred. Extending downstream of the coil, each drain pan length should be at least one-half the coil height, and somewhat greater when coil airflow face velocities and/or humidity levels are higher.

When water is likely to carry over from the air-conditioning unit into external air ductwork, and no other means of prevention is provided, eliminator plates should be installed downstream of the coils. Usually, eliminator plates are not included in packaged units because other means of preventing carryover, such as space made available within the unit design for longer drain pan(s), are included in the design.

However, on sprayed-coil units (Figure 6), eliminators are usually included in the design. Such cooling and dehumidifying coils are sometimes sprayed with water to increase the rate of heat transfer, provide outlet air approaching saturation, and continually wash the surface of the coil. Coil sprays require a collecting tank, eliminators, and a recirculating pump. Figure 6 also shows an air bypass, which helps a thermostat control maintain the humidity ratio by diverting a portion of the return air from the coil.

In field-assembled systems or factory-assembled central station air-handling units, fans are usually positioned downstream from the coil(s) in a draw-through arrangement. This arrangement provides acceptable airflow uniformity across the coil face more often than does the blow-through arrangement. In a blow-through arrangement, fans upstream from the coils may require air baffles or diffuser plates between the fan discharge and cooling coil to obtain uniform airflow. This is often the case in packaged multizone unit

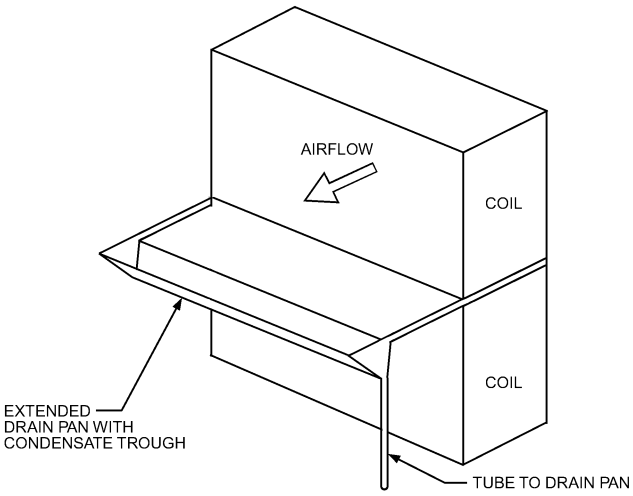

Fig. 5 Coil Bank Arrangement with Intermediate Condensate Pan

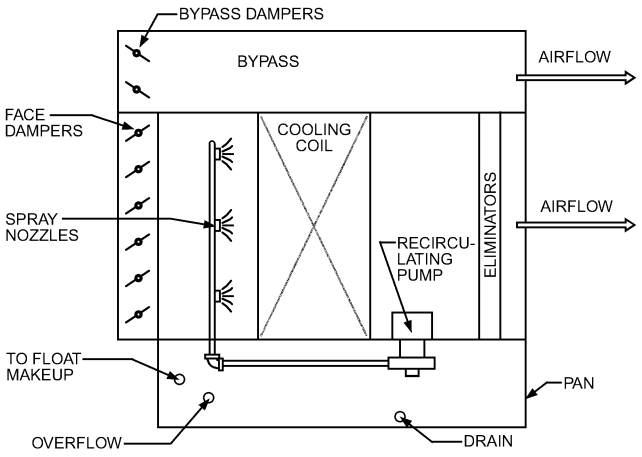

Fig. 6 Sprayed-Coil System with Air Bypass

design. Airflow is considered to be uniform when measured flow across the entire coil face varies no more than 20%.

Air-cooling and dehumidifying coil frames, as well as all drain pans and troughs, should be of an acceptable corrosion-resistant material suitable for the system and its expected useful service life. The air handler's coil section enclosure should be corrosion resistant; be properly double-wall insulated; and have adequate access doors for changing air filters, cleaning coils, adjusting flow control valves, and maintaining motors.

Where suction line risers are used for air-cooling coils in direct-expansion refrigeration systems, the suction line must be sized properly to ensure oil return from coil to compressor at minimum load conditions. Oil return is normally intrinsic with factory-assembled, self-contained air conditioners but must be considered for factory-assembled central station units or field-installed cooling coil banks where suction line risers are required and are assembled at the job site. Sizing, design, and arrangement of suction lines and their risers are described in Chapter 2 of the 2022 *ASHRAE Handbook—Refrigeration*.

3. COIL SELECTION

When selecting a coil, consider the following factors:

- Job requirements: cooling, dehumidifying, and capacity required to properly balance with other system components (e.g., compressor equipment in the case of direct-expansion coils)
- Entering air dry-bulb and wet-bulb temperatures
- Available cooling media and operating temperatures
- Space and dimensional limitations
- Air and cooling fluid quantities, including distribution and limitations
- Allowable frictional resistances in air circuit (including coils)
- Allowable frictional resistances in cooling media piping system (including coils)
- Characteristics of individual coil designs and circuitry possibilities
- Individual installation requirements such as type of automatic control to be used; presence of corrosive atmosphere; design pressures; and durability of tube, fins, and frame material

Chapters 17 and 18 of the 2021 *ASHRAE Handbook—Fundamentals* provide information on load calculation.

Air quantity is affected by factors such as design parameters, codes, space, and equipment. Resistance through the air circuit influences fan power and speed. This resistance may be limited to allow the use of a given size fan motor, to keep operating expense low, or because of sound-level requirements. Air friction loss across the cooling coil (in summation with other series air-pressure drops for elements such as air filters, water sprays, heating coils, air grilles, and ductwork) determines the static pressure requirement for the complete airway system. The static pressure requirement is used in selecting fans and drives to obtain the design air quantity under operating conditions. See Chapter 21 for a description of fan selection.

The conditioned-air face velocity is determined by economic evaluation of initial and operating costs for the complete installation as influenced by (1) heat transfer performance of the specific coil surface type for various combinations of face areas and row depths as a function of air velocity; (2) air-side frictional resistance for the complete air circuit (including coils), which affects fan size, power, and sound-level requirements; and (3) condensate water carryover considerations. Allowable friction through the water or brine coil circuitry may be dictated by the pressure available from a given size pump and pump motor, as well as the same economic factors governing the air side made applicable to the water side. Additionally, the adverse effect of high cooling-water velocities on erosion/corrosion of tube walls is a major factor in sizing and circuitry to keep tube velocity below the recommended maximums. On larger coils, water pressure drop limits of 45 to 60 kPa usually keep such velocities within acceptable limits of 0.6 to 1.2 m/s, depending on circuit design.

Coil ratings are based on a uniform velocity. Design interference with uniform airflow through the coil makes predicting coil performance difficult as well as inaccurate. Such airflow interference may be caused by air entering at odd angles or by inadvertent partial blocking of the coil face. To obtain rated performance, the volumetric airflow quantity must be adjusted on the job to that at which the coil was rated and must be kept at that value. At start-up for air balance, the most common causes of incorrect airflow are the lack of altitude correction to standard air (where applicable) and ductwork problems. At commissioning, the most common causes of an air quantity deficiency are filter fouling and dirt or frost collection on the coils. These difficulties can be avoided through proper design, start-up checkout, and regular servicing.

The required total heat capacity of the cooling coil should be in balance with the capacity of other refrigerant system components such as the compressor, water chiller, condenser, and refrigerant liquid metering device. Chapter 5 of the 2022 *ASHRAE Handbook—Refrigeration* describes methods of estimating balanced system capacity under various operating conditions when using direct-expansion coils for both factory- and field-assembled systems.

For dehumidifying coils, it is important that the proper amount of surface area be installed to obtain the ratio of air-side sensible-to-total heat required to maintain air dry-bulb and wet-bulb temperatures in the conditioned space. This is an important consideration when preconditioning is done by reheat arrangement. The method for calculating the sensible and total heat loads and leaving-air conditions at the coil to satisfy the sensible-to-total heat ratio required for the conditioned space is covered in Appendix D of *Cooling and Heating Load Calculation Principles* (Pedersen et al. 1998).

The same room air conditions can be maintained with different air quantities (including outdoor and return air) through a coil. However, for a given total air quantity with fixed percentages of outdoor and return air, there is only one set of air conditions leaving the coil that will precisely maintain room design air conditions. Once air quantity and leaving-air conditions at the coil have been selected, there is usually only one combination of face area, row depth, and air face velocity for a given coil surface that will precisely maintain the required room ambient conditions. Therefore, in making final coil selections it is necessary to recheck the initial selection to ensure that the leaving-air conditions, as calculated by a coil selection computer program or other procedure, match those determined from the cooling load estimate.

Coil ratings and selections can be obtained from manufacturers' catalogs. Most catalogs contain extensive tables giving the performance of coils at various air and water velocities and entering humidity and temperatures. Most manufacturers provide computerized coil selection programs to potential customers. The final choice can then be made based on system performance and economic requirements.

Performance and Ratings

The long-term performance of an extended-surface air-cooling and dehumidifying coil depends on its correct design to specified conditions and material specifications, proper matching to other system components, proper installation, and proper maintenance as required.

In accordance with AHRI *Standard* 410, dry-surface (sensible cooling) coils and dehumidifying coils (which both cool and dehumidify), particularly those for field-assembled coil banks or factory-assembled packaged units using different combinations of coils, are usually rated within the following parameters:

Entering air dry-bulb temperature: 18 to 38°C
Entering air wet-bulb temperature: 15 to 30°C (if air is not dehumidified in the application, select coils based on sensible heat transfer)
Air face velocity: 1 to 4 m/s
Evaporator refrigerant saturation temperature: –1 to 13°C at coil suction outlet (refrigerant vapor superheat at coil suction outlet is 3 K or higher)
Entering chilled-water temperature: 1.5 to 18°C
Water velocity: 0.3 to 2.4 m/s
For ethylene glycol solution: 0.3 to 1.8 m/s, –18 to 32°C entering dry-bulb temperature, 15 to 27°C entering wet-bulb temperature, 10 to 60% aqueous glycol concentration by mass

The air-side ratio of sensible to total heat removed by dehumidifying coils varies in practice from about 0.6 to 1.0 (i.e., sensible heat is from 60 to 100% of the total, depending on the application). For information on calculating a dehumidifying coil's sensible heat ratio, see the section on Performance of Dehumidifying Coils, or Appendix D of *Cooling and Heating Load Calculation Principles* (Pedersen et al. 1998). For a given coil surface design and arrangement, the required sensible heat ratio may be satisfied by wide variations in and combinations of air face velocity, in-tube temperature, flow rate, entering air temperature, coil depth, etc., although the variations may be self limiting. The maximum coil air face velocity should be limited to a value that prevents water carryover into the air ductwork. Dehumidifying coils for comfort applications are frequently selected in the range of 2.0 to 2.5 m/s air face velocity.

Operating ratings of dehumidifying coils for factory-assembled, self-contained air conditioners are generally determined in conjunction with laboratory testing for the system capacity of the complete unit assembly. For example, a standard rating point has been 54 L/s per kilowatt of refrigeration effect, not to exceed 60 L/s per kilowatt for unitary equipment. Refrigerant (e.g., R-22) duty would be 3 to 6 K superheat for an appropriate balance at 7°C saturated suction. For water coils, circuitry would operate at 1.2 m/s, 5.5°C inlet water, 6.7 K rise (or 36 mL/s per kilowatt of refrigeration effect). The standard ratings at 26.7°C db and 19.5°C wb are representative of the entering air conditions encountered in many comfort operations. Although indoor conditions are usually lower than 19.5°C wb, it is usually assumed that introducing outdoor air brings the air mixture to the cooling coil up to about 26.7°C db/19.5°C wb entering air design conditions.

Dehumidifying coils for field-assembled projects and central station air-handling units were formerly selected according to coil rating tables but are now selected by computerized selection programs. Either way, selecting coils from the load division indicated by the load calculation works satisfactorily for the usual human comfort applications. Additional design precautions and refinements are necessary for more exacting industrial applications and for all types of air conditioning in humid areas. One such refinement, the dual-path air process, uses a separate cooling coil to cool and dehumidify ventilation air before mixing it with recirculated air. This process dehumidifies what is usually the main source of moisture: makeup outdoor air. Condenser heat reclaim (when available) is another refinement required for some industrial applications and is finding greater use in commercial and comfort applications.

Airflow ratings are based on standard air of 1.20 kg/m^3 at 20°C and a barometric pressure of 101.325 kPa. In some mountainous areas with a sufficiently large market, coil ratings and altitude-corrected psychrometrics are available for their particular altitudes.

When checking the operation of dehumidifying coils, climatic conditions must be considered. Most problems are encountered at light-load conditions, when the cooling requirement is considerably less than at design conditions. In hot, dry climates, where the outdoor dew point is consistently low, dehumidifying is not generally a problem, and the light-load design point condition does not pose any special problems. In hot, humid climates, the light-load condition has a higher proportion of moisture and a correspondingly lower proportion of sensible heat. The result is higher dew points in the conditioned spaces during light-load conditions unless a special means for controlling inside dew points (e.g., reheat or dual path) is used.

Fin surface freezing at light loads should be avoided. Freezing occurs when a dehumidification coil's surface temperature falls below 0°C. Freezing does not occur with standard coils for comfort installations unless the refrigerant evaporating temperature at the coil outlet is below –4 to –2°C saturated; the exact value depends on the design of the coil, its operating dew point, and the amount of loading. With coil and condensing units to balance at low temperatures at peak loads (not a customary design choice), freezing may occur when load suddenly decreases. The possibility of this type of surface freezing is greater if a bypass is used because it causes less air to be passed through the coil at light loads.

4. AIRFLOW RESISTANCE

A cooling coil's airflow resistance (air friction) depends on the tube pattern and fin geometry (tube size and spacing, fin configuration, and number of in-line or staggered rows), coil face velocity, and amount of moisture on the coil. The coil air friction may also be affected by the degree of aerodynamic cleanliness of the coil core; burrs on fin edges may increase coil friction and increase the tendency to pocket dirt or lint on the faces. A completely dry coil, removing only sensible heat, offers approximately one-third less resistance to airflow than a dehumidifying coil removing both sensible and latent heat.

For a given surface and airflow, increasing the number of rows or fins increases airflow resistance. Therefore, final selection involves economic balancing of the initial cost of the coil against the operating costs of the coil geometry combinations available to adequately meet the performance requirements.

The aluminum fin surfaces of new dehumidifying coils tend to inhibit condensate sheeting action until they have aged for a year. Hydrophilic aluminum fin surface coatings reduce water droplet surface tension, producing a more evenly dispersed wetted surface action at initial start-up. Manufacturers have tried different methods of applying such coatings, including dipping the coil into a tank, coating the fin stock material, or subjecting the material to a chemical etching process. Tests have shown as much as a 30% reduction in air pressure drop across a hydrophilic coil as opposed a new untreated coil.

5. HEAT TRANSFER

The heat transmission rate of air passing over a clean tube (with or without extended surface) to a fluid flowing in it is impeded principally by three thermal resistances: (1) surface air-side film thermal resistance from the air to the surface of the exterior fin and tube assembly; (2) metal thermal resistance to heat conductance through the exterior fin and tube assembly; and (3) in-tube fluid-side film thermal resistance, which impedes heat flow between the internal surface of the metal and the fluid flowing within the tube. For some applications, an additional thermal resistance is factored in to account for external and/or internal surface fouling. Usually, the combination of metal and tube-side film resistance is considerably lower than the air-side surface resistance.

For a reduction in thermal resistance, the fin surface is fabricated with die-formed corrugations instead of the traditional flat design. At low airflows or wide fin spacing, the air-side transfer coefficient is virtually the same for flat and corrugated fins. Under normal comfort conditioning operation, the corrugated fin surface is designed to reduce the boundary air film thickness by undulating the passing airstream within the coil; this produces a marked improvement in heat transfer without much airflow penalty. Further fin enhancements, including louvered and lanced fin designs, have been driven by the desire to duplicate throughout the coil depth the thin boundary air film characteristic of the fin's leading edge. Louvered fin design maximizes the number of fin surface leading edges throughout the entire secondary surface area and increases the external secondary surface area A_s through the multiplicity of edges.

Where an application allows economical use of coil construction materials, the mass and size of the coil can be reduced when boundary air and water films are lessened. For example, the exterior surface resistance can be reduced to nearly the same as the fluid-side resistance by using lanced and/or louvered fins. External as well as internal tube fins (or internal turbulators) can economically decrease overall heat transfer surface resistances. Also, water sprays applied to a flat fin coil surface may increase overall heat transfer slightly, although they may better serve other purposes such as air and coil cleaning.

Heat transfer between the cooling medium and the airstream across a coil is influenced by the following variables:

- Temperature difference between fluids
- Design and surface arrangement of coil
- Velocity and character of airstream
- Velocity and character of in-tube coolant

With water coils, only the water temperature rises. With coils of volatile refrigerants, an appreciable pressure drop and a corresponding change in evaporating temperature through the refrigerant circuit often occur. Alternative refrigerants to R-22, such as R-407C, which has a temperature glide, have an evaporation temperature rise of 4 to 7 K through the evaporator. This must be considered in design and performance calculation of the coil. A compensating pressure drop in the coil may partially, or even totally, compensate for the low-side temperature glide of a zeotropic refrigerant blend. Rating direct-expansion coils is further complicated by the refrigerant evaporating in part of the circuit and superheating in the remainder. Thus, for halocarbon refrigerants, a cooling coil is tested and rated with a specific distributing and liquid-metering device, and the capacities are stated with the superheat condition of the leaving vapor.

At a given air mass velocity, performance depends on the turbulence of airflow into the coil and the uniformity of air distribution over the coil face. The latter is necessary to obtain reliable test ratings and realize rated performance in actual installations. Air resistance through the coils helps distribute air properly, but the effect is frequently inadequate where inlet duct connections are brought in at sharp angles to the coil face. Reverse air currents may pass through a portion of the coils. These currents reduce capacity but can be avoided with proper inlet air vanes or baffles. Air blades may also be required. Remember that coil performance ratings (AHRI *Standard* 410) represent optimum conditions resulting from adequate and reliable laboratory tests (ASHRAE *Standard* 33).

For cases when available data must be extended, for arriving at general design criteria for a single, unique installation, or for understanding the calculation progression, the following material and illustrative examples for calculating cooling coil performance are useful guides.

6. PERFORMANCE OF SENSIBLE COOLING COILS

The performance of sensible cooling coils depends on the following factors. See the section on Symbols for an explanation of the variables.

- The overall coefficient U_o of sensible heat transfer between airstream and coolant fluid
- The mean temperature difference Δt_m between airstream and coolant fluid
- The physical dimensions of and data for the coil (such as coil face area A_a and total external surface area A_o) with characteristics of the heat transfer surface

The sensible heat cooling capacity q_{td} of a given coil is expressed by the following equation:

$$q_{td} = U_o F_s A_a N_r \Delta t_m \tag{1a}$$

with

$$F_s = A_o / A_a N_r \tag{1b}$$

Assuming no extraneous heat losses, the same amount of sensible heat is lost from the airstream:

$$q_{td} = 1000 w_a c_p (t_{a1} - t_{a2}) \tag{2a}$$

with

$$w_a = 60 \rho_a A_a V_a \tag{2b}$$

The same amount of sensible heat is absorbed by the coolant; for a nonvolatile type, it is

$$q_{td} = 1000 w_r c_r (t_{r2} - t_{r1}) \tag{3}$$

For a nonvolatile coolant in thermal counterflow with the air, the mean temperature difference in Equation (1a) is expressed as

$$\Delta t_m = \frac{(t_{a1} - t_{r2}) - (t_{a2} - t_{r1})}{\ln[(t_{a1} - t_{r2}) / (t_{a2} - t_{r1})]} \tag{4}$$

Proper temperature differences for various cross-flow situations are given in many texts, including Mueller (1973). These calculations are based on various assumptions, among them that U for the total external surface is constant. Although this assumption is generally not valid for multirow coils, using cross-flow temperature differences from Mueller (1973) or other texts should be preferable to Equation (4), which applies only to counterflow. However, using the log mean temperature difference is widespread.

The overall heat transfer coefficient U_o for a given coil design, whether bare-pipe or finned-type, with clean, nonfouled surfaces, consists of the combined effect of three individual heat transfer coefficients:

- The **film coefficient f_a** of sensible heat transfer between air and the external surface of the coil
- The **unit conductance $1/R_{md}$** of the coil material (i.e., tube wall, fins, tube-to-fin thermal resistance)
- The **film coefficient f_r** of heat transfer between the internal coil surface and the coolant fluid within the coil

These three individual coefficients acting in series form an overall coefficient of heat transfer in accordance with the material given in Chapters 4 and 25 to 27 of the 2021 *ASHRAE Handbook—Fundamentals*.

For a bare-pipe coil, the overall coefficient of heat transfer for sensible cooling (without dehumidification) can be expressed by a simplified basic equation:

$$U_o = \frac{1}{(1/f_a) + (D_o - D_i)/2000k + (B/f_r)} \quad (5a)$$

When pipe or tube walls are thin and of high-conductivity material (as in typical heating and cooling coils), the term $(D_o - D_i)/2000k$ in Equation (5a) frequently becomes negligible and is generally disregarded. (This effect in typical bare-pipe cooling coils seldom exceeds 1 to 2% of the overall coefficient.) Thus, the overall coefficient for bare pipe in its simplest form is

$$U_o = \frac{1}{(1/f_a) + (B/f_r)} \quad (5b)$$

For finned coils, the equation for the overall coefficient of heat transfer can be written

$$U_o = \frac{1}{(1/\eta f_a) + (B/f_r)} \quad (5c)$$

where the **fin effectiveness** η allows for the resistance to heat flow encountered in the fins. It is defined as

$$\eta = (EA_s + A_p)/A_o \quad (6)$$

For typical cooling surface designs, the surface ratio B ranges from about 1.03 to 1.15 for bare-pipe coils and from 10 to 30 for finned coils. Chapter 4 of the 2021 *ASHRAE Handbook—Fundamentals* describes how to estimate fin efficiency and calculate the tube-side heat transfer coefficient f_r for nonvolatile fluids. Table 3 in AHRI *Standard* 410 lists thermal conductivity k of standard coil materials.

Estimating the air-side heat transfer coefficient f_a is more difficult because well-verified general predictive techniques are not available. Hence, direct use of experimental data is usually necessary. For plate fin coils, some correlations that satisfy several data sets are available (Kusuda 1970; McQuiston 1981). Webb (1980) reviewed air-side heat transfer and pressure drop correlations for various geometries. Mueller (1973) and Chapter 4 of the 2021 *ASHRAE Handbook—Fundamentals* provide guidance on this subject.

For analyzing a given heat exchanger, the concept of **effectiveness** is useful. Expressions for effectiveness have been derived for various flow configurations and can be found in Kusuda (1970) and Mueller (1973). The cooling coils covered in this chapter actually involve various forms of cross-flow. However, the case of counterflow is addressed here to illustrate the value of this concept. The air-side effectiveness E_a for counterflow heat exchangers is given by the following equations:

$$q_{td} = 1000 w_a c_p (t_{a1} - t_{r1}) E_a \quad (7a)$$

with

$$E_a = \frac{t_{a1} - t_{a2}}{t_{a1} - t_{r1}} \quad (7b)$$

or

$$E_a = \frac{1 - e^{-c_o(1-M)}}{1 - Me^{-c_o(1-M)}} \quad (7c)$$

with

$$c_o = \frac{A_o U_o}{1000 w_a c_p} = \frac{F_s N_r U_o}{1000 \rho_a V_a c_p} \quad (7d)$$

and

$$M = \frac{w_a c_p}{w_r c_r} = \frac{\rho_a A_a V_a c_p}{w_r c_r} \quad (7e)$$

Note the following two special conditions:

If $M = 0$, then $E_a = 1 - e^{-c_o}$

If $M \geq 1$, then

$$E_a = \frac{1}{(1/c_o) + 1}$$

With a given design and arrangement of heat transfer surface used as cooling coil core material for which basic physical and heat transfer data are available to determine U_o from Equations (5a), (5b), and (5c), the selection, sizing, and performance calculation of sensible cooling coils for a particular application generally fall into either of two categories:

1. Heat transfer surface area A_o or coil row depth N_r for a specific coil size is required and initially unknown. Sensible cooling capacity q_{td}, flow rates for both air and coolant, entrance and exit temperatures of both fluids, and mean temperature difference between fluids are initially known or can be assumed or determined from Equations (2a), (3), and (4). A_o or N_r can then be calculated directly from Equation (1a).
2. Sensible cooling capacity q_{td} for a specific coil is required and initially unknown. Face area and heat transfer surface area are known or can be readily determined. Flow rates and entering temperatures of air and coolant are also known. Mean temperature difference Δt_m is unknown, but its determination is unnecessary to calculate q_{td}, which can be found directly by solving Equation (7a). Equation (7a) also provides a basic means of determining q_{td} for a given coil or related family of coils over the complete rating ranges of air and coolant flow rates and operating temperatures.

The two categories of application problems are shown in Examples 1 and 2, respectively:

Example 1. Standard air flowing at a mass rate equivalent to 4.2 m³/s is to be cooled from 29.5 to 24°C, using 2.5 kg/s chilled water supplied at 10°C in thermal counterflow arrangement. Assuming an air face velocity of V_a = 3 m/s and no air dehumidification, calculate coil face area A_a, sensible cooling capacity q_{td}, required heat transfer surface area A_o, coil row depth N_r, and coil air-side pressure drop Δp_{st} for a clean, nonfouled, thin-walled bare copper tube surface design for which the following physical and performance data have been predetermined:

B = surface ratio = 1.07
c_p = 1.0 kJ/(kg·K)
c_r = 4.18 kJ/(kg·K)
F_s = (external surface area)/(face area)(rows deep) = 1.34
f_a = 85 W/(m²·K)
f_r = 4500 W/(m²·K)
$\Delta p_{st}/N_r$ = 6.7 Pa/number of coil rows
ρ_a = 1.20 kg/m³

Solution: Calculate the coil face area required.

$$A_a = 4.2/\!/ = 1.4 \text{ m}^2$$

Neglecting the effect of tube wall, from Equation (5b),

$$U_o = \frac{1}{(1/85) + (1.07/4500)} = 83.3 \text{ W/(m}^2\cdot\text{K)}$$

From Equations (2a) and (2b), the sensible cooling capacity is

$$q_{td} = 1000 \times 1.20 \times 1.4 \times 3 \times 1.0(29.5 - 24) = 27\,700 \text{ W}$$

From Equation (3),

$$t_{r2} = 10 + 27\,700/(1000 \times 2.5 \times 4.18) = 12.7°\text{C}$$

From Equation (4),

$$\Delta\Delta t_m = \frac{(29.5 - 12.7) - (24 - 10)}{\ln[(29.5 - 12.7)/(24 - 10)]} = 15.4°C$$

From Equations (1a) and (1b), the surface area required is

$$A_o = 27\,700/(83.3 \times 15.4) = 21.6 \text{ m}^2 \text{ external surface}$$

From Equation (1b), the required row depth is

$$N_r = 21.6/(1.34 \times 1.4) = 11.5 \text{ rows deep}$$

The installed 1.4 m^2 coil face, 12 rows deep, slightly exceeds the required capacity. The air-side pressure drop for the installed row depth is then

$$\Delta\Delta\Delta p_{st} = (\Delta p_{st}/N_r)N_r = 6.7 \times 12 = 80 \text{ Pa at } 20°C$$

In this example, for some applications where such items as V_a, w_r, t_{r1}, and f_r may be arbitrarily varied with a fixed design and arrangement of heat transfer surface, a trade-off between coil face area A_a and coil row depth N_r is sometimes made to obtain alternative coil selections that produce the same sensible cooling capacity q_{td}. For example, an eight-row coil could be selected, but it would require a larger face area A_a with lower air face velocity V_a and a lower air-side pressure drop Δp_{st}.

Example 2. An air-cooling coil using a finned tube-type heat transfer surface has physical data as follows:

A_a = 1.0 m^2
A_o = 75 m^2 external
B = surface ratio = 20
F_s = (external surface area)/(face area)(rows deep) = 27
N_r = 3 rows deep

Air at a face velocity of V_a = 4 m/s and 35°C entering air temperature is to be cooled by 1.0 L/s of well water supplied at 13°C. Calculate the sensible cooling capacity q_{td}, leaving-air temperature t_{a2}, leaving-water temperature t_{r2}, and air-side pressure drop Δp_{st}. Assume clean and nonfouled surfaces, thermal counterflow between air and water, no air dehumidification, standard barometric air pressure, and that the following data are available or can be predetermined:

c_p = 1.0 kJ/(kg·K)
c_r = 4.18 kJ/(kg·K)
f_a = 97 W/(m^2·K)
f_r = 2800 W/(m^2·K)
η = fin effectiveness = 0.9
$\Delta p_{st}/N_r$ = 55 Pa/number of coil rows
ρ_a = 1.20 kg/m^3
ρ_w = 998 kg/m^3

Solution: From Equation (5c),

$$U_o = \frac{1}{1/(0.9 \times 97) + (20/2800)} = 54 \text{ W/(m}^2\cdot\text{K)}$$

From Equations (7d) and (2b),

$$c_o = \frac{75 \times 54}{1000 \times 1.20 \times 1.0 \times 4 \times 1.0} = 0.84$$

From Equation (7e),

$$M = \frac{1.20 \times 1.0 \times 4 \times 1.0}{1.0 \times 0.998 \times 4.18} = 1.15$$

Substituting in,

$$-c_o(1 - M) = -0.84(1 - 1.15) = 0.125$$

From Equation (7c),

$$E_a = \frac{1 - e^{0.126}}{1 - 1.15e^{0.126}} = 0{,}441$$

From Equation (7a), the sensible cooling capacity is

$$q_{td} = 1000 \times 1.20 \times 1.0 \times 4 \times 1.0(35 - 13) \times 0.441 = 46\,600 \text{ W}$$

From Equation (2a), the leaving-air temperature is

$$t_{a2} = 35 - \frac{46\,600}{1000 \times 1.20 \times 1.0 \times 4 \times 1.0} = 25.3°C$$

From Equation (3), the leaving-water temperature is

$$t_{r2} = 13 + \frac{46\,600}{1000 \times 1.0 \times 0.998 \times 4.18} = 24.2°C$$

The air-side pressure drop is

$$\Delta p_{st} = 55 \times 3 = 165 \text{ Pa}$$

The preceding equations and examples demonstrate the method for calculating thermal performance of sensible cooling coils that operate with a dry surface. However, when cooling coils operate wet or act as dehumidifying coils, performance cannot be predicted without including the effect of air-side moisture (latent heat) removal.

7. PERFORMANCE OF DEHUMIDIFYING COILS

A dehumidifying coil normally removes both moisture and sensible heat from entering air. In most air-conditioning processes, the air to be cooled is a mixture of water vapor and dry air gases. Both lose sensible heat when in contact with a surface cooler than the air. Latent heat is removed through condensation only on the parts of the coil where the surface temperature is lower than the dew point of the air passing over it. Figure 2 in Chapter 4 shows the assumed psychrometric conditions of this process. As the leaving dry-bulb temperature drops below the entering dew-point temperature, the difference between leaving dry-bulb temperature and leaving dew point for a given coil, airflow, and entering air condition is lessened.

When the coil starts to remove moisture, the cooling surfaces carry both the sensible and latent heat load. As the air approaches saturation, each degree of sensible cooling is nearly matched by a corresponding degree of dew-point decrease. The latent heat removal per degree of dew-point change is considerably greater. The following table compares the amount of moisture removed from air at standard barometric pressure that is cooled from 16 to 15°C at both wet and dry conditions.

Dew Point	h_s, kJ/kg	Dry Bulb	h_{da}, kJ/kg
16°C	44.966	16°C	16.093
15°C	42.115	15°C	15.087
Difference	2.850	Difference	1.006

Note: These numerical values conform to Table 2 in Chapter 1 of the 2021 *ASHRAE Handbook—Fundamentals*.

For volatile refrigerant coils, the refrigerant distributor assembly must be tested at the higher and lower capacities of its rated range. Testing at lower capacities checks whether the refrigerant distributor provides equal distribution and whether the control is able to modulate without hunting. Testing at higher capacities checks the maximum feeding capacity of the flow control device at the greater pressure drop that occurs in the coil system.

Most manufacturers develop and produce their own performance rating tables using data obtained from suitable tests. ASHRAE *Standard* 33 specifies the acceptable method of lab-testing coils. AHRI *Standard* 410 gives a method for rating thermal performance of dehumidifying coils by extending data from laboratory tests on prototypes to other operating conditions, coil sizes, and row depths. To account for simultaneous transfer of both sensible and latent heat from the airstream to the surface, AHRI *Standard* 410 uses essentially the same method for arriving at cooling and dehumidifying coil thermal performance as determined by McElgin and Wiley (1940) and described in the context of *Standard* 410 by Anderson (1970). In systems operating at partial flow such as in thermal storage, accurate performance predictions for 2300 < Re < 4000 flows have been obtained by using the Gnielinski correlation. This work was presented in detail comparable to *Standard* 410 by Mirth et al. (1993).

The potential or driving force for transferring total heat q_t from the airstream to the tube-side coolant is composed of two compo-

nents in series heat flow: (1) an air-to-surface air enthalpy difference ($h_a - h_s$) and (2) a surface-to-coolant temperature difference ($t_s - t_r$).

Figure 7 is a typical thermal diagram for a coil in which the air and a nonvolatile coolant are arranged in counterflow. The top and bottom lines in the diagram indicate, respectively, changes across the coil in the airstream enthalpy h_a and the coolant temperature t_r. To illustrate continuity, the single middle line in Figure 7 represents both surface temperature t_s and the corresponding saturated air enthalpy h_s, although the temperature and air enthalpy scales do not actually coincide as shown. The differential surface area dA_w represents any specific location within the coil thermal diagram where operating conditions are such that the air-surface interface temperature t_s is lower than the local air dew-point temperature. Under these conditions, both sensible and latent heat are removed from the airstream, and the cooler surface actively condenses water vapor.

Neglecting the enthalpy of condensed water vapor leaving the surface and any radiation and convection losses, the total heat lost from the airstream in flowing over dA_w is

$$dq_t = -w_a(dh_a) \tag{8}$$

This same total heat is transferred from the airstream to the surface interface. According to McElgin and Wiley (1940),

$$dq_t = \frac{(h_a - h_s)dA_w}{c_p R_{aw}} \tag{9}$$

The total heat transferred from the air-surface interface across the surface elements and into the coolant is equal to that given in Equations (8) and (9):

$$dq_t = \frac{(t_s - t_r)dA_w}{R_{mw} + R_r} \tag{10}$$

The same quantity of total heat is also gained by the nonvolatile coolant in passing across dA_w:

$$dq_t = -w_r c_r (dt_r) \tag{11}$$

If Equations (9) and (10) are equated and the terms rearranged, an expression for the coil characteristic C is obtained:

$$C = \frac{R_{mw} + R_r}{c_p R_{aw}} = \frac{t_s - t_r}{h_a - h_s} \tag{12}$$

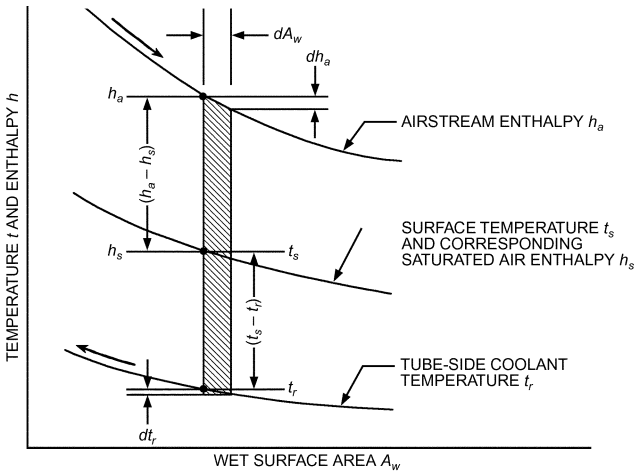

Fig. 7 Two-Component Driving Force Between Dehumidifying Air and Coolant

Equation (12) shows the basic relationship of the two components of the driving force between air and coolant in terms of three principal thermal resistances. For a given coil, these three resistances of air, metal, and in-tube fluid (R_{aw}, R_{mw}, and R_r) are usually known or can be determined for the particular application, which gives a fixed value for C. Equation (12) can then be used to determine point conditions for the interrelated values of airstream enthalpy h_a, coolant temperature t_r, surface temperature t_s, and enthalpy h_s of saturated air corresponding to the surface temperature. When both t_s and h_s are unknown, a trial-and-error solution is necessary; however, this can be solved graphically by a surface temperature chart such as Figure 8.

Figure 9 shows a typical thermal diagram for a portion of the coil surface when it is operating dry. The illustration is for counterflow with a halocarbon refrigerant. The diagram at the top of the figure shows a typical coil installation in an air duct with tube passes circuited countercurrent to airflow. Locations of the entering and leaving boundary conditions for both air and coolant are shown.

The thermal diagram in Figure 9 is the same type as in Figure 7, showing three lines to illustrate local conditions for the air, surface, and coolant throughout a coil. The dry/wet boundary conditions are

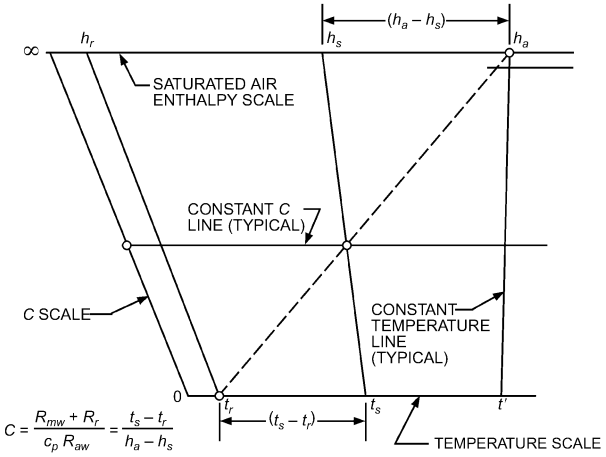

Fig. 8 Surface Temperature Chart

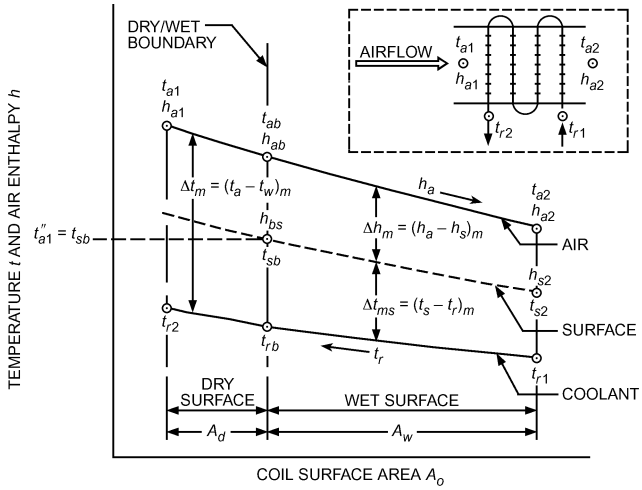

Fig. 9 Thermal Diagram for General Case When Coil Surface Operates Partially Dry

located where the coil surface temperature t_{sb} equals the entering air dew-point temperature t''_{a1}. Thus, the surface area A_d to the left of this boundary is dry, with the remainder A_w of the coil surface area operating wet.

When using fluids or halocarbon refrigerants in a thermal counterflow arrangement as shown in Figure 9, the dry/wet boundary conditions can be determined from the following relationships:

$$y = \frac{t_{r2} - t_{r1}}{h_{a1} - h_{a2}} = \frac{w_a}{w_r c_r} \tag{13}$$

$$h_{ab} = \frac{t''_{a1} - t_{r2} + y h_{a1} + C h''_{a1}}{C + y} \tag{14}$$

The value of h_{ab} from Equation (14) serves as an index of whether the coil surface is operating fully wetted, partially dry, or completely dry, according to the following three limits:

1. If $h_{ab} \geq h_{a1}$, the surface is fully wetted.
2. If $h_{a1} > h_{ab} > h_{a2}$, the surface is partially dry.
3. If $h_{ab} \leq h_{a2}$, the surface is completely dry.

Other dry/wet boundary properties are then determined:

$$t_{sb} = t''_{a1} \tag{15}$$

$$t_{ab} = t_{a1} - (h_{a1} - h_{ab})/c_p \tag{16}$$

$$t_{rb} = t_{r2} - y c_p (t_{a1} - t_{ab}) \tag{17}$$

The dry surface area A_d required and capacity q_{td} are calculated by conventional sensible heat transfer relationships, as follows.

The overall thermal resistance R_o comprises three basic elements:

$$R_o = R_{ad} + R_{md} + R_r \tag{18}$$

with

$$R_r = B/f_r \tag{19}$$

The mean difference between air dry-bulb temperature and coolant temperature, using symbols from Figure 9, is

$$\Delta t_m = \frac{(t_{a1} - t_{r2}) - (t_{ab} - t_{rb})}{\ln[(t_{a1} - t_{r2})/(t_{ab} - t_{rb})]} \tag{20}$$

The dry surface area required is

$$A_d = \frac{q_{td} R_o}{\Delta t_m} \tag{21}$$

The air-side total heat capacity is

$$q_{td} = 1000 w_a c_p (t_{a1} - t_{ab}) \tag{22a}$$

From the coolant side,

$$q_{td} = 1000 w_r c_r (t_{r2} - t_{rb}) \tag{22b}$$

The wet surface area A_w and capacity q_{tw} are determined by the following relationships, using terminology in Figure 9.

For a given coil size, design, and arrangement, the fixed value of the coil characteristic C can be determined from the ratio of the three prime thermal resistances for the job conditions:

$$C = \frac{R_{mw} + R_r}{c_p R_{aw}} \tag{23}$$

Knowing coil characteristic C for point conditions, the interrelations between airstream enthalpy h_a, coolant temperature t_r, and surface temperature t_s and its corresponding enthalpy of saturated air h_s can be determined by using a surface temperature chart (Figure 8) or by a trial-and-error procedure using Equation (24):

$$C = \frac{t_{sb} - t_{rb}}{h_{ab} - h_{sb}} = \frac{t_{s2} - t_{r1}}{h_{a2} - h_{s2}} \tag{24}$$

The mean effective difference in air enthalpy between airstream and surface from Figure 9 is

$$\Delta h_m = \frac{(h_{ab} - h_{sb}) - (h_{a2} - h_{s2})}{\ln[(h_{ab} - h_{sb})/(h_{a2} - h_{s2})]} \tag{25}$$

Similarly, the mean temperature difference between surface and coolant is

$$\Delta t_{ms} = \frac{(t_{sb} - t_{rb}) - (t_{s2} - t_{r1})}{\ln[(t_{sb} - t_{rb})/(t_{s2} - t_{r1})]} \tag{26}$$

The wet surface area required, calculated from air-side enthalpy difference, is

$$A_w = \frac{q_{tw} R_{aw} c_p}{\Delta h_m} \tag{27a}$$

Calculated from the coolant-side temperature difference,

$$A_w = \frac{q_{tw}(R_{mw} + R_r)}{\Delta t_{ms}} \tag{27b}$$

The air-side total heat capacity is

$$q_{tw} = 1000 w_a [h_{a1} - (h_{a2} + h_{fw})] \tag{28a}$$

The enthalpy h_{fw} of condensate removed is

$$h_{fw} = (W_1 - W_2) c_{pw} (t'_{a2} - 0) \tag{28b}$$

where c_{pw} = specific heat of water = 4.18 kJ/(kg·K).

Note that h_{fw} for normal air-conditioning applications is about 0.5% of the airstream enthalpy difference $(h_{a1} - h_{a2})$ and is usually neglected.

The coolant-side heat capacity is

$$q_{tw} = 1000 w_r c_r (t_{rb} - t_{r1}) \tag{28c}$$

The total surface area requirement of the coil is

$$A_o = A_d + A_w \tag{29}$$

The total heat capacity for the coil is

$$q_t = q_{td} + q_{tw} \tag{30}$$

The leaving-air dry-bulb temperature is found by the method shown in Figure 10, which represents part of a psychrometric chart showing the air saturation curve and lines of constant air enthalpy closely corresponding to constant-wet-bulb temperature lines.

For a given coil and air quantity, a straight line projected through the entering and leaving-air conditions intersects the air saturation curve at a point denoted as the effective coil surface temperature $t_{\bar{s}}$. Thus, for fixed entering air conditions t_{a1} and h_{a1} and a given effective surface temperature t_s, leaving air dry bulb t_{a2} increases but is still located on this straight line if air quantity is increased or coil depth is reduced. Conversely, a decrease in air quantity or an increase in coil depth produces a lower t_{a2} that is still located on the same straight-line segment.

An index of the air-side effectiveness is the heat transfer exponent c, defined as

$$c = \frac{A_o}{1000 w_a c_p R_{ad}} \tag{31}$$

This exponent c, sometimes called the number of air-side transfer units NTU_a, is also defined as

$$c = \frac{t_{a1} - t_{a2}}{\Delta t_{\bar{m}}} \tag{32}$$

The temperature drop $(t_{a1} - t_{a2})$ of the airstream and mean temperature difference $\Delta t_{\bar{m}}$ between air and effective surface in Equation (32) are shown at the top of Figure 10.

Knowing the exponent c and entering and leaving enthalpies h_{a1} and h_{a2} for the airstream, the enthalpy of saturated air $h_{\bar{s}}$ corresponding to effective surface temperature $t_{\bar{s}}$ is calculated as follows:

$$h_{\bar{s}} = h_{a1} - \frac{h_{a1} - h_{a2}}{1 - e^{-c}} \tag{33}$$

After finding the value of $t_{\bar{s}}$ that corresponds to $h_{\bar{s}}$ from the saturated air enthalpy tables, the leaving-air dry-bulb temperature can be determined:

$$t_{a2} = t_{\bar{s}} + e^{-c}(t_{a1} - t_{\bar{s}}) \tag{34}$$

The air-side sensible heat ratio SHR can then be calculated:

$$\text{SHR} = \frac{c_p(t_{a1} - t_{a2})}{h_{a1} - h_{a2}} \tag{35}$$

For thermal performance of a coil to be determined from the foregoing relationships, values of the following three principal resistances to heat flow between air and coolant must be known:

- Total metal thermal resistances across the fin R_f and tube assembly R_t for both dry R_{md} and wet R_{mw} surface operation
- Air-film thermal resistances R_{ad} and R_{aw} for dry and wet surfaces, respectively
- Tube-side coolant film thermal resistance R_r

In AHRI *Standard* 410, metal thermal resistance R_m is calculated based on the physical data, material, and arrangement of the fin and tube elements, together with the fin efficiency E for the specific fin configuration. R_m is variable as a weak function of the effective air-side heat transfer coefficient f_a for a specific coil geometry, as shown in Figure 11.

For wetted-surface application, Brown (1954), with certain simplifying assumptions, showed that f_a is directly proportional to the rate of change m'' of saturated air enthalpy h_s with the corresponding surface temperature t_s. This slope m'' of the air enthalpy saturation curve is shown in the small inset graph at the top of Figure 11.

The abscissa for f_a in the main graph of Figure 11 is an effective value, which, for a dry surface, is the simple thermal resistance reciprocal $1/R_{ad}$. For a wet surface, f_a is the product of the thermal resistance reciprocal $1/R_{aw}$ and the multiplying factor m''/c_p. AHRI *Standard* 410 outlines a method for obtaining a mean value of m''/c_p for a given coil and job condition. The total metal resistance R_m in Figure 11 includes the resistance R_t across the tube wall. For most coil designs, R_t is quite small compared to the resistance R_f through the fin metal.

The air-side thermal resistances R_{ad} and R_{aw} for dry and wet surfaces, together with their respective air-side pressure drops $\Delta p_{st}/N_r$ and $\Delta p_{sw}/N_r$, are determined from tests on a representative coil model over the full range in the rated airflow. Typical plots of experimental data for these four performance variables versus coil air face velocity V_a at 20°C are shown in Figure 12.

If water is used as the tube-side coolant, the heat transfer coefficient f_r is calculated from Equation (8) in AHRI *Standard* 410. For evaporating refrigerants, many predictive techniques for calculating coefficients of evaporation are listed in Table 2 in Chapter 5 of the 2021 *ASHRAE Handbook—Fundamentals*. The most verified predictive technique is the Shah correlation (Shah 1976, 1982). A series of tests is specified in AHRI *Standard* 410 for obtaining heat transfer data for direct-expansion refrigerants inside tubes of a given diameter.

ASHRAE *Standard* 33 specifies laboratory apparatus and instrumentation, including procedure and operating criteria for conducting tests on representative coil prototypes to obtain basic performance data. Procedures are available in AHRI *Standard* 410 for reducing these test data to the performance parameters necessary to rate a line or lines of various air coils. This information is available from various coil manufacturers for use in selecting AHRI *Standard* 410 certified coils.

The following example shows a method for selecting coil size, row depth, and performance data to satisfy specified job requirements. The application is for typical cooling and dehumidifying coil selection under conditions in which a part of the coil surface on the enter-

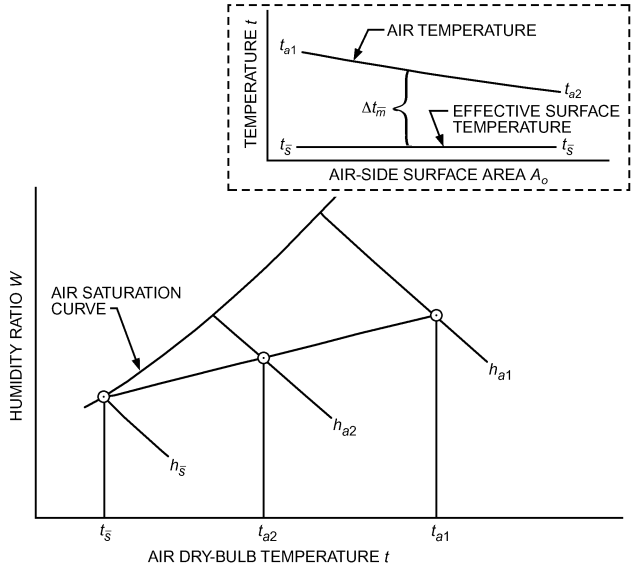

Fig. 10 Leaving-Air Dry-Bulb Temperature Determination for Air-Cooling and Dehumidifying Coils

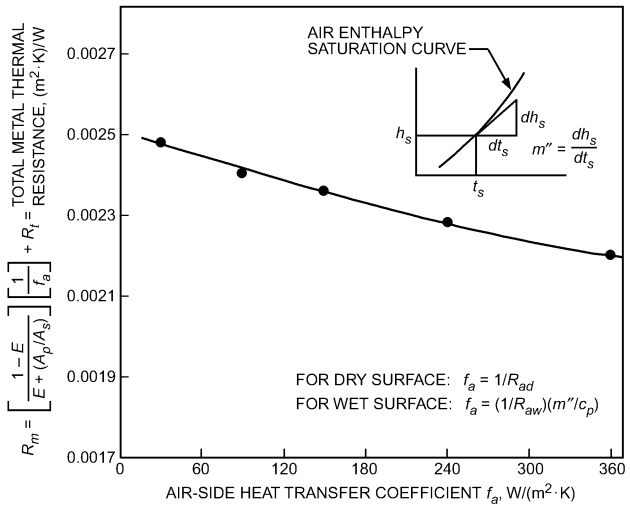

Fig. 11 Typical Total Metal Thermal Resistance of Fin and Tube Assembly

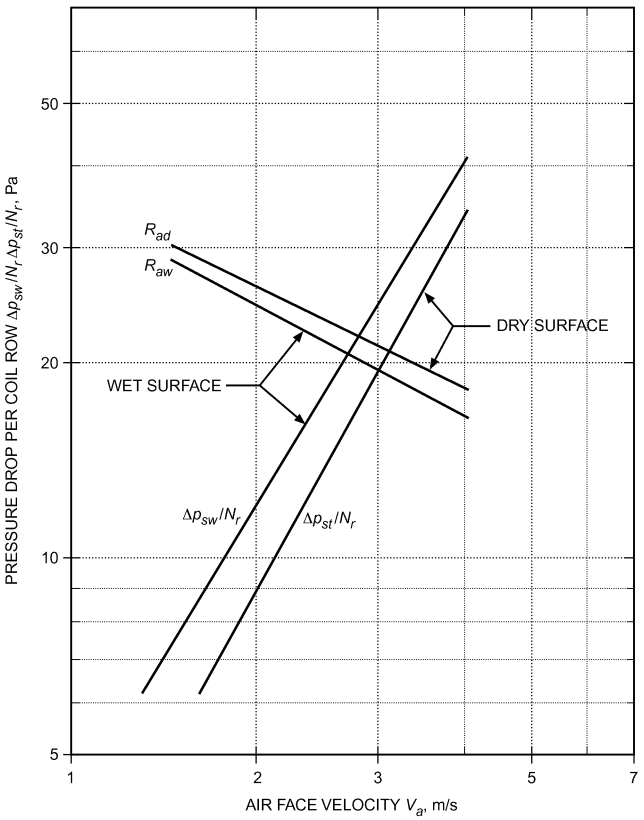

Fig. 12 Typical Air-Side Application Rating Data Determined Experimentally for Cooling and Dehumidifying Water Coils

ing air side operates dry, with the remaining surface wet with condensing moisture. Figure 9 shows the thermal diagram, dry/wet boundary conditions, and terminology used in the problem solution.

Example 3. Standard air flowing at a mass rate equivalent of 3.2 m³/s enters a coil at 27°C db (t_{a1}) and 19.5°C wb (t'_{a1}). The air is to be cooled to 13.5°C leaving wet-bulb temperature t'_{a2} using 2.5 L/s of chilled water supplied to the coil at an entering temperature t_{r1} of 6.5°C, in thermal counterflow arrangement. Assume a standard coil air face velocity of V_a = 2.8 m/s and a clean, nonfouled, finned-tube heat transfer surface in the coil core, for which the following physical and performance data (such as shown in Figures 11 and 12) can be predetermined:

B = surface ratio = 25.9
c_p = 1.00 kJ/(kg·K)
F_s = (external surface area)/(face area)(row deep) = 31.2
f_r = 4260 W/(m²·K)
$\Delta p_{sd}/N_r$ = 40 Pa/number of coil rows, dry surface
$\Delta p_{sw}/N_r$ = 65 Pa/number of coil rows, wet surface
R_{ad} = 0.013 (m²·K)/W
R_{aw} = 0.012 (m²·K)/W
R_{md} = 0.004 (m²·K)/W
R_{mw} = 0.003 (m²·K)/W
ρ_a = 1.20 kg/m³
ρ_w = 998 kg/m³

Referring to Figure 9 for the symbols and typical diagram for applications in which only a part of the coil surface operates wet, determine (1) coil face area A_a, (2) total refrigeration load q_t, (3) leaving coolant temperature t_{r2}, (4) dry/wet boundary conditions, (5) heat transfer surface area required for dry A_d and wet A_w sections of the coil core, (6) leaving-air dry-bulb temperature t_{a2}, (7) total number N_{ri} of installed coil rows, and (8) dry Δp_{st} and wet Δp_{sw} coil air friction.

Solution: The psychrometric properties and enthalpies for dry and moist air are based on Figure 1 (ASHRAE Psychrometric Chart No. 1) and Tables 2 and 3 in Chapter 1 of the 2021 *ASHRAE Handbook—Fundamentals* as follows:

h_{a1} = 55.6 kJ/kg h''_{a1} = 43.81 kJ/kg
W_1 = 11.2 g/kg $*h_{a2}$ = 37.93 kJ/kg
t''_{a1} = 15.6°C $*W_2$ = 9.7 g/kg

*As an approximation, assume leaving air is saturated (i.e., $t_{a2} = t'_{a2}$).

Calculate coil face area required:

$$A_a = 3.2/2.8 + 1.14 \text{ m}^2$$

From Equation (28b), find condensate heat rejection:

$$h_{fw} = (11.2 - 9.7)(4.18)(13.5)/1000 = 0.085 \text{ kJ/kg}$$

Compute the total refrigeration load from the following equation:

$$q_t = \rho_a w_a[h_{a1} - (h_{a2} + h_{fw})] = 1.20 \times 3.2[55.6 - (37.93 + 0.085)] = 67.6 \text{ kW}$$

From Equation (3), calculate coolant temperature leaving coil:

$$t_{r2} = t_{r1} + q_t / w_r c_r = 6.5 + 67.6/(2.5 \times 0.998 \times 4.18) = 13.0°\text{C}$$

From Equation (19), determine coolant film thermal resistance:

$$R_r = 25.9/4260 = 0.006(\text{m}^2 \cdot \text{K})/\text{W}$$

Calculate the wet coil characteristic from Equation (23):

$$C = \frac{0.003 + 0.006}{1.00 \times 0.012} = 0.75(\text{kg} \cdot \text{K})/\text{kJ}$$

Calculate from Equation (13):

$$y = \frac{13.0 - 6.5}{55.6 - 37.93} = 0.371(\text{kg} \cdot \text{K})/\text{kJ}$$

The dry/wet boundary conditions are determined as follows:
From Equation (14), the boundary airstream enthalpy is

$$h_{ab} = \frac{(15.7 - 13) + (0.367 \times 55.6) + (0.75 \times 43.81)}{0.75 + 0.371} = 48.93 \text{ kJ/kg}$$

According to limit (2) under Equation (14), part of the coil surface on the entering air side will be operating dry, because $h_{a1} > 50.5 > h_{a2}$ (see Figure 8).

From Equation (16), the boundary airstream dry-bulb temperature is

$$t_{ab} = 27 - (55.6 - 49.93)/1.00 = 21.33°\text{C}$$

The boundary surface conditions are

$$t_{sb} = t''_{a1} = 15.7°\text{C} \quad \text{and} \quad h_{sb} = h''_{a1} = 43.98 \text{ kJ/kg}$$

From Equation (17), the boundary coolant temperature is

$$t_{rb} = 13.0 - 0.367 \times 1.00(27 - 21.8) = 10.92°\text{C}$$

The cooling load for the dry surface part of the coil is now calculated from Equation (22b):

$$q_{td} = 2.5 \times 0.998 \times 4.18(13.0 - 10.92) = 19.8 \text{ kW}$$

From Equation (18), the overall thermal resistance for the dry surface section is

$$R_o = 0.013 + 0.004 + 0.006 = 0.023 \text{ (m}^2 \cdot \text{K)/W}$$

From Equation (20), the mean temperature difference between air dry bulb and coolant for the dry surface section is

$$\Delta t_m = \frac{(27 - 13.0) - (21.33 - 10.92)}{\ln[(27 - 13.0)/(21.33 - 10.92)]} = 12.12 \text{ K}$$

The dry surface area required is calculated from Equation (21):

$$A_d = 19.8 \times 0.023 \times 1000/12.12 = 37.6 \text{ m}^2$$

From Equation (30), the cooling load for the wet surface section of the coil is

$$q_{tw} = 67.6 - 19.8 = 47.8 \text{ kW}$$

Knowing C, h_{a2}, and t_{r1}, the surface condition at the leaving-air side of the coil is calculated by trial and error using Equation (24):

$$C = 0.75 = (t_{s2} - 6.5)/(38.0 - h_{s2})$$

The numerical values for t_{s2} and h_{s2} are then determined directly by using a surface temperature chart (as shown in Figure 8 or in Figure 9 of AHRI *Standard* 410) and saturated air enthalpies from Table 2 in Chapter 1 of the 2021 *ASHRAE Handbook—Fundamentals*:

$$t_{s2} = 10.8°\text{C} \quad \text{and} \quad h_{s2} = 31.16 \text{ kJ/kg}$$

From Equation (25), the mean effective difference in air enthalpy between airstream and surface is

$$\Delta h_m = \frac{(49.93 - 43.81) - (37.93 - 31.16)}{\ln[(49.93 - 43.81)/(37.93 - 31.16)]} = 6.44 \text{ kJ/kg}$$

From Equation (27a), the wet surface area required is

$$A_w = 47.8 \times 1000 \times 0.012 \times 1.00/6.44 = 89 \text{ m}^2$$

From Equation (29), the net total surface area requirement for the coil is then

$$A_o = 37.6 + 89 = 126.6 \text{ m}^2 \text{ external}$$

From Equation (31), the net air-side heat transfer exponent is

$$c = 126.6/(1000 \times 1.20 \times 1.14 \times 2.8 \times 1.00 \times 0.013) = 2.54$$

From Equation (33), the enthalpy of saturated air corresponding to the effective surface temperature is

$$h_{\bar{s}} = 55.6 - \frac{55.6 - 38.0}{1 - e^{-2.54}} = 36.4 \text{ kJ/kg}$$

The effective surface temperature that corresponds to $h_{\bar{s}}$ is then obtained from Table 2 in Chapter 1 of the 2021 *ASHRAE Handbook—Fundamentals* as $t_{\bar{s}} = 13.0°\text{C}$.

The leaving-air dry-bulb temperature is calculated from Equation (34):

$$t_{a2} = 13.0 + e^{-2.54}(27 - 13.0) = 14.1°\text{C}$$

The air-side sensible heat ratio is then found from Equation (35):

$$\text{SHR} = \frac{1.00(27 - 14.1)}{55.6 - 37.9} = 0.729$$

From Equation (1b), the calculated coil row depth N_{rc} to match job requirements is

$$N_{rc} = A_o/A_a F_s = 135/(1.14 \times 31.2) = 3.80 \text{ rows deep}$$

In most coil selection problems of this type, the initial calculated row depth to satisfy job requirements is usually a noninteger value. In many cases, there is sufficient flexibility in fluid flow rates and operating temperature levels to recalculate the required row depth of a given coil size to match an available integer row depth more closely. For this example, if the calculated row depth is $N_{rc} = 3.8$, and coils of three or four rows deep are commercially available, the coil face area, operating conditions, and fluid flow rates and/or velocities could possibly be changed to recalculate a coil depth close to either three or four rows. Although core tube circuitry has limited possibilities on odd (e.g., three or five) row coils, alternative coil selections for the same job are often made desirable by trading off coil face size for row depth.

Most coil manufacturers have computer programs to run the iterations needed to predict operating values for specific coil performance requirements. The next highest integral row depth than computed is then selected for a commercially available coil with an even number of circuits, same end connected. For this example, assume that the initial coil selection requiring 3.8 rows deep is sufficiently refined that no recalculation is necessary, and that a 4-row coil with 4-pass coil circuitry is available. Thus, the installed row depth N_{ri} is

$$N_{ri} = 4 \text{ rows deep}$$

The amount of heat transfer surface area installed is

$$A_{oi} = A_a F_s N_{ri} = 1.14 \times 31.2 \times 4 = 142 \text{ m}^2 \text{ external}$$

The completely dry and completely wetted air-side frictions are, respectively,

$$\Delta p_{sd} = (A_d/A_o)(\Delta p_{sd}/N_{ri})N_{ri} = (37/135) \times 40 \times 4 = 44 \text{ Pa}$$

and

$$\Delta p_{sw} = (A_w/A_o)(\Delta p_{sw}/N_{ri})N_{ri} = (98/135) \times 65 \times 4 = 189 \text{ Pa}$$

$$\Delta p_{st} = (A_{oi}/A_o)\Delta p_{sd} + \Delta p_{sw} = (142/135) \times (44 + 189) = 245 \text{ Pa total}$$

A more realistic Δp estimate of a coil operating at >70% wetted surface and a velocity > 2 m/s would be to consider the entire surface as wetted. Therefore, 65 × 4 = 260 Pa would be the coil's operating air-side static pressure.

In summary,

A_a = 1.14 m^2 coil face area
N_{ri} = 4 rows installed coil depth
A_{oi} = 142 m^2 installed heat transfer surface area
A_o = 135 m^2 required heat transfer surface area
q_t = 67.6 kW total refrigeration load
t_{r2} = 13.0°C leaving coolant temperature
t_{a2} = 13.9°C leaving-air dry-bulb temperature
SHR = 0.740 air sensible heat ratio
Δp_{sw} = 189 Pa wet-coil surface air friction
Δp_{sd} = 44 Pa dry-coil surface air friction
Δp_{st} = 245 Pa total coil surface air friction

8. DETERMINING REFRIGERATION LOAD

The following calculation of refrigeration load distinguishes between the true sensible and latent heat loss of the air, which is accurate within the data's limitations. This division will not correspond to load determination obtained from approximate factors or constants.

The total refrigeration load q_t of a cooling and dehumidifying coil (or air washer) per unit mass of dry air is indicated in Figure 13 and consists of the following components:

- The sensible heat q_s removed from the dry air and moisture in cooling from entering temperature t_1 to leaving temperature t_2
- The latent heat q_e removed to condense the moisture at the dew-point temperature t_4 of the entering air

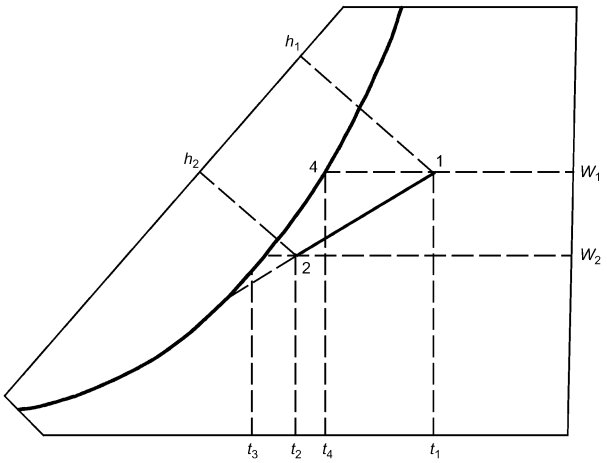

Fig. 13 Psychrometric Performance of Cooling and Dehumidifying Coil

- The heat q_w removed to further cool the condensate from its dew point t_4 to its leaving condensate temperature t_3

The preceding components are related by the following equation:

$$q_t = q_s + q_e + q_w \quad (36)$$

If only the total heat value is desired, it may be computed by

$$q_t = (h_1 - h_2) - (W_1 - W_2)h_{w3} \quad (37)$$

where

h_1 and h_2 = enthalpy of air at points 1 and 2, respectively
W_1 and W_2 = humidity ratio at points 1 and 2, respectively
h_{w3} = enthalpy of saturated liquid at final temperature t_3

If a breakdown into latent and sensible heat components is desired, the following relations may be used.

Latent heat may be found from

$$q_e = (W_1 - W_2)h_{fg4} \quad (38)$$

where

h_{fg4} = enthalpy representing latent heat of water vapor at condensing temperature t_4

Sensible heat may be shown to be

$$q_s + q_w = (h_1 - h_2) - (W_1 - W_2)h_{g4} + (W_1 - W_2)(h_{w4} - h_{w3}) \quad (39)$$

or

$$q_s + q_w = (h_1 - h_2) - (W_1 - W_2)(h_{fg4} + h_{w3}) \quad (39a)$$

where

$h_{g4} = h_{fg4} + h_{w4}$ = enthalpy of saturated water vapor at condensing temperature t_4
h_{w4} = enthalpy of saturated liquid at condensing temperature t_4

The last term in Equation (39a) is the heat of subcooling the condensate from t_4 to its final temperature t_3. Then,

$$q_w = (W_1 - W_2)(h_{w4} - h_{w3}) \quad (40)$$

The final condensate temperature t_3 leaving the system is subject to substantial variations, depending on the method of coil installation, as affected by coil face orientation, airflow direction, and air duct insulation. In practice, t_3 is frequently the same as the leaving wet-bulb temperature. Within the normal air-conditioning range, precise values of t_3 are not necessary because the heat q_t of condensate removed from the air usually represents about 0.5 to 1.5% of the total refrigeration cooling load.

Example 4. Air enters a coil at 32°C db, 24°C wb; it leaves at 16°C db, 14.5°C wb; leaving-water temperature is assumed to be 12°C, which is between the leaving-air dew-point and coil surface temperatures. Find the total, latent, and sensible cooling loads on the coil with air at standard barometric pressure.

Solution: Using Figure 1 (or the indicated equations) from Chapter 1 of the 2021 *ASHRAE Handbook—Fundamentals*,

h_1 = 72.04 kJ/kg (dry air) (32)
h_2 = 40.69 kJ/kg (dry air) (32)
W_1 = 0.01557 kg (water)/kg (dry air) (35)
W_2 = 0.00972 kg (water)/kg (dry air) (35)
t_4 = 20.85°C dew point of entering air (39)
h_{w4} = 4.186 × 20.85 = 87.28 kJ/kg (34)
h_{w3} = 4.186 × 12.00 = 50.23 kJ/kg (34)
h_{g4} = 2501 + (1.805 × 20.85) = 2538.63 kJ/kg (31)
$h_{fg4} = h_{g4} - h_{w4}$ = 2451.35 kJ/kg (31)

From Equation (37), the total heat is

$$q_t = (72.04 - 40.69) - (0.01557 - 0.00972)50.23 = 31.06 \text{ kJ/kg}$$

From Equation (38), the latent heat is

$$q_e = (0.01557 - 0.00972)2451.35 = 14.34 \text{ kJ/kg}$$

The sensible heat is therefore

$$q_s + q_w = q_t - q_e = 31.06 - 14.34 = 16.72 \text{ kJ/kg}$$

The sensible heat may be computed from Equation (39a) as

$$q_s + q_w = (72.04 - 40.69) - (0.01557 - 0.00972)2538.63 + (0.01557 - 0.00972)(87.28 - 50.23) = 16.72 \text{ kJ/kg}$$

The same value is found using Equation (39b). The subcooling of the condensate as a part of the sensible heat is indicated by the last term of the equation, 0.19 kJ/kg.

9. MAINTENANCE

If the coil is to deliver its full cooling capacity, both its internal and external surfaces must be clean. The tubes generally stay clean in pressurized water or brine systems. Tube surfaces can be cleaned in a number of ways, but are often washed with low-pressure water spray and mild detergent. Water coils should be completely drained if freezing is possible. When coils use built-up system refrigerant evaporators, oil can accumulate. Check and drain oil occasionally, and check for leaks and refrigerant dryness.

Air Side. The best maintenance for the outside finned area is consistent inspection and service of inlet air filters. Surface cleaning of the coil with pressurized hot water and a mild detergent should be done only when necessary (primarily when a blockage occurs under severe fin-surface-fouling service conditions, or bacterial growth is seen or suspected). Pressurized cleaning is more thorough if done first from the air exit side of the coil and then from the air entry side. Foaming chemical sprays and washes should be used instead of high pressure on fragile fins, or when fin density is too restrictive to allow proper in-depth cleaning with pressurized water spray. In all cases, limit spray water temperature to below 65°C on evaporator coils containing refrigerant. In cases of marked neglect or heavy-duty use (especially in restaurants where grease and dirt have accumulated) coils must sometimes be removed and the accumulation washed off with steam, compressed air and water, or hot water.

The surfaces can also be brushed and vacuumed. Best practice is to inspect and service the filters frequently. Also, condensate drain pan(s) and their drain lines, including open drain areas, should be kept clean and clear at all times.

Water Side. The best service for the inside tube coil surface is keeping the circulated fluid (water or glycol) free of sediment, corrosive products, and biological growth. Maintaining proper circulated water chemistry and velocity and filtering out solids should minimize the water-side fouling factor. If large amounts of scale form when untreated water is used as coolant, chemical or mechanical (rod) cleaning of internal surfaces at frequent intervals is necessary. A properly maintained chilled-water system using a glycol solution as the circulated fluid is not considered to ever have water-side fouling, as such, but glycol solutions must be analyzed seasonally to determine alkalinity, percent concentration, and corrosion inhibitor condition. Consult a glycol expert or the manufacturer's agent for detailed recommendations on proper use and control of glycol solutions.

Refrigerant Side. Moisture content of the refrigerant should be checked yearly, and acidity of the compressor oil as often as monthly. For built-up direct-expansion (DX) systems, normal is ≤50 mg/kg of moisture for systems with mineral oil, and ≤100 mg/kg for some refrigerant types in systems with polyol ester (POE) compressor oil. The actual values are set by the compressor manufacturer, and should be checked and verified during operation by moisture-indicating sight-glass viewing, and yearly by laboratory sample analysis reports. Depending on temperature and velocity, excessive moisture coming to the cooling coil through refrigerant might cause internal freeze-up around the coil's expansion valve. Generally, moisture in a system contributes to forma-

tion of acids, sludge, copper plating, and corrosion. Oil breakdown (by excessive compressor overheat) can form organic, hydrofluoric, and hydrochloric acids in the lubricant oil, all of which can corrode copper.

The refrigerant must be of high quality and meet AHRI *Standard* 700 purity requirements. Application design ratings of the coil or coil bank are based on purity and dryness. This is a primary requirement of refrigerant evaporator coil maintenance.

DX coil replacement often coincides with refrigerant change-out to a chlorine-free refrigerant. Special care should be taken to ensure that the system is retrofitted in accordance with the compressor and refrigerant manufacturers' written procedures.

10. SYMBOLS

A_a = coil face or frontal area, m^2
A_d = dry external surface area, m^2
A_o = total external surface area, m^2
A_p = exposed external prime surface area, m^2
A_s = external secondary surface area, m^2
A_w = wet external surface area, m^2
B = ratio of external to internal surface area, dimensionless
C = coil characteristic as defined in Equations (12) and (23), (kg·K)/kJ
c = heat transfer exponent, or NTU_a, as defined in Equations (31) and (32), dimensionless
c_o = heat transfer exponent, as defined in Equation (7d), dimensionless
c_p = specific heat of humid air = 1.019 kJ/(kg·K) for cooling coils
c_{pw} = specific heat of water = 4.18 kJ/(kg·K)
c_r = specific heat of nonvolatile coolant, kJ/(kg·K)
D_i = tube inside diameter, mm
D_o = tube outside diameter, mm
E_a = air-side effectiveness defined in Equation (7b), dimensionless
F_s = coil core surface area parameter = (external surface area)/(face area) (no. of rows deep)
f = convection heat transfer coefficient, $W/(m^2 \cdot K)$
h = air enthalpy (actual in airstream or saturation value at surface temperature), kJ/kg
Δh_m = mean effective difference of air enthalpy, as defined in Equation (25), kJ/kg
k = thermal conductivity of tube material, W/(m·K)
M = ratio of nonvolatile coolant-to-air temperature changes for sensible heat cooling coils, as defined in Equation (7e), dimensionless
m'' = rate of change of air enthalpy at saturation with air temperature, kJ/(kg·K)
N_r = number of coil rows deep in airflow direction, dimensionless
Δp_{sd} = isothermal dry surface air-side at standard conditions (20°C, 101.325 kPa), Pa
Δp_{sw} = wet surface air-side at standard conditions (20°C, 101.325 kPa), Pa
q = heat transfer capacity, W
q_e = latent heat removed from entering air to condense moisture, kJ/kg
q_s = sensible heat removed from entering air, kJ/kg
q_t = total refrigeration load of cooling and dehumidifying coil, kJ/kg
q_w = sensible heat removed from condensate to cool it to leaving temperature, kJ/kg
R = thermal resistance, referred to external area A_o, $(m^2 \cdot K)/W$
SHR = ratio of air sensible heat to air total heat, dimensionless
t = temperature, °C
Δt_m = mean effective temperature difference, air dry bulb to coolant temperature, K
Δt_{ms} = mean effective temperature difference, surface-to-coolant, K
$\Delta t_{\bar{m}}$ = mean effective temperature difference, air dry bulb to effective surface temperature $t_{\bar{s}}$, K
U_o = overall sensible heat transfer coefficient, $W/(m^2 \cdot K)$
V_a = coil air face velocity at 20°C, m/s
W = air humidity ratio, kilograms of water per kilogram of air
w = mass flow rate, kg/s
y = ratio of nonvolatile coolant temperature rise to airstream enthalpy drop, as defined in Equation (13), (kg·K)/kJ
η = fin effectiveness, as defined in Equation (6), dimensionless
ρ_a = air density = 1.20 kg/m^3 at 20°C at sea level

Superscripts

′ = wet bulb
″ = dew point

Subscripts

1 = condition entering coil
2 = condition leaving coil
a = airstream
ab = air, dry/wet boundary
ad = dry air
aw = wet air
b = dry/wet surface boundary
d = dry surface
e = latent
f = fin (with R); saturated liquid water (with h)
g = saturated water vapor
i = installed, selected (with A_o, N_r)
m = metal (with R) and mean (with other symbols)
md = dry metal
mw = wet metal
o = overall (except for A)
r = coolant
rb = coolant dry/wet boundary
s = surface (with d, t, and w) and saturated (with h)
$\bar{s}$ = effective surface
sb = surface dry/wet boundary
t = tube (with R) and total (with s and q)
td = total heat capacity, dry surface
tw = total heat capacity, wet surface
w = water (with ρ), condensate (with h and subscript number), and wet surface (with other symbols)

Equipment Operating Recommendations 24.12
Applications for Atmospheric-Pressure Dehumidification 24.13
Desiccant Drying at Elevated Pressure 24.15
Equipment Types 24.16
Applications 24.16

DEHUMIDIFICATION is the removal of water vapor from air, gases, or other fluids. There is no pressure limitation in this definition, and sorption dehumidification equipment has been designed and operated successfully for system pressures ranging from subatmospheric to as high as 40 MPa. In common practice, *dehumidification* refers to equipment operating at atmospheric pressures and built to standards similar to other types of air-handling equipment. For drying gases under pressure, or liquids, the term **dryer** or **dehydrator** is normally used.

This chapter mainly covers equipment and systems that dehumidify air rather than those that dry other gases or liquids. Both liquid and solid desiccants are used; they either adsorb water on the desiccant's surface (adsorption) or chemically combine with water (absorption).

Nonregenerative equipment uses hygroscopic salts such as calcium chloride, urea, or sodium chloride. Regenerative systems usually use a form of silica or alumina gel; activated alumina; molecular sieves; or lithium chloride, calcium chloride, or glycol solution. In regenerative equipment, the water removal mechanism is reversible. The choice of desiccant depends on installation requirements, equipment design, and chemical compatibility with the gas to be treated or impurities in the gas. Chapter 32 of the 2021 *ASHRAE Handbook—Fundamentals* has more information on desiccant materials and how they operate.

Some applications of desiccant dehumidification include

- Ventilating buildings with cooled and dried outdoor air
- Addressing buildings with high internal humidity loads, such as pools, fitness centers, and beverage/food processing
- Keeping buildings and HVAC systems dry to prevent mold growth
- Lowering relative humidity to facilitate manufacturing and handling of hygroscopic materials
- Lowering the dew point to prevent condensation on products manufactured in low-temperature processes
- Providing protective atmospheres for heat treatment of metals
- Controlling humidity in warehouses and caves used for storage
- Preserving ships, aircraft, and industrial equipment that would otherwise deteriorate
- Maintaining a dry atmosphere in a closed space or container, such as the cargo hold of a ship or numerous static applications
- Eliminating condensation and subsequent corrosion
- Speeding drying of heat-sensitive products, such as candy, seeds, and photographic film
- Drying natural gas
- Drying gases that are be liquefied
- Drying instrument and plant air
- Drying process and industrial gases

The preparation of this chapter is assigned to TC 8.12, Desiccant Dehumidification Equipment and Components.

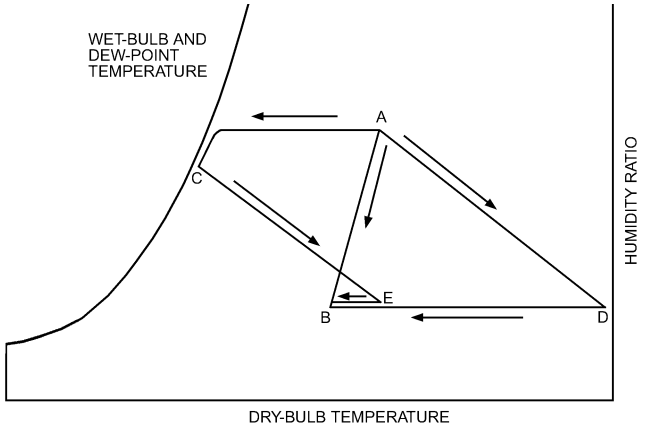

Fig. 1 Methods of Dehumidification

- Dehydration of liquids
- Dehumidifying buildings using chilled beams
- Frost-free cooling for low-temperature process areas such as brewery cellars; blast freezers; and refrigerated warehouses
- Offering frost-free dehumidification for processes that require air at a subfreezing dew-point humidity
- Maintaining low dew points for electronics and battery production
- Maintaining low-dew-point space conditions for surgical suites
- Providing appropriate conditions for pneumatic conveying of hygroscopic materials
- Providing appropriate conditions for engine test cells
- Improving indoor air quality (IAQ)
- Eliminating fog formation and ceiling condensation in ice rinks.
- Minimizing frost build-up on refrigerated display cases in supermarkets.

This chapter covers (1) the types of dehumidification equipment for liquid and solid desiccants, including high-pressure equipment; (2) performance curves; (3) variables of operation; and (4) some typical applications. Using desiccants to dry refrigerants is addressed in Chapter 8 of the 2022 *ASHRAE Handbook—Refrigeration*.

1. METHODS OF DEHUMIDIFICATION

Air may be dehumidified by (1) cooling it or increasing its pressure, reducing its capacity to hold moisture, or (2) removing moisture by attracting the water vapor with a liquid or solid desiccant. Frequently, systems use a combination of these methods to maximize operating efficiency and minimize installed cost.

Figure 1 illustrates three methods to dehumidify with desiccant materials or equipment. Air in the condition at Point A is dehumidified

and cooled to Point B. In a liquid-desiccant unit, air is simultaneously cooled and dehumidified directly from Point A to Point B. In a solid-desiccant unit, this process can be completed by precooling and dehumidifying from Point A to Point C, then desiccating from Point C to Point E, and finally cooling to Point B. It could also be done with solid-desiccant equipment by dehumidifying from Point A to Point D and then cooling from Point D to Point B.

Compression

Compressing air reduces its capacity to hold moisture. The resulting condensation reduces the air's moisture content in absolute terms, but produces a saturated condition: 100% relative humidity at elevated pressure. In atmospheric-pressure applications, this method is too expensive, but is worthwhile in pressure systems such as instrument air. Other dehumidification equipment, such as coolers or desiccant dehumidifiers, often follows the compressor to avoid problems associated with high relative humidity in compressed-air lines.

Cooling

Refrigerating air below its dew point is the most common method of dehumidification. This is advantageous when the gas is comparatively warm, has a high moisture content, and the desired outlet dew point is above 5°C. Frequently, refrigeration is combined with desiccant dehumidification to obtain an extremely low dew point at minimum cost.

Liquid Desiccants

Liquid desiccant conditioners (absorbers) contact the air with a liquid desiccant, such as a solution of lithium chloride or glycol (Figures 2A, 2B, and 3), to dehumidify and often cool that air. When the water vapor pressure of such a solution is lower than the partial pressure of water in the surrounding air, the solution will collect moisture, thereby decreasing its concentration and dehumidifying the air. The solution's water vapor pressure is a function of its temperature and concentration. Solutions of higher desiccant concentration and/or lower temperature result in lower water vapor pressures and have a stronger dehumidifying effect on the contacted air.

Conversely, liquid desiccant regenerators also contact the air with the same liquid desiccant. When the water vapor pressure of such a solution is higher than the partial pressure of water in the surrounding air, the solution will reject moisture, thereby increasing its concentration and humidifying the air. Solutions of lower desiccant concentration and/or higher temperature result in higher water vapor pressures and have a humidifying effect on the contacted air.

A simple way to show this relationship is to graph the humidity ratio of air in equilibrium with a liquid desiccant as a function of its concentration and temperature. Figure 4 presents this relationship for lithium chloride/water solutions in equilibrium with air at 101.325 kPa. The graph has the same general shape as a psychrometric chart, with the relative humidity lines replaced by desiccant concentration lines.

To dehumidify air, a first airstream (either outdoor, return, or mixed air) contacts a cooled solution in the conditioner; water condenses into the desiccant solution from the air, and the solution is diluted. The diluted solution is continuously reconcentrated in the regenerator, where it is heated to elevate its water vapor pressure and equilibrium humidity ratio. A second airstream, usually outdoor air, contacts the heated solution in the regenerator; water evaporates from the desiccant solution into the air, and the solution is reconcentrated. Desiccant solution is continuously circulated between the conditioner and regenerator to complete the cycle. Liquid desiccant conditioners typically have high contact efficiency, so air leaves the conditioner at a temperature and humidity ratio very close to the entering temperature and equilibrium humidity ratio of the desiccant.

Liquid desiccants are typically very effective antifreeze. As a result, liquid-desiccant heat pumps can continuously deliver air at subfreezing temperatures without frosting or freezing problems. Lithium chloride/water solution, for example, has a eutectic point below –68°C; liquid desiccant conditioners using this solution can cool air to temperatures as low as –45°C.

LiCl is an ionic salt that is widely used as a liquid desiccant. Other options that have been used include similar salts such as CaCl, which has a more limited operating range but is significantly cheaper. The properties of these and more novel liquid desiccant options are discussed in more detail in Chapter 32 of the 2021 *ASHRAE Handbook—Fundamentals*.

Liquid desiccant (LD) systems circulate the desiccant between a conditioner that supplies the process air and a regenerator that restores the desiccant concentration by removing the humidity absorbed at the conditioner from the desiccant. The change in concentration is typically 1 to 3% per circulation. Absorption and desorption are driven by vapor pressure differences between the air flowing over the desiccant and the desiccant surface. Effective heat exchangers will therefore have similar vapor pressures in the air at the conditioner and the regenerator, corresponding to similar relative humidity levels. Figure 4 shows the equilibrium relative humidity levels for LD at different temperatures and concentrations, as well as areas where the solution either freezes (concentration <25%, temperatures <<0°C) or crystalizes in different combinations of LiCl and H_2O crystals. Typical supply conditioner requirements are 50% rh, which requires a concentration of about 30% LiCL.

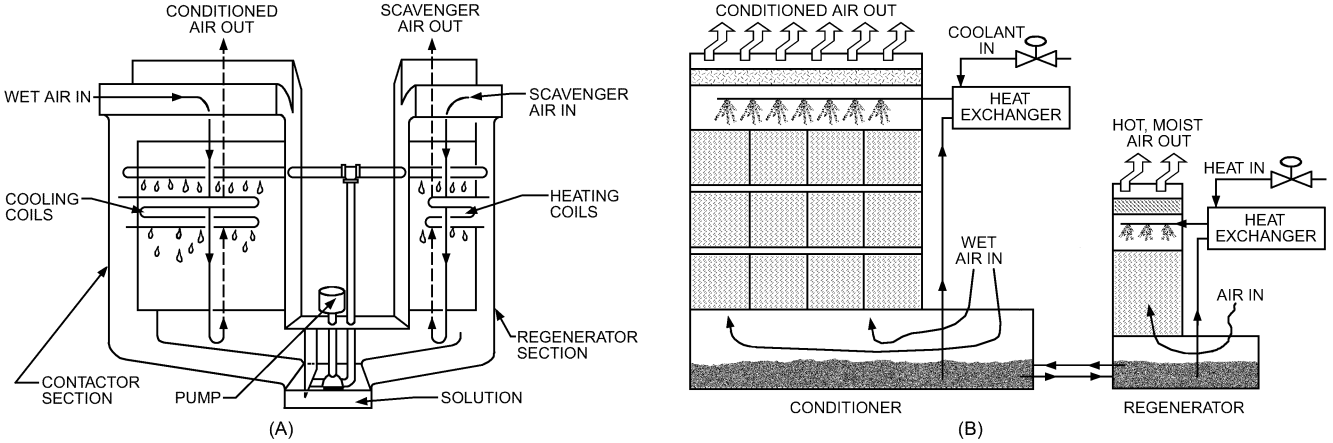

Fig. 2 Flow Diagram for Liquid-Absorbent Dehumidifier (A) Without and (B) With Extended Surface Contact Medium

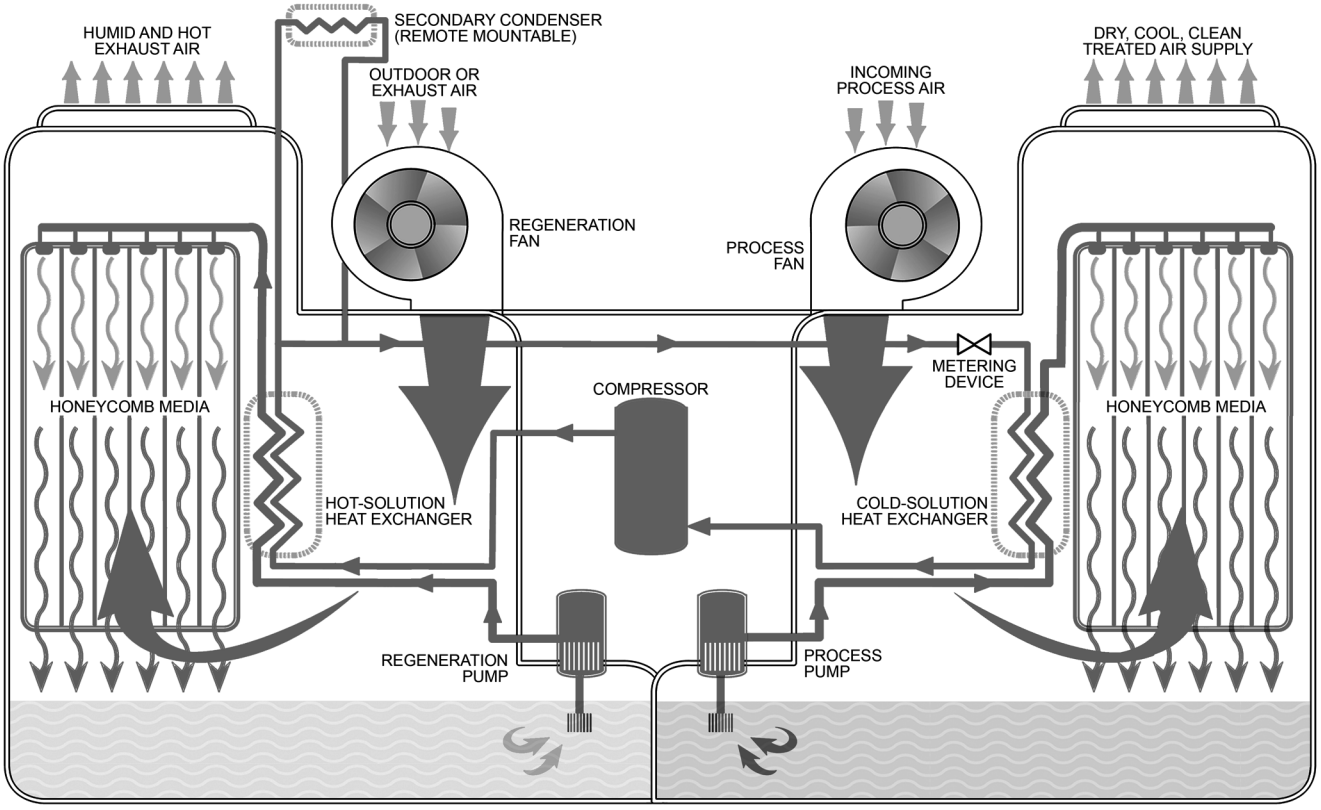

Fig. 3 Flow Diagram for Liquid-Absorbent Unit with Onboard Refrigeration System

LiCl is an effective desiccant and can achieve lower dew-point levels then CaCL and other cheaper alternatives. Since lithium is now widely used in many applications, in particular batteries, pricing has responded to the increased demand. Salts like LiCl and CaCL are also corrosive. As a result, work is being done on other ionic fluids that have less corrosive properties (see Chapter 32 of the 2021 *ASHRAE Handbook—Fundamentals*). These tend to have significantly higher viscosity as well as other differences in properties that require significant redesign.

To deal with the corrosive nature of the desiccant salts like LiCL, liquid desiccant heat exchangers (LDHX) using LiCL are made of polymers and covered with membranes that allow humidity to pass but block the transfer of liquids (i.e., the salt solution).

Internal cooling of the panel is critical. A typical salt solution of 30% can dehumidify air to point B in Figure 5 adiabatically but to point A if the absorption heat is removed by a heat transfer fluid. Solid desiccants can typically dehumidify to much lower relative humidity levels, which makes adiabatic cooling possible. But liquid desiccants typically supply air at 40 to 60% rh, which at temperatures of 35°C results in dew points of 20°C or higher. They are typically cooled using a heat transfer fluid (e.g., water or glycol). Direct cooling with a refrigerant involves pressures that are difficult to handle with noncorrosive materials.

Creating heat exchangers that are internally cooled, with thin layer of desiccant covered on the outside by a membrane, has been a challenging design task, requiring using advanced manufacturing techniques. Recent published results (Wood et al. 2022) show performance within 10% of the modeled theoretical potential of this approach compared to about 50% using earlier solutions.

Figure 5 shows 2003 Conde data comparing theoretical to actual performance for a wide variety of research programs. Actual performance of liquid desiccant systems generally was a fraction of the theoretical potential. After 2010, significant improvements were achieved, resulting in low-flow systems performing close to theoretical performance.

Low-flow systems have a mass flow ratio of desiccant to air of 5 to 20%. This is important for overall performance because the desiccant needs to be moved between regenerator and conditioner. A low mass flow ratio reduces the energy losses that occur in that process. The alternative is a complex desiccant flow management system to increase the delta in concentration between regenerator and conditioner, which affects system costs.

Regeneration using waste heat of a compressor should be able to make efficient use of this heat without overheating the condenser. Regeneration tends to be more efficient at higher temperatures, but those higher temperatures also result in a higher lift and thus lower performance of the compressor. As a result, optimized systems tend to run at moderate concentrations of 25 to 35% LiCL, which can be maintained at condenser temperatures of 38 to 49°C, resulting in a supply air of about 50% rh at 18 to 24°C.

Overall efficiency of compressor-based systems is driven by the fact that they dehumidify to target dew point at much higher temperatures. Condensing systems cool to the dew point. The difference is 15 to 20% in cooling requirements. By using LDHX, compressor systems can avoid reheat by not overcooling the air. The condenser is cooled using a combination of evaporation and sensible cooling, which reduces fan power requirements and reduces overall lift at high load operating conditions. In heat pump mode, systems avoid the need for defrost cycles, which improves heating efficiency and increases the temperature range at which the heat pump can operate efficiently. LDHX can also maintain 30 to 50% rh in the space using humidity available outdoors.

Of course, where waste heat is easily available from fuels cells, cogeneration and other waste heat sources, regeneration can be done at higher temperatures. With such waste heat, systems can dehumid-

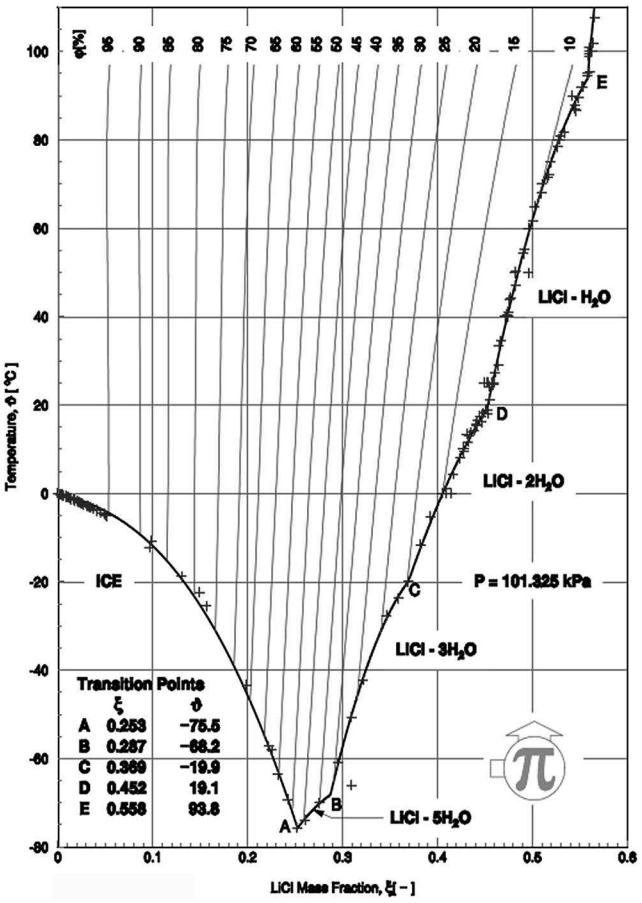

Fig. 4 Lithium Chloride Equilibrium in Air in Psychrometric Diagram

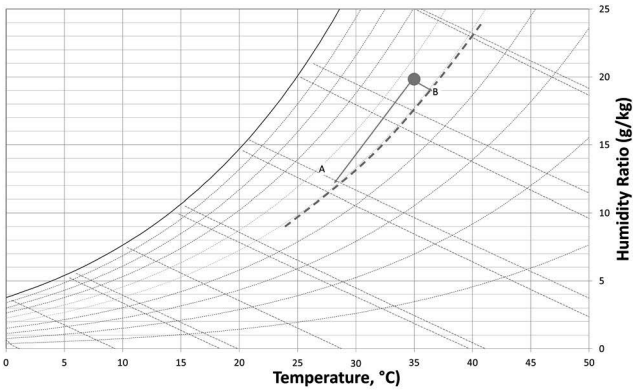

Fig. 5 Liquid Desiccant Panel

(Conde liquid desiccant performance results, 2003)

ify air to 7 to 13°C using cooling tower water at 18 to 24°C. This makes it possible to use evaporative cooling systems in humid climates as well as in desert conditions with very high wet-bulb conditions (see Figure 8).

The cool air from the conditioner and the hot air from the regenerator have approximately the same relative humidity, since the changes in desiccant concentration are within 1 to 2%. Figure 6

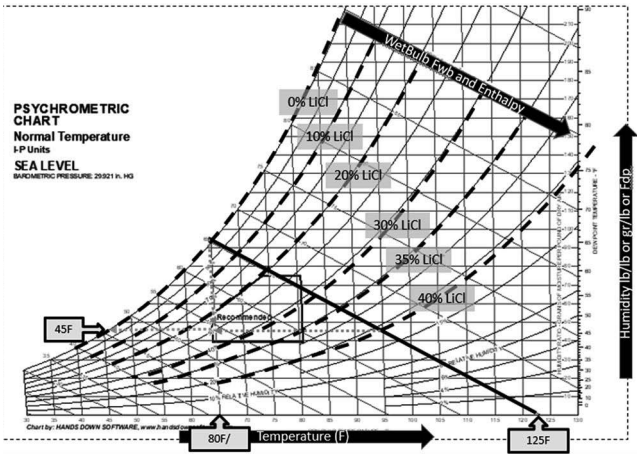

Fig. 6 Lithium Chloride Equilibrium

shows the conditions for lithium chloride where the vapor pressure in the desiccant at a certain concentration balances with a specific concentration. The psychrometric chart shows vertical lines of constant dry-bulb temperature, horizontal lines of constant absolute humidity expressed either in the dew-point temperature, ratio of the mass of the water in the air versus the total mass of the air. The angled lines show constant enthalpy of the air. The lines of constant relative humidity and those for the vapor pressure of the desiccant at a constant concentration are parallel. A concentration of LiCl of 20 to 30% corresponds to a relative humidity of 60 to 40% at 18 to 24°C. Those are target conditions that have shown to be in the health and comfort zone of the psychrometric chart.

Liquid desiccant performance compared to standard DX system is shown in Figure 7. At outdoor air condition A, the liquid desiccant will supply air at condition B and regenerate at condition C. In equilibrium, the moisture removed from the conditioned air needs to be released in the regeneration air. The relative humidity of the supply air and of the regenerator air are similar since they both use the same circulating liquid desiccant. Q_{evap} is the work that the compressor has to do to cool and dehumidify the air from A to B. Q_{evap} plus the waste energy from the compressor I^2R is the energy available for regeneration. The temperature difference between the evaporator and condenser is typically 22 to 28 K. Unlike typical DX systems, condenser airflows tend to comparable or much smaller than evaporator airflows. Effective regeneration at 50% rh requires a temperature over 38°C, with most of the energy dissipated through evaporation. At low loads and cool very humid outside air conditions, regeneration is most effective with low airflows at similar temperatures of 38 to 49°C.

A traditional DX system (dotted lines) needs to cool the air to dew point and needs to do more about 15% more work to cool the air to the target dew point at 100% rh. Condenser airflows tend to be several times larger than airflows at the evaporator and total lift is typically has a larger lift of 33 to 38 K. High capacity condensing coils tend to be deep with high pressure drop, resulting in high fan loads for both conditioner and regenerator.

Figure 8 shows a typical layout of a liquid desiccant system with membrane enabled three-way heat exchangers. It shows the conditioner and regenerator with the liquid desiccant flowing through a heat exchanger. As the liquid desiccant circulates between the cold conditioner and a hot regenerator, the heat exchanger is essential to minimize the heat loss of this circulation. The heat transfer fluid, which can be water, glycol or other high-heat-capacity fluids, is cooled and heated in the evaporator and condenser HX of a com-

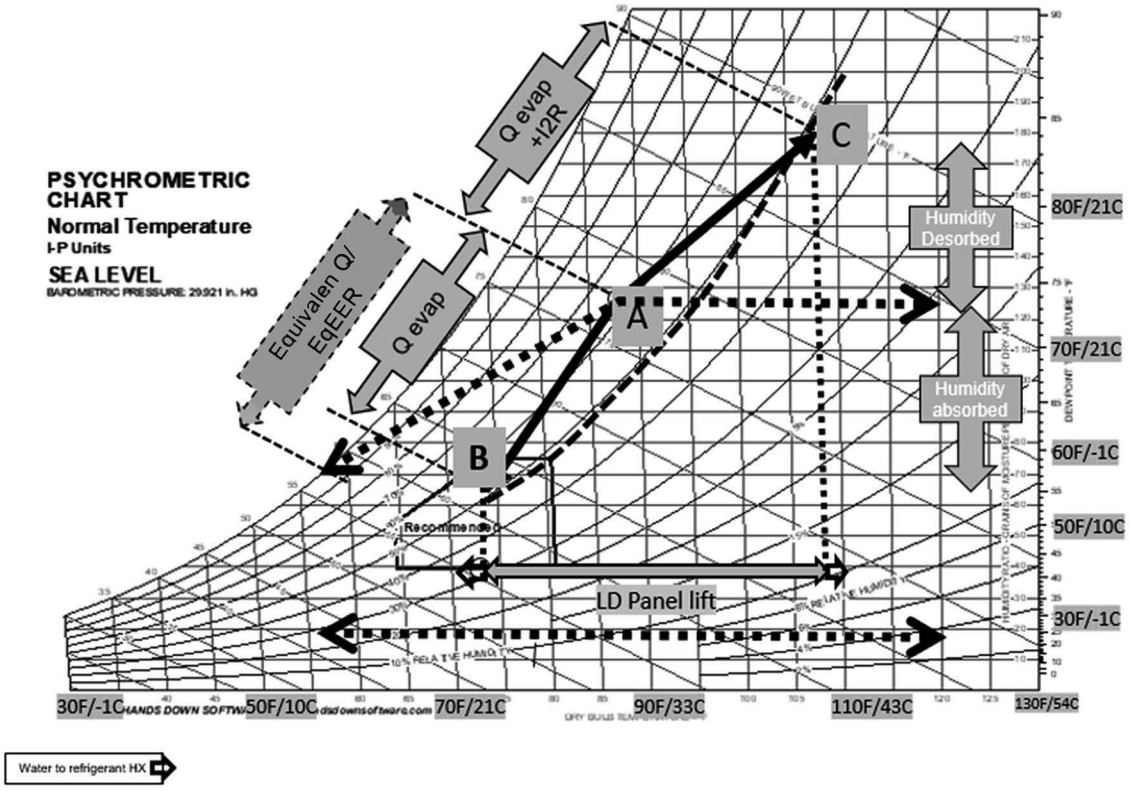

Fig. 7 Liquid Desiccant Performance

pressor. This makes the unit a drop-in replacement for existing DX systems.

The liquid desiccant concentration can be varied by changing the airflow through the regenerator. When more control is needed, air-cooled coils can be added. They reduce or increase the available heat for regeneration. The HDC or heat dump coil rejects compressor heat, reducing the regenerator temperature and thereby lowing the concentration of the desiccant, which increases the relative humidity of the supply air and the SHR of the system.

For humid and cool conditions, a second heat recovery coil (HRC) can be used. This coil cools down the regen air providing additional load for the compressor which allows the regenerator to increase the desiccant concentration. This allows for adiabatic or near adiabatic dehumidification of the conditioned supply air.

Where relative dry exhaust air is available the heat requirements of the regenerator is reduced. This increases system efficiency by 10 to 20% especially during humid and cool conditions.

The system can be used as a heat pump by changing the heat transfer fluid flow, so that the fluid going into the conditioner is heated, while the regenerator dehumidifies and cools the outside air. Alternatively, the refrigerant flow in the compressor can be switched. The cold outside air at the regenerator is dehumidified and cooled. As a result, frost forming and thus frost cycles can be avoided.

The efficiency of the system shown in Figure 8 is improved compared to traditional DX systems by using smaller compressors, with a smaller lift, doing less work to dehumidify the air. In addition, or as an alternative for the compressor, other heat and cold sources can be used. In particular, cooling tower water can be used to manage the dehumidification load of these liquid desiccant systems, with waste, geothermal, or solar heat used for regeneration. This further reduces power requirements for cooling and dehumidification. The fit of these configurations depends on the relative cost and sustainability of electricity versus the availability and cost of waste heat and evaporative cooling sources.

LiCl is widely used as a desiccant given its favorable characteristics at typical outside air and supply air conditions. Alternatives like CaCl and potassium can be used, depending on the application. Because of the corrosive character of the desiccant salts , the heat exchangers are made of polymers to avoid corrosion. The membrane prevents the desiccant from entering the airstream while ensuring that the desiccant is spread out across the surface of the heat exchanger. In addition, mist eliminators can be added if there are concerns about damage to the membranes.

To meet UL 900 requirements the plastic heat exchangers are protected by a low pressure drop fire protector. This is visible in an early version of a three-way membrane-enabled liquid desiccant heat exchanger (Figure 9).

Characteristically, liquid desiccant systems are used where there are significant outside air requirements in humid climates. They perform well when humidity control is important and the system needs to be able to operate at a low or variable SHR. In climates that combine hot and humid conditions during part of the year or day, with extremely hot and dry conditions, the desiccant needs to be diluted to avoid crystallization. This can be done by adding demineralized water directly to the desiccant solution, or by maintaining a high relative humidity in the regenerator, the conditioner, or both by humidifying the outside air with a evaporative pad or misting device.

Where other sources of heating and cooling are available, the desiccant heat exchangers can be used to dehumidify and regenerate the liquid desiccant solution. To maintain the concentration of the desiccant requires that the available regeneration heat is greater than the cooling energy. When used as a DOAS system, the performance of liquid desiccant systems is measured in kg/kW. When overall efficiency is measured the ratio of kilowatts cooling to kilowatts of

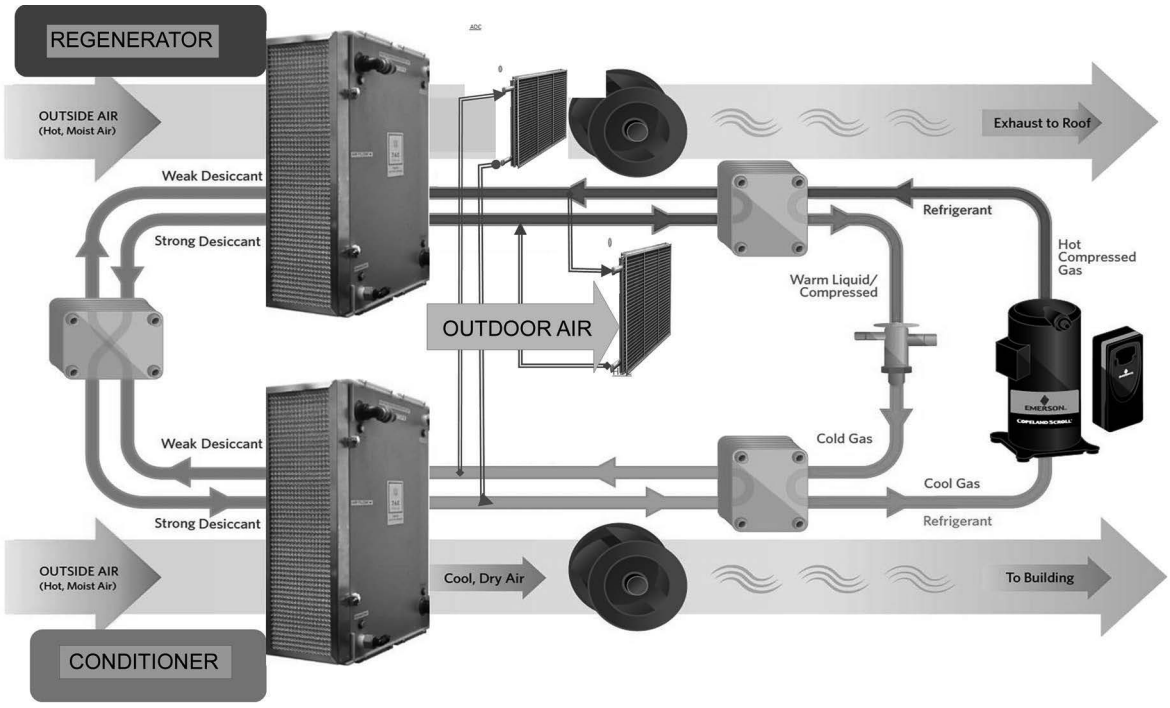

Fig. 8 Liquid Desiccant System Layout

Fig. 9 Three-Way Membrane-Enabled Desiccant Heat Exchanger

(Courtesy Emerson Climate System 2022)

power used by the system can be used, measured at the relevant conditions for that system (i.e., not necessarily at the conditions described in AHRI *Standard* 340).

Performance of liquid desiccant systems can be measured in several ways:

- Liquid desiccant dedicated outside air systems are evaluated based on their performance against the 920 standard, which measures the system **integrated seasonal moisture removal rate (ISMRE)**, a measure of energy required to remove humidity.
- Air handlers using dedicated outdoor air systems can be evaluated using COP or EER, which evaluate the total energy removed or added to air divided by the system energy required to do this work. To measure the advantage that LD systems have in removing humidity at higher operating temperatures, their performance can be best compared to standard systems that condense outdoor air by using an equivalent EER or COP that compares the work done by the unit to the work that would be required by a standard unit cooling the air to the target dew point.
- Heat exchangers can be evaluated using sensible and latent effectiveness. Latent effectiveness is typically measured as the actual change in moisture in the air divided by the delta between the initial moisture level (kg/kg) compared to the moisture removal potential. Typically this is measured by calculating air moisture at a temperature equal to that of the incoming cooling/water fluid and at a vapor pressure equal to that of the liquid desiccant at the concentration entering the heat exchanger. An alternative measure that gives a better comparison to typical heat exchangers measures the target condition based on the temperature and concentration of the liquid desiccant leaving the HX
- Actual system and module performance can be predicted using a physics-based model (Woods et al. 2022), with all the physical properties of the unit. A comparison between that modeled performance and actual performance then shows how close the unit is to the theoretical optimum predicted by the model, which is a good indicator of the maturity of the design. As indicated above, this used to be between 30 and 70% of theoretical performance; however, recent results are much closer at about 90% of theoretical performance. Such measures are critical for evaluating production results and for understanding the trade-offs between system size and complexity and actual performance. In Woods et al. (2022), predicted performance was shown as shown in Figure 10, showing the actual and modeled results for a liquid desiccant system at the four 920 conditions (1 = 920A, 2 = 920B, etc.). For reference, the minimum ISMRE requirement for DOAS systems under the 2019 standard is 1.6 kg/kW.

Solid Sorption

Solid sorption passes air through a bed of granular desiccant or through a structured packing impregnated with desiccant. Humid air passes through the desiccant, which when active has a vapor pressure

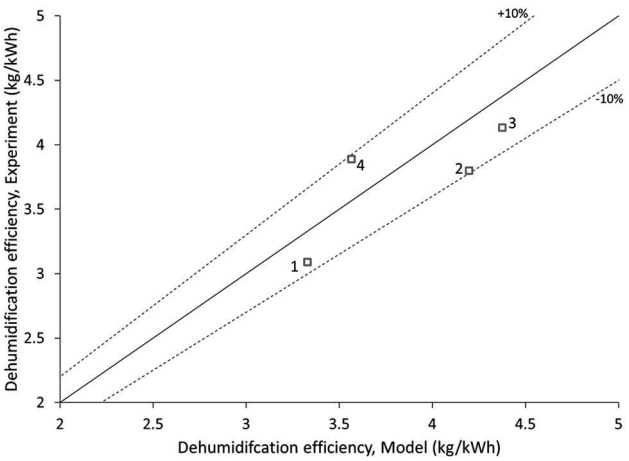

Fig. 10 Predicted Versus Actual Performance of Liquid Desiccant System at Four Standard Conditions

(Woods et al. 2022)

below that of the humid air. This vapor pressure differential drives water vapor from the air onto the desiccant. After becoming loaded with moisture, the desiccant is reactivated (dried out) by heating, which raises the vapor pressure of the material above that of the surrounding air. With the vapor pressure differential reversed, water vapor moves from the desiccant to a second airstream called the *reactivation air*, which carries moisture away from the equipment.

2. DESICCANT DEHUMIDIFICATION

Both liquid and solid desiccants may be used in equipment designed for drying air or other gases at atmospheric or elevated pressures. Regardless of pressure levels, basic principles remain the same.

Desiccant capacity and actual dew-point performance depend on the specific equipment used, characteristics of the various desiccants, initial temperature and moisture content of the gas to be dried, reactivation methods, etc. Factory-assembled units are available up to a capacity of about 38 m^3/s. Greater capacities can be obtained with field-erected units.

2.1 LIQUID DESICCANT EQUIPMENT

Liquid desiccant dehumidifiers are shown in Figures 2 and 3. In Figure 2A, liquid desiccant is distributed onto a cooling coil, which acts as both a contact surface and a means of removing heat released when the desiccant absorbs moisture from the air. In Figure 2B, liquid desiccant is distributed onto an extended heat and mass transfer surface (a packing material similar to that used in cooling towers and chemical reactors). Additionally, Figure 3 demonstrates a liquid desiccant air-conditioning system with an onboard refrigeration system, offering a packaged solution. The packing provides a great deal of surface for air to contact the liquid desiccant, allowing the desiccant to dehumidify and cool the air. It also uses a heat exchanger outside the airstream to cool the desiccant, thereby removing the heat of absorption and any other heat transferred from the air into the desiccant. Air can be passed through the contact surface vertically or horizontally to suit the best arrangement of air system equipment.

Depending on the air and desiccant solution inlet conditions, air can be either simultaneously cooled and dehumidified; heated and dehumidified; heated and humidified; or cooled and humidified. When the enthalpy of the air is to be increased in the conditioner unit, heat must be added either by preheating the air before it enters the conditioner or by heating the desiccant solution with a second heat exchanger. Conversely, when the enthalpy of the air is to be decreased in the conditioner unit, heat must be removed with a heat exchanger. When the air is to be humidified, makeup water is automatically added to the desiccant solution to keep it at the desired concentration. When air is to be dehumidified, a regenerator to reject the collected moisture to an exhaust airstream and a mechanism for transporting the gathered water from the collector to the regenerator are required.

Moisture Removal

In the conditioner, a pump continuously circulates the desiccant solution through a heat exchanger and distributes it over the packed bed contactor surface. The heat exchanger cools the desiccant solution either through an onboard refrigeration system or by transferring heat to an appropriate heat sink such as chilled water, ground water, or other low-temperature heat sink (e.g., even chilled ammonia for extremely low-temperature and low-dew-point applications). This maintains the water vapor pressure of the desiccant used for conditioning lower than that of the air to be treated.

Moisture is absorbed from or desorbed into the air because of the difference in water vapor pressure between the air and the desiccant solution. By controlling the temperature and concentration of the desiccant solution, the conditioner unit can deliver air at a precisely controlled temperature and humidity regardless of inlet air conditions. Therefore, a unit can dehumidify the air during humid weather and humidify it during dry weather. Thus, liquid desiccant conditioners can accurately control humidity without face-and-bypass dampers or after-humidifiers. System performance can easily be controlled as process drying requirements change by altering temperature, concentration, or both to meet the new requirements. Similarly, solution strength can be easily monitored and adjusted while the unit is in operation. The solution strength can be monitored while in operation and can easily be adjusted to compensate for aging. In most cases, the solution retains its effectiveness for the life of the equipment, assuming that proper filtration is maintained.

Heat Removal

When a liquid desiccant absorbs moisture, heat is generated. This heat of absorption consists of the latent heat of condensation of water vapor at the desiccant temperature and the heat of solution (heat of mixing) of the condensed water and the desiccant. The heat of mixing is a function of the equilibrium relative humidity of the desiccant: a lower equilibrium relative humidity produces a greater heat of mixing.

The total heat that must be absorbed by the desiccant solution consists of the (1) heat of absorption, (2) sensible heat associated with reducing the dry-bulb temperature of the air, and (3) residual heat carried to the conditioner by the warm, concentrated desiccant returning from the regenerator unit. This total heat is removed by cooling the desiccant solution in the conditioner heat exchanger (Figure 2B). Any coolant can be used, including cooling tower water, groundwater, seawater, chilled water or brine, and direct-expansion or flooded refrigerants.

Regenerator residual heat, generally called regenerator heat dumpback, can be substantially reduced by using a liquid-to-liquid heat exchanger to precool the warm, concentrated desiccant transferred to the conditioner using the cool, dilute desiccant transferred from the conditioner to the regenerator. This also improves the thermal efficiency of the system, typically reducing coolant and heat input by 10 to 15%.

Regeneration

When the conditioner is dehumidifying, water is automatically removed from the liquid desiccant to maintain the desiccant at the proper concentration. Removal takes place in a separate regenerator. A small sidestream of the desiccant solution is transferred to the regenerator unit. In the regenerator, a separate pump continu-

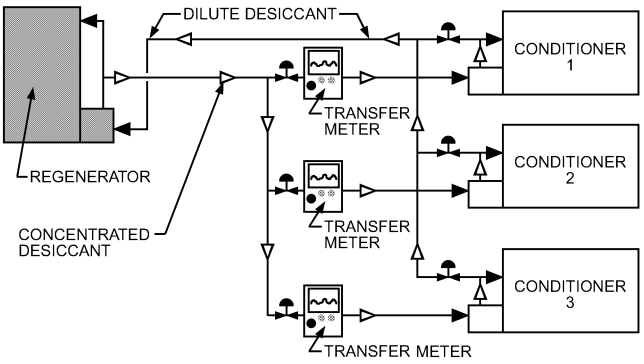

Fig. 11 Liquid Desiccant System with Multiple Conditioners

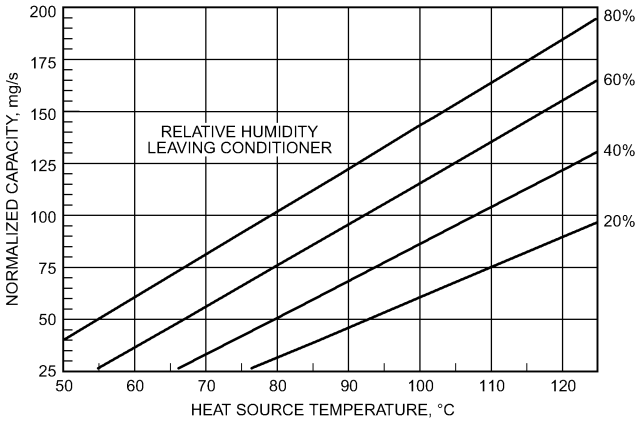

Fig. 12 Liquid Desiccant Regenerator Capacity

ously circulates the desiccant solution through a heat exchanger and distributes it over the packed bed contactor surface. The heat exchanger heats the desiccant solution with waste energy from the onboard compressor system or low-pressure steam or hot water (e.g., from a boiler, solar water heater, or waste heat source) so that the water vapor pressure of the desiccant used for regeneration is substantially higher than that of the outdoor air. Outdoor air is passed through the packing, and water evaporates into it from the desiccant solution, concentrating the solution. The hot, moist air from the regenerator is discharged to the outdoors. A sidestream of concentrated solution is transferred to the conditioner to replace the sidestream of weak solution transferred from the conditioner and completes the cycle.

The regenerator's water removal capacity is controlled to match the moisture load handled by the conditioner. This is accomplished by regulating heat flow to the regenerator heat exchanger to maintain a constant desiccant solution concentration. This is most commonly done by maintaining a constant solution level in the system with a level controller, but specific-gravity or boiling-point controllers are used under some circumstances. Regenerator heat input is regulated to match the instantaneous water removal requirements, so no heat input is required if there is no moisture load on the conditioner. When the conditioner is used to humidify the air, the regenerator fan and desiccant solution pump are typically stopped to save energy.

The conditioner and regenerator can be in a single housing or in separate housings. If in a single housing, the installation, electrical wiring, and equipment cost can be lower than a unit with separate housings. If separated, they can be in different locations and connected by piping; this approach can substantially lower ductwork cost and required mechanical space. Commonly, a single regenerator serves several conditioner units (Figure 11). In the simplest control arrangement, concentrated desiccant solution is metered to each conditioner at a fixed rate. The return flow of weak solution from each conditioner is regulated to maintain a constant operating level in the conditioner. A level controller on the regenerator regulates heat flow to the regenerator solution heater to maintain a constant volume of desiccant solution, and hence a practically constant solution concentration.

The regenerator can be sized to match the dehumidification load of the conditioner unit or units. Regenerator capacity is affected by regenerator heat source temperatures (higher source temperatures increase capacity) and by desiccant concentration (higher concentrations reduce capacity). The relative humidity of air leaving the conditioner is practically constant for a given desiccant concentration, so regenerator capacity can be shown as a function of delivered air relative humidity and regenerator heat source temperature. Figure 12 is a normalized graph showing this relationship. For a given moisture load, various regenerator heat sources may be used if the regenerator is sized for the heat source selected. In many cases, the greater capital cost of a larger regenerator is paid back very quickly by reduced operating cost when a lower-cost or waste-heat source (e.g., condenser heat, especially from the onboard refrigeration system; solar hot water; process or turbine tail stream; jacket heat from an engine-driven generator or compressor) is used.

2.2 SOLID-SORPTION EQUIPMENT

Solid desiccants, such as silica gel, zeolites (molecular sieves), activated alumina, or hygroscopic salts, are generally used to dehumidify large volumes of moist air, and are continuously reactivated. Solid desiccants can also be used in (1) nonreactivated, disposable packages and (2) periodically reactivated desiccant cartridges.

Disposable packages of solid desiccant are often sealed into packaging for consumer electronics, pharmaceutical tablets, and military supplies. Disposable desiccant packages rely entirely on vapor diffusion to dehumidify, because air is not forced through the desiccant. This method is used only in applications where there is no anticipated moisture load at all (such as hermetically sealed packages) because the moisture absorption capacity of any nonreactivated desiccant is rapidly exceeded if a continuous moisture load enters the dehumidified space. Disposable packages generally serve as a form of insurance against unexpected, short-term leaks in small, sealed packages.

Periodically reactivated cartridges of solid desiccant are used where the expected moisture load is continuous, but very small. A common example is the breather, a tank of desiccant through which air can pass, compensating for changes in liquid volume in petroleum storage tanks or drums of hygroscopic chemicals. Air dries as it passes through the desiccant, so moisture will not contaminate the stored product. When the desiccant is saturated, the cartridge is removed and heated in an oven to restore its moisture sorption capacity. Desiccant cartridges are used where there is no requirement for a constant humidity control level and where the moisture load is likely to exceed the capacity of a small, disposable package of desiccant.

Desiccant dehumidifiers for drying liquids and gases other than air often use a variation of this reactivation technique. Two or more pressurized containers of solid desiccant are arranged in parallel, and air is forced through one container for drying, while desiccant in the other container is reactivated. These units are often called dual-tower or twin-tower dehumidifiers.

Continuous reactivation dehumidifiers are the most common type used in high-moisture-load applications such as humidity control systems for buildings and industrial processes. In these units, humid process air is dehumidified in one part of the desiccant bed while a different part of the bed is dried for reuse by a second airstream (reactivation air). The desiccant generally rotates slowly between these two airstreams, so that dry, high-capacity desiccant leaving the reactivation air is always available to remove moisture

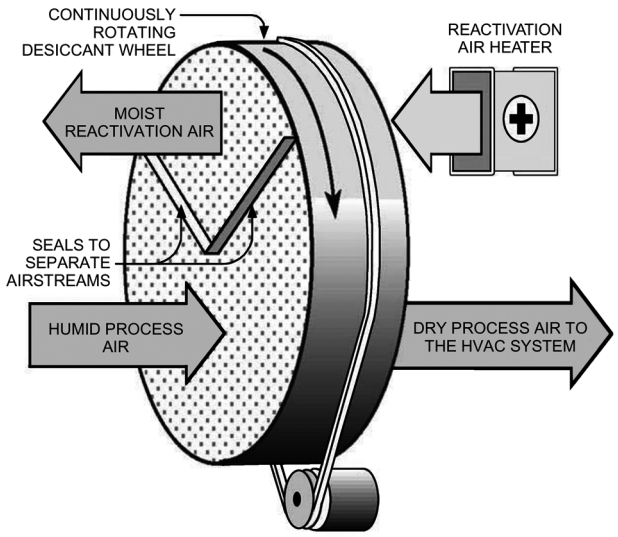

Fig. 13 Typical Rotary Dehumidification Wheel

from the process air. This type of equipment is generally called a rotary desiccant dehumidifier. It is most commonly used in building air-handling systems, and the section on Rotary Solid-Desiccant Dehumidifiers describes its function in greater detail.

2.3 ROTARY SOLID-DESICCANT DEHUMIDIFIERS

Operation

Figure 13 illustrates the principle of operation and arrangement of major components of a typical rotary solid-desiccant dehumidifier. The desiccant can be beads of granular material packed into a bed, or it can be finely divided and impregnated throughout a structured medium. The structured medium resembles corrugated cardboard rolled into a drum, so that air can pass freely through flutes aligned lengthwise through the drum.

In both granular and structured-medium units, the desiccant itself can be either a single material, such as silica gel, or a combination, such as silica gel blended with zeolites. The wide range of dehumidification applications requires flexibility in selecting desiccants to minimize operating and installed costs.

In rotary desiccant dehumidifiers, more than 20 variables can affect performance. In general, equipment manufacturers fix most of these to provide predictable performance in common applications for desiccant systems. Primary variables left to the system designer to define include the following for both process and reactivation air:

- Inlet air temperature
- Moisture content
- Velocity at face of the desiccant bed

In any system, these variables change because of weather, variations in moisture load, and fluctuations in reactivation energy levels. It is useful for the system designer to understand the effect of these normal variations on dehumidifier performance.

Figures 14 to 18 show changes in process air temperature and moisture leaving a generic rotary desiccant dehumidifier as modeled by a finite difference analysis program (Worek and Zheng 1991). Commercial unit performance differs from this model because such units are generally optimized for very deep drying. However, for illustration purposes, the model accurately reflects the relationships between the key variables.

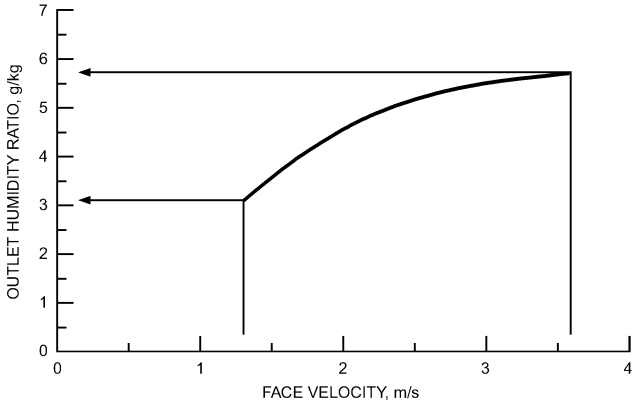

Fig. 14 Effect of Changes in Process Air Velocity on Dehumidifier Outlet Moisture

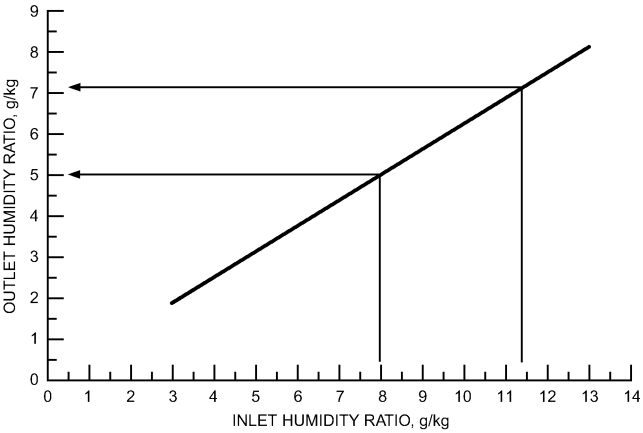

Fig. 15 Effect of Changes in Process Air Inlet Moisture on Dehumidifier Outlet Moisture

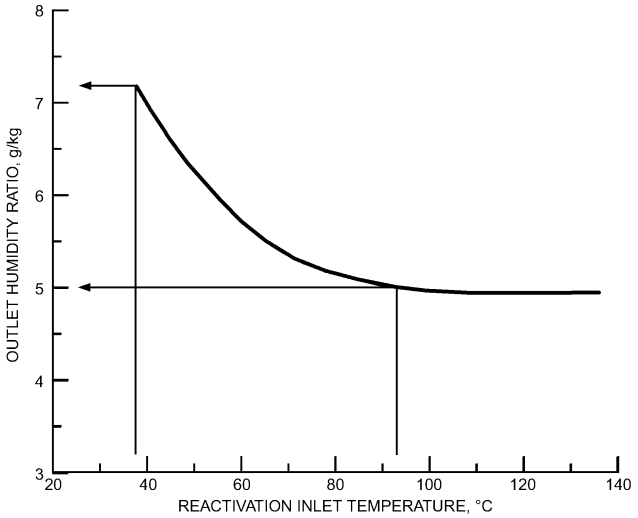

Fig. 16 Effect of Changes in Reactivation Air Inlet Temperature on Dehumidifier Outlet Moisture

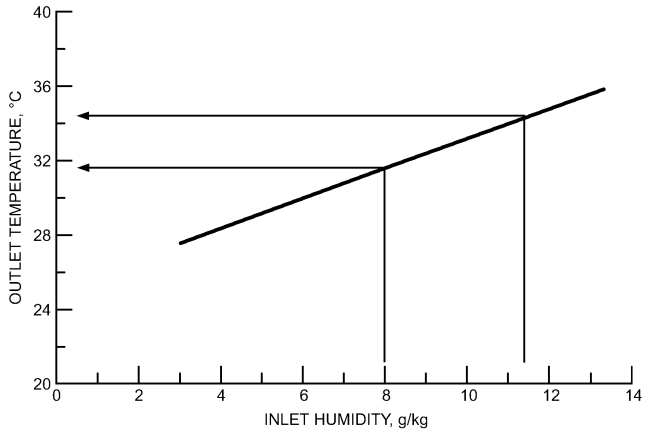

Fig. 17 Effect of Changes in Process Air Inlet Moisture on Dehumidifier Outlet Temperature

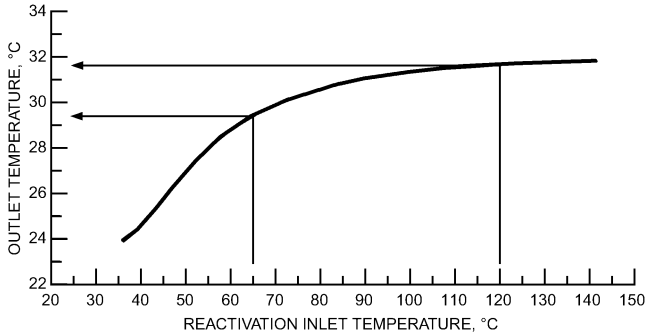

Fig. 18 Effect of Changes in Reactivation Air Inlet Temperature on Dehumidifier Outlet Temperature

The desiccant used for the model is silica gel; the bed is a structured, fluted medium; the bed depth is 400 mm in the direction of airflow; and the ratio of process air to reactivation air is approximately 3:1. **Process air velocity** through the desiccant bed strongly affects leaving moisture. As shown in Figure 14, if the entering moisture is 8.0 g/kg and all other variables are held constant, the outlet moisture varies from 3.1 g/kg at 1.3 m/s to 5.7 g/kg at 3.6 m/s. Thus, air that passes through the bed more slowly is dried more deeply. Therefore, if air must be dried very deeply, a large unit (slower air velocities) must be used.

Process air inlet moisture content affects outlet moisture: if air is more humid entering the dehumidifier, it will be more humid leaving the unit. For example, Figure 15 indicates that, for an inlet humidity of 8.0 g/kg, the outlet humidity is 5.0 g/kg. If inlet moisture content rises to 11.4 g/kg, the outlet humidity rises to 7.1 g/kg. Therefore, if constant outlet humidity is necessary, the dehumidifier needs capacity control unless the process inlet airstream does not vary in temperature or moisture throughout the year (a rare circumstance).

Reactivation air inlet temperature changes the outlet moisture content of the process air. From 38 to 120°C, as more heat is added to the reactivation air, the desiccant dries more completely, which means that it can attract more moisture from the process air (see Figure 16). If reactivation air is only heated to 38°C, process outlet moisture is 7.1 g/kg, or only 0.9 g/kg lower than the entering humidity. In contrast, if reactivation air is heated to 93°C, the outlet moisture is 5.0 g/kg, so that almost 40% of the original moisture is removed.

This relationship has two important consequences. If the design needs dry air, it is generally more economical to use high reactivation air temperatures. Conversely, if leaving humidity from the dehumidifier need not be especially low, inexpensive, low-grade heat sources (e.g., solar heat, waste heat, cogeneration heat, or rejected heat from refrigeration condensers) can be used to reactivate the desiccant.

Process air outlet temperature is higher than the inlet air temperature primarily because the heat of sorption of moisture removed from the air is converted to sensible heat. The heat of sorption includes the latent heat of condensation of the removed moisture, plus additional chemical heat, which varies depending on the desiccant type and process air outlet humidity. Also, some heat is carried over to the process air from the reactivation sector because the desiccant is warm as it enters the relatively cooler process air. Generally, 80 to 90% of the temperature rise of process air is from the heat of sorption, and the balance is from heat carried over from reactivation.

Process outlet temperature versus inlet humidity is shown in Figure 17. Note that as more moisture is removed (higher inlet humidity), outlet temperature rises. Air entering at room comfort conditions of 21°C, 8.0 g/kg leaves the dehumidifier at 31.7°C. If the dehumidifier removes more moisture, such as when the inlet humidity is 11.4 g/kg, outlet temperature rises to 34.4°C. The increase in temperature rise is roughly proportional to the increase in moisture removal.

Process outlet temperature versus reactivation air temperature is shown in Figure 18, which shows the effect of increasing reactivation temperature when the moisture content of the process inlet air stays constant. If the reactivation sector is heated to elevated temperatures, more moisture is removed on the process side, so the temperature rise from latent-to-sensible heat conversion is slightly greater. In this constant-moisture inlet situation, if the reactivation sector is very hot, more heat is carried from reactivation to process as the desiccant mass rotates from reactivation to process. Figure 18 shows that if reactivation air is heated to 65°C, the process air leaves the dehumidifier at 29.4°C. If reactivation air is heated to 120°C, the process air outlet temperature rises to 31.6°C. The 2.2 K increase in process air temperature is primarily caused by the increase in heat carried over from reactivation.

One consequence of this relationship is that desiccant equipment manufacturers constantly seek to minimize the "waste mass" in a desiccant dehumidifier, to avoid heating and cooling extra, nonfunctional material such as heavy desiccant support structures or extra desiccant that air cannot reach. Theoretically, the most efficient desiccant dehumidifier has an infinitely large effective desiccant surface combined with an infinitely low mass.

Use of Cooling

In process drying applications, desiccant dehumidifiers are sometimes used without additional cooling because the temperature increase from dehumidification helps the drying process. In semiprocess applications such as controlling frost formation in supermarkets, excess sensible cooling capacity may be present in the system as a whole, so warm air from a desiccant unit is not a major consideration. However, in most other applications for desiccant dehumidifiers, provision must be made to remove excess sensible heat from process air after dehumidification.

In a liquid-desiccant system, heat is removed by cooling the liquid desiccant itself, so process air emerges from the desiccant medium at the appropriate temperature. In a solid-desiccant system, cooling is accomplished downstream of the desiccant bed with cooling coils. The source of this cooling can affect the system's operating economics.

In some systems, postcooling is accomplished in two stages, with cooling tower water as the primary source followed by compression or absorption cooling. Alternatively, various combinations of indirect and direct evaporative cooling equipment are used to cool the dry air leaving the desiccant unit.

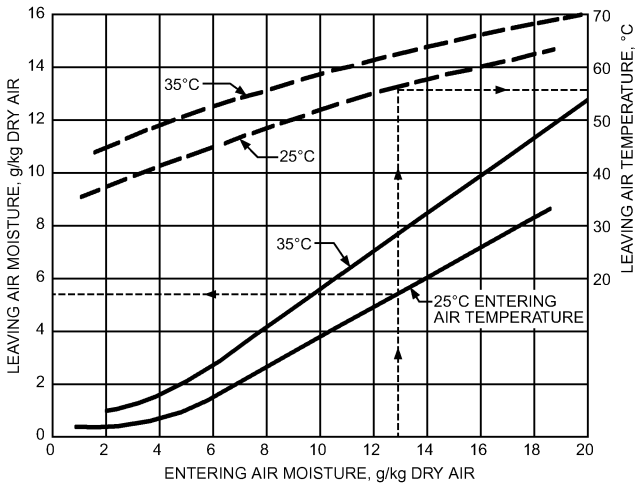

Fig. 19 Typical Performance Data for Rotary Solid Desiccant Dehumidifier

In systems where the latent and sensible loads peak at different times, the sensible cooling capacity of the basic air-conditioning system is sufficient to handle the process air temperature rise without additional equipment. Systems in moderate climates with high ventilation requirements often combine high latent loads in the morning, evening, and night with high sensible loads at midday, so desiccant subsystems to handle latent loads are especially economical.

Using Units in Series

Solid-desiccant dehumidifiers are often used to provide air at low dew points. Applications requiring large volumes of air at moisture contents of 0.7 g/kg (–18°C dew point) are quite common and can be easily achieved by rotary desiccant units in a single pass beginning with inlet moisture contents as high as 6.5 g/kg (7.5°C dew point). Some solid-desiccant units commonly deliver air at 0.3 g/kg (–28°C dew point) without special design considerations. Where extremely low dew points must be achieved, or where air leakage inside the unit may be a concern, two desiccant dehumidifiers can be placed in series, with dry air from one unit feeding both process and reactivation air to a second unit. The second unit delivers very dry air, because there is reduced risk of moisture being carried over from reactivation to process air when dry air is used to reactivate the second unit.

Industrial Rotary Desiccant Dehumidifier Performance

Figures 14 to 18 are based on the generalized model of a desiccant dehumidifier described by Worek and Zheng (1991). The model, however, differs somewhat from commercial products. Figure 19 shows typical performance of an industrial desiccant dehumidifier.

2.4 EQUIPMENT RATINGS

ASHRAE *Standard* 139 describes the parameters used in the desiccant industry to calculate desiccant dehumidifier performance:

- Moisture removal capacity (MRC)
- Regeneration specific heat input (RSHI)
- Process outlet temperature
- Pressure drop through the wheel

These performance parameters can be obtained from any manufacturer by means of performance curves or selection software. However, they are generally rated at sea-level conditions.

ASHRAE research project RP-1339 (Fumo and Mago 2011) investigated how the performance parameters are affected by altitude. The main objectives were to test a desiccant dehumidifier both at sea level and at altitude, and then to develop a general methodology that can be applied to any desiccant wheel to estimate performance at altitude. The test results showed that, by keeping process and regeneration mass flow rates, inlet temperature, and inlet humidity ratio constant between sea level and altitude, performance of a solid-desiccant dehumidifier at altitudes up to 1524 m is constant regardless of altitude, except for pressure drop through the desiccant wheel. Therefore, the MRC, RSHI, and process-out temperature obtained from the manufacturer's performance data at sea level do not require correction for altitude.

Note that, when air at altitude is near saturation, its humidity ratio can be above saturation at sea level. In this situation, determine the relative humidity of the air at altitude and use the same mass flow rate, temperature, and relative humidity with the manufacturer's sea-level performance data when determining MRC and process outlet temperature. The humidity ratio change (grain depression) used to calculate MRC will be the same at altitude and should be subtracted from the inlet humidity ratio at altitude to determine the exit condition.

The pressure drop through the wheel obtained from the manufacturer's performance data at sea level must be corrected by the ratio of atmospheric pressure at sea level and altitude using the density ratio methodology:

$$\Delta P_z = \frac{\rho_0}{\rho_z}\Delta P_0$$

or

$$\Delta P_z = \frac{1}{(1 - 2.25577 \times 10^{-5} Z)^{5.2559}}\Delta P_0$$

where

ΔP_z = wheel pressure drop at altitude, kPa
ΔP_0 = wheel pressure drop at sea level, kPa
ρ_z = moist air density at altitude, kg/m^3
ρ_0 = moist air density at sea level, kg/m^3
Z = elevation, m

The following example shows the method for rating desiccant equipment at altitude.

Example 1. Find the exit air humidity ratio and wheel pressure drop for a dehumidifier operating at Denver International Airport with process air precooled to 12.78°C and 98.0% rh.

Solution: Design inlet conditions are based on the 1% design conditions from Chapter 14 of the 2021 *ASHRAE Handbook—Fundamentals*.

Site altitude:	1655 m
Process flow rate	1359 m^3/h
Process inlet humidity ratio W_{pi}	11.08 g/kg
Regeneration flow rate	454 m^3/h
Regeneration inlet temperature	19.9°C (before heater)
Regeneration inlet humidity ratio W_{ri}	13.17 g/kg (73.5% rh)
Regeneration inlet temperature	120°C (after heater)

Convert humidity ratios at altitude to equivalent values at sea level.

Process airstream:	
Dry-bulb temperature:	12.78°C
Relative humidity	98%
Humidity ratio W_p	9.04 g/kg
Regeneration airstream:	
Dry-bulb temperature:	19.9°C
Relative humidity	73.8%
Humidity ratio W_r	10.75 g/kg

Obtain sea-level performance data from dehumidifier manufacturer using above psychrometric inputs.

Process airstream out:

Dry-bulb temperature:	36.5°C
Humidity ratio W_{po}	2.24 g/kg
Pressure drop	157 Pa

Regeneration airstream out:

Dry-bulb temperature:	48.9°C
Humidity ratio W_{ro}	31.06 g/kg
Pressure drop	214 Pa

Calculate humidity ratio change and MRC, where

$$\text{MRC} = \text{m}^3/\text{h} \times 0.0012 \times \Delta W_p = \text{kg/h}$$

$$\Delta W_p = 9.04 - 2.24 = 6.8 \text{ g/kg}$$

$$\Delta W_r = 31.06 - 10.75 = 20.31 \text{ g/kg}$$

$$\text{MRC} = 1360 \times 0.0012 \times 6.8 = 11.09 \text{ kg/h}$$

Restate outlet conditions for altitude.

$$W_{po,z} = W_{pi,z} - \Delta W_p = 11.08 - 6.8 = 4.27 \text{ g/kg}$$
$$W_{ro,z} = W_{ri,z} + \Delta W_r = 13.17 + 20.31 = 33.48 \text{ g/kg}$$
$$\text{MRC}_z = \text{MRC}_0 = 11.09 \text{ kg/h}$$

Restate wheel pressure drops for altitude.

$$\Delta P_{p,z} = \frac{1}{1 - 2.25577 \times 10^{-5}(1655)^{5.2559}}(157) = 192 \text{ Pa}$$

$$\Delta P_{r,z} = \frac{1}{1 - 2.25577 \times 10^{-5}(1655)^{5.2559}}(214) = 262 \text{ Pa}$$

2.5 EQUIPMENT OPERATING RECOMMENDATIONS

Desiccant equipment tends to be very durable if maintained properly, often operating at high efficiency 30 years after it was originally installed. Required maintenance is specific to the type of desiccant equipment, the application, and the installation. Each system requires a somewhat different maintenance and operational routine. The information in this section does not substitute for or supersede any recommendations of equipment manufacturers, and it is not a substitute for owners' experience with specific applications.

Process Air Filters

Clean filters are the most important item in a maintenance routine. If a solid desiccant is clogged with particulates, or if a liquid desiccant's sorption characteristics are changed by entrained particulates, the material may have to be replaced prematurely. Filters are much less expensive and much easier to change than the desiccant. Although each application is different, the desiccant usually must be replaced, replenished, or reconditioned after 5 to 10 years of operation. Without attention to filters, desiccant life can be reduced to 1 or 2 years of operation or less. Filters should be checked at least four times per year, and more frequently when airstreams are heavily laden with particulates. Differential pressure sensors across the filter bank to detect loading and alarm a building management system (BMS) may be an alternative to manual inspection.

The importance of filter maintenance requires that filter racks and doors on desiccant systems be freely accessible and that enough space be allowed to inspect, remove, and replace filters. Optimal design ensures that filter locations, as well as the current condition of each filter, are clearly visible to maintenance personnel.

Reactivation/Regeneration Filters

Air is filtered before entering the heater of a desiccant unit. If filters are clogged and airflow is reduced, unit performance may be reduced because there is not enough air to carry all the moisture away from the desiccant. If electrical elements or gas burners are used to heat the air, reducing airflow may damage the heaters. Thus, the previous suggestions for maintaining process air filters also apply to reactivation/regeneration filters.

Liquid-Phase Strainers

In liquid-desiccant systems, clean strainers are an important item in a maintenance routine. Depending on the atmospheric cleanliness and air-phase filtration used, strainers in both the process and regeneration desiccant systems require rinsing every 3 to 6 months.

Reactivation/Regeneration Ductwork

Air leaving the reactivation/regeneration section is hot and moist. When units first start up in high-moisture-load applications, the reactivation air may be nearly saturated and even contain water droplets. Thus, ductwork that carries air away from the unit should be corrosion resistant, because condensation can occur inside the ducts, particularly if the ducts pass through unheated areas in cool weather. If heavy condensation seems probable, the ductwork should be designed with drains at low points or arranged to let condensation flow out of the duct where the air is vented to the weather. The high temperature and moisture of the leaving air may make it necessary to use dedicated ductwork, rather than combining the air with other exhaust airflows, unless the other flows have similar characteristics.

Leakage

All desiccant units produce dry air in part of the system. If humid air leaks into either the dry air ductwork or the unit itself, system efficiency is reduced. Energy is also wasted if dry air leaks out of the distribution duct connections. Therefore, duct connections for desiccant systems should be sealed tightly. In applications requiring very low dew points (below –12°C), the ductwork and desiccant system are almost always tested for leaks at air pressures above those expected during normal operation. In applications at higher dew points, similar leak testing is considered good practice and is recommended by many equipment manufacturers.

Because desiccant equipment tends to be durably constructed, workers often drill holes in the dehumidifier unit casing to provide support for piping, ductwork, or instruments. Such holes eventually leak air, desiccant, or both. Designers should provide other means of support for external components so contractors do not puncture the system unnecessarily.

Contractors installing desiccant systems should be aware that any holes made in the system must be sealed tightly using both mechanical means and sealant compounds. Sealants must be selected for long life at the working temperatures of the application and of the casing walls that have been punctured. For example, reactivation/regeneration sections often operate in a range from a cold winter ambient of –40°C to a heated temperature as high as 150°C. Process sections may operate in a range of –40°C at the inlet to 65°C at the outlet.

Airflow Indication and Control

As explained in the section on Rotary Solid-Desiccant Dehumidifiers, performance depends on how quickly air passes through the desiccant; changes in air velocity affect performance. Thus, it is important to quantify the airflow rate through both the process and reactivation/regeneration parts of the unit. Unless both airflows are known, it is impossible to determine whether the unit is operating properly. In addition, if velocity exceeds the maximum design value, the air may carry desiccant particles or droplets out of the unit and into the supply air ductwork. Thus, manufacturers often provide airflow gages on larger equipment so the owner can be certain the unit is operating within the intended design parameters.

Smaller equipment is not always provided with airflow indicators because precise performance may be less critical in applications such as small storage rooms. However, in any system using large

equipment, or if performance is critical in smaller systems, unit airflow should be quantified and clearly indicated, so operating personnel can compare current flow rates through the system with design values.

Many desiccant units are equipped with manual or automatic flow control dampers to control the airflow rate. If these are not provided with the unit, they should be installed elsewhere in the system. Airflows for process and reactivation/regeneration must be correctly set after all ductwork and external components are attached, but before the system is put into use.

Commissioning

Heat and moisture on the dry-air side of desiccant equipment is balanced equally by the heat and moisture on the regeneration/reactivation side. To confirm that a solid-desiccant system is operating as designed, the commissioning technician must measure airflow, temperature, and moisture on each side to calculate a mass balance. In liquid systems, these six measurements are taken on the process-air side. On the regenerator side, the liquid temperature is read in the sump and at the spray head to confirm the regenerator's heat transfer rate at peak-load conditions.

If the dehumidification unit does not provide the means, the system should be designed to facilitate taking the readings that are essential to commissioning and troubleshooting. Provisions must be made to measure flow rates, temperatures, and moisture levels of airstreams as they enter and leave the desiccant. For liquid systems, provisions must be made for measuring the solution temperature and concentration at different points in the system. Four precautions for taking these readings at different points in a desiccant system follow.

Airflow. Airflow instruments measure the actual volumetric flow rate, which must be converted to standard flow rate to calculate mass flow. Because temperatures in a desiccant system are often well above or below standard temperature, these corrections are essential.

Air Temperature. Most airstreams in a desiccant system have temperatures between –20 and 150°C, but temperature can be widely varied and stratified as air leaves the desiccant in solid-desiccant systems. Air temperature readings must be averaged across the duct for accurate calculations. Readings taken after a fan tend to be more uniform, but corrections must be made for heat added by the fan itself.

Process Air Moisture Leaving Dry Desiccant. In solid-desiccant equipment, air leaving the desiccant bed or wheel is both warm and dry: usually below 20% rh, often below 10%, and occasionally below 2%. Most low-cost instruments have limited accuracy below 15% rh, and all but the most costly instruments have an error of ±2% rh. Consequently, to measure relative humidities near 2%, technicians use very accurate instruments such as manual dew cups or automated optical dew-point hygrometers. ASHRAE *Standard* 41.6 describes these instruments and procedures for their proper use. When circumstances do not allow the use of dew-point instruments, other methods may be necessary. For example, an air sample may need to be cooled to produce a higher, more easily measured relative humidity.

Low humidity readings can be difficult to take with wet-bulb thermometers because the wet wick dries out very quickly, sometimes before the true wet-bulb reading is reached. Also, when the wet-bulb temperature is below the freezing point of water, readings take much longer, which may allow the wick to dry out, particularly in solid-desiccant systems where there may be considerable heat in the air leaving the desiccant. Therefore, wicks must be monitored for wetness. Many technicians avoid wet-bulb readings in air leaving a solid-desiccant bed, partly for these reasons, and partly because of the difficulty and time required to obtain average readings across the whole bed.

Like air temperature, air moisture level leaving a solid-desiccant bed varies considerably; if taken close to the bed, readings must be averaged to obtain a true value for the whole air mass.

When very low dew points are expected, the commissioning technician should be especially aware of limitations of the air-sampling system and the sensor. Even the most accurate sensors require more time to come to equilibrium at low dew points than at moderate moisture levels. For example, at dew points below –30°C, the sensor and air sample tubing may take many hours rather than a few minutes to equilibrate with the air being measured. Time required to come to equilibrium also depends on how much moisture is on the sensor before it is placed into the dry airstream. For example, taking a reading in the reactivation/regeneration outlet essentially saturates the sensor, so it will take much longer than normal to equilibrate with the low relative humidity of the process leaving air.

Reactivation/Regeneration Air Moisture Leaving Desiccant. Air leaving the reactivation/regeneration side of the desiccant is warm and close to saturation. If the humidity measurement sensor is at ambient temperature, moisture may condense on its surface, distorting the reading. It is good practice to warm the sensor (e.g., by taking the moisture reading in the warm, dry air of the process-leaving airstream) before reading moisture in reactivation air. If a wet-bulb instrument is used, water for the wet bulb must be at or above the dry-bulb temperature of the air, or the instrument will read lower than the true wet-bulb temperature of the air.

Owners' and Operators' Perspectives

Designers and new owners are strongly advised to consult other equipment owners and the manufacturer's service department early in design to gain the useful perspective of direct operating experience (Harriman 2003).

2.6 APPLICATIONS FOR ATMOSPHERIC-PRESSURE DEHUMIDIFICATION

Preservation of Materials in Storage

Special moisture-sensitive materials are sometimes kept in dehumidified warehouses for long-term storage. Tests by the Bureau of Supplies and Accounts of the U.S. Navy (DOD 1987, 2004) concluded that 40% rh is a safe level to control deterioration of materials. Others (Sterling et al. 1985) have indicated that 60% rh is low enough to control microbiological attack. With storage at 40% rh, no undesirable effects on metals or rubber compounds have been noted. Some organic materials such as sisal, hemp, and paper may lose flexibility and strength, but they recover these characteristics when moisture is regained.

Commercial storage relies on similar equipment for applications that include beer fermentation rooms, meat storage, and penicillin processing, as well as storage of machine tools, candy, food products, furs, furniture, seeds, paper stock, and chemicals. For recommended conditions of temperature and humidity, refer to Chapters 21 and 28 to 42 of the 2021 *ASHRAE Handbook—Refrigeration*.

Process Dehumidification

Requirements for dehumidification in industrial processes are many and varied. Some of these processes are as follows:

- Metallurgical processes, with controlled-atmosphere annealing of metals
- Conveying hygroscopic materials
- Film drying
- Manufacturing candy, chocolate, and chewing gum
- Manufacturing drugs and chemicals
- Manufacturing plastic materials
- Manufacturing laminated glass
- Packaging moisture-sensitive products

- Assembling motors and transformers
- Solid propellant mixing
- Manufacturing electronic components, such as transistors and microwave components
- Processing poultry and other meats
- Processing food and other powders

For information about the effect of low-dew-point air on drying, refer to Chapters 20, 22, 25, and 30 of the 2023 *ASHRAE Handbook—HVAC Applications*.

Ventilation Air Dehumidification

Over a full year, ventilation air loads a cooling system with much more moisture than heat. Except in desert and high-altitude regions, ventilation moisture loads in the United States exceed sensible loads by at least 3:1, and often by as much as 5:1 (Harriman et al. 1997). Consequently, desiccant systems are used to dehumidify ventilation air before it enters the main air-conditioning system.

Drying ventilation air has gained importance because building codes mandate larger amounts of ventilation air than in the past, in an effort to improve indoor air quality. Large amounts of humid ventilation air carry enough moisture to upset the operation of high-efficiency cooling equipment, which is generally designed to remove more sensible heat than moisture (Kosar et al. 1998). Removing excess moisture from the ventilation air with a ventilation dehumidification system improves both humidity control and cooling system effectiveness. For example, field tests suggest that when the environment is kept dry, occupants prefer warmer temperatures, which in turn saves cooling operational costs (Fischer and Bayer 2003). Also, cooling equipment is often oversized to remove ventilation-generated moisture. Predrying with a desiccant system may reduce the building's construction cost, if excess cooling capacity is removed from the design (Spears and Judge 1997).

Figures 20, 21, and 22 show the relative importance of moisture load from ventilation, how a commercial building can use a desiccant system to remove that load, and how such a system is applied in the field (Harriman et al. 2001).

Ventilation dehumidification is most cost effective for buildings with high ventilation airflow rather than high sensible loads from internal heat or from heat transmitted through the building envelope. As a result, this approach is most common in densely occupied buildings such as schools, theaters, elder care facilities, large-scale retail buildings, and restaurants (Harriman 2003).

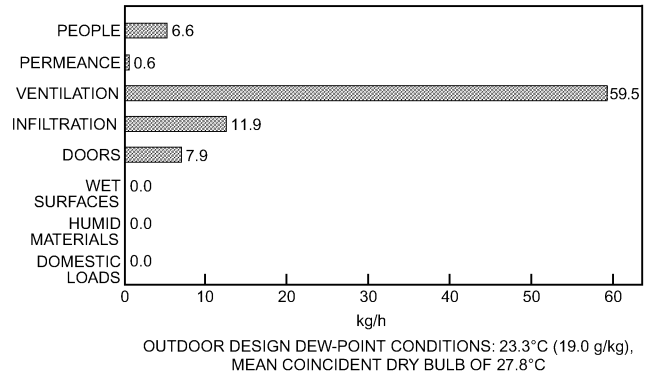

Fig. 20 Typical Peak Moisture Loads for Medium-Sized Retail Store in Atlanta, Georgia

(Harriman et al. 2001)

Condensation Prevention

Many applications require moisture control to prevent condensation. Airborne moisture condenses on cold cargo in a ship's hold when it reaches a moist climate. Moisture condenses on a ship when the moist air in its cargo hold is cooled by the hull and deck plates as the ship passes from a warm to a cold climate.

A similar problem occurs when aircraft descend from high, cold altitudes into a high dew point at ground level. Desiccant dehumidifiers are used to prevent condensation inside the airframe and avionics that leads to structural corrosion and failure of electronic components.

In pumping stations and sewage lift stations, moisture condenses on piping, especially in the spring when the weather warms and water in the pipes is still cold. Dehumidification is also used to prevent airborne moisture from dripping into oil and gasoline tanks and open fermentation tanks.

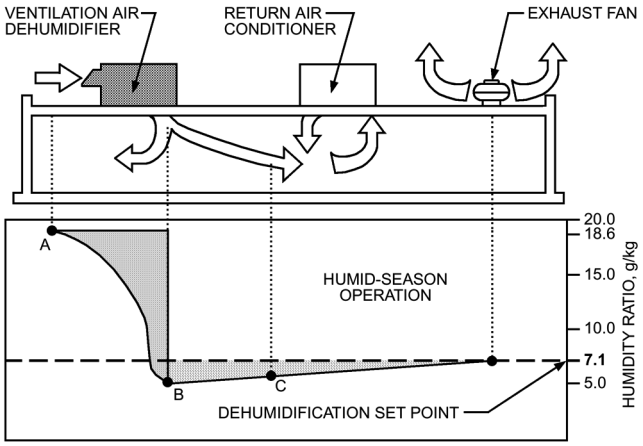
Electronic equipment is often cooled by refrigeration, and dehumidifiers are required to prevent internal condensation of moisture. Electronic and instrument compartments in missiles are purged with low-dew-point air before launching to prevent malfunctioning caused by condensation.

Waveguides and radomes are also usually dehumidified, as are telephone exchanges and relay stations. For proper operation of their components, missile and radar sites depend largely on prevention of condensation on interior surfaces.

Dry Air-Conditioning Systems

Cooling-based air-conditioning systems remove moisture from air by condensing it onto cooling coils, producing saturated air at a lower absolute moisture content. In many circumstances, however, there is a benefit to using a desiccant dehumidifier to remove the latent load from the system, avoiding problems caused by condensation, frost, and high relative humidity in air distribution systems.

For example, low-temperature product display cases in supermarkets operate less efficiently when humidity in the store is high because condensate freezes on the cooling coils, increasing operating cost. Desiccant dehumidifiers remove moisture from the air, using rejected heat from refrigeration condensers to reduce the cost of desiccant reactivation. Combining desiccants and conventional



A. OUTDOOR AIR
Hot and humid in summertime, it must be cooled and dehumidified.

B. VENTILATION DEHUMIDIFIER
Dries incoming air to a condition below the desired humidity set point.

C. DRY VENTILATION AIR
Removes moisture loads generated inside building.

Fig. 21 Predrying Ventilation Air to Dehumidify a Commercial Building

(Harriman et al. 2003)

cooling can lower installation and operating costs (Calton 1985). For information on the effect of humidity on refrigerated display cases, see Chapter 15 of the 2022 *ASHRAE Handbook—Refrigeration* and Chapter 2 of the 2023 *ASHRAE Handbook—HVAC Applications*.

Air conditioning in hospitals, nursing homes, and other medical facilities is particularly sensitive to biological contamination in condensate drain pans, filters, and porous insulation inside ductwork. These systems often benefit from drying ventilation air with a desiccant dehumidifier before final cooling. Condensate does not form on cooling coils or drain pans, and filters and duct lining stay dry so that mold and mildew cannot grow inside the system. Refer to ASHRAE *Standard* 62.1 for guidance concerning maximum relative humidity in air distribution systems. Chapter 8 of the 2023 *ASHRAE Handbook—HVAC Applications* has information on ventilation of health care facilities.

Hotels and large condominium buildings historically suffer from severe mold and mildew problems caused by excessive moisture in the building structure. Desiccant dehumidifiers are sometimes used to dry ventilation air so it can act as a sponge to remove moisture from walls, ceilings, and furnishings (AHMA 1991). Dehumidified ventilation air that positively pressurizes the building may help counter moist air infiltration. See Chapter 6 of the 2023 *ASHRAE Handbook—HVAC Applications* for more information on ventilating hotels and similar structures.

Like supermarkets, ice rinks have large exposed cold surfaces that condense and freeze moisture in the air, particularly during spring and summer. Desiccant dehumidifiers remove excess humidity from air above the rink surface, preventing fog and improving both the ice surface and operating economics of the refrigeration plant. For recommended temperature and humidity for ice rinks, see Chapter 44 of the 2022 *ASHRAE Handbook—Refrigeration*.

Indoor Air Quality Contaminant Control

Desiccant sorption is not restricted to water vapor. Both liquid and solid desiccants collect both water and large organic molecules at the same time (Hines et al. 1993). As a result, desiccant systems can be used to remove volatile organic compound (VOC) emissions from building air systems.

In addition to preventing growth of mold, mildew, and bacteria by keeping buildings dry, desiccant systems can supplement filters to remove bacteria from the air itself. This is particularly useful for hospitals, medical facilities, and related biomedical manufacturing facilities where airborne microorganisms can cause costly problems. The usefulness of certain liquid and solid desiccants in such systems stems from their ability to either kill microorganisms or avoid sustaining their growth (Battelle 1971; SUNY Buffalo School of Medicine 1988).

Testing

Many test procedures require dehumidification with sorption equipment. Frequently, other means of dehumidification may be used with sorbent units, but the low moisture content required can be obtained only by liquid or solid sorbents. Some typical testing applications are as follows:

- Wind tunnels
- Spectroscopy rooms
- Paper and textile testing
- Bacteriological and plant growth rooms
- Dry boxes
- Environmental rooms and chambers

3. DESICCANT DRYING AT ELEVATED PRESSURE

The same sorption principles that pertain to atmospheric dehumidification apply to drying high-pressure air and process or other gases. The sorbents described previously can be used with equal effectiveness.

3.1 EQUIPMENT TYPES

Absorption

Solid absorption systems use a calcium chloride desiccant, generally in a single-tower unit that requires periodic replacement of the desiccant that is dissolved by the absorbed moisture. Normally, inlet air or gas temperature does not exceed 32 to 38°C saturated. The rate of desiccant replacement is proportional to the moisture in the inlet process flow. A dew-point depression of 10 to 20 K at pressure can be obtained when the system is operated in the range of 15 to 38°C saturated entering temperature and 700 kPa (gage) operating pressure. At lower pressures, the ability to remove moisture decreases in proportion to absolute pressure. Such units do not require a power source for operation because the desiccant is not regenerated. However, additional desiccant must be added to the system periodically.

Adsorption

Drying with an adsorptive desiccant such as silica gel, activated alumina, or a molecular sieve usually incorporates regeneration equipment, so the desiccant can be reactivated and reused. These desiccants can be readily reactivated by heat, purging with dry gas, or both. Depending on the desiccant selected, dew-point performance expected is in the range of –40 to –75°C measured at the operating pressure with inlet conditions of 32 to 38°C saturated and 700 kPa (gage). Figure 23 shows typical performance using activated alumina or silica gel desiccant.

Equipment design may vary considerably in detail, but most basic adsorption units use twin-tower construction for continuous operation, with an internal or external heat source, with air or process gas as the reactivation purge for liberating moisture adsorbed previously. A single adsorbent bed may be used for intermittent drying requirements. Adsorption units are generally constructed in the same manner as atmospheric-pressure units, except that the vessels are suitable for the operating pressure. Units have been operated successfully at pressures as high as 40 MPa.

Prior compression or cooling (by water, brine, or refrigeration) to below the dew point of the gas to be dried reduces the total moisture load on the sorbent, permitting the use of smaller drying units. The cost of compression, cooling, or both must be balanced against the cost of a larger adsorption unit.

The many different dryer designs can be grouped into the following basic types:

Heat-reactivated, purge dryers. Normally operating on 4 h (or longer) adsorption periods, these dryers are generally designed with heaters embedded in the desiccant. They use a small portion of dried process gas as a purge to remove the moisture liberated during reactivation heating (see Figure 24).

Heatless dryers. These dryers operate on a short adsorption period (usually 60 to 300 s). Depressurizing gas in the desiccant tower lowers the vapor pressure, so adsorbed moisture is liberated from the desiccant and removed by a high purge rate of the dried process gas. Using an ejector reduces the purge gas requirements.

Convection dryers. These dryers usually operate on 4 h (or longer) adsorption periods and are designed with an external heater and cooler as the reactivation system. Some designs circulate reactivation process gas through the system by a blower; others divert some or all of the process gas flow through the reactivation system before adsorption. Both heating and cooling are by convection.

Radiation dryers. Also operating on 4 h (or longer) adsorption periods, radiation dryers are designed with an external heater and blower to force heated atmospheric air through the desiccant tower for reactivation. Desiccant tower cooling is by radiation to atmosphere.

3.2 APPLICATIONS

Material Preservation

Generally, materials in storage are preserved at atmospheric pressure, but a few materials are stored at elevated pressures, especially when the dried medium is an inert gas. These materials deteriorate when subjected to high relative humidity or oxygen content in the surrounding medium. Drying high-pressure air, subsequently reduced to 24 to 70 kPa (gage), has been used most effectively in pressurizing coaxial cables to eliminate electrical shorts caused by moisture infiltration. This same principle, at somewhat lower pressures, is also used in waveguides and radomes to prevent moisture film on the envelope.

Process Drying of Air and Other Gases

Drying instrument air to a dew point of –40°C, particularly where air lines are outdoors or exposed to temperatures below the dew point of air leaving the aftercooler, prevents condensation or freeze-up in instrument control lines.

To prevent condensation and freezing, it is necessary to dry plant air used for pneumatically operated valves, tools, and other equipment where piping is exposed to low ambient temperatures. Additionally, dry air prevents rusting of the air lines, which produces abrasive impurities, causing excessive wear on tools.

Industrial gases or fuels such as natural gas are dried. For example, fuels (including natural gas) are cleaned and dried before stor-

age underground to ensure that valves and transmission lines do not freeze from condensed moisture during extraordinarily cold weather, when the gas is most needed. Propane must also be clean and dry to prevent ice accumulation. Other gases, such as bottled oxygen, nitrogen, hydrogen, and acetylene, must have a high degree of dryness. In liquid oxygen and ozone manufacturing, air supplied to the process must be clean and dry.

Drying air or inert gas for conveying hygroscopic materials in a liquid or solid state ensures continuous, trouble-free plant operation. Normally, gases for this purpose are dried to a –40°C dew point. Purging and blanketing operations in the petrochemical industry depend on using dry inert gas for reducing problems such as explosive hazards and the reaction of chemicals with moisture or oxygen.

Equipment Testing

Dry, high-pressure air is used extensively for testing refrigeration condensing units to ensure tightness of components and to prevent moisture infiltration. Similarly, dry inert gas is used in testing copper tubing and coils to prevent corrosion or oxidation. Manufacture and assembly of solid-state circuits and other electronic components require exclusion of all moisture, and final testing in dry boxes must be carried out in moisture-free atmospheres. Simulation of dry high-altitude atmospheres for testing aircraft and missile components in wind tunnels requires extremely low dew-point conditions.

CHAPTER 25

MECHANICAL DEHUMIDIFIERS AND RELATED COMPONENTS

Mechanical Dehumidifiers 25.1
Controls and Sensors 25.10
Installation and Service Considerations 25.11
Wraparound Heat Exchangers 25.11

THE correct moisture level in the air is important for health and comfort. Controlling humidity and condensation is important to prevent moisture damage and mold or mildew development, thus protecting buildings and occupants, and preserving building contents. This chapter covers mechanical dehumidification using a cooling process only, including basic dehumidifier models (with moisture removal capacity of less than 1.4 kg/h) used for home basements and small storage areas, as well as larger sizes required for commercial applications.

Most mechanical dehumidifiers are used in applications where dew points of 7°C and above are maintained. Specialized mechanical dehumidification equipment may achieve as low as a 2°C dew point at a lower moisture removal rate. For applications requiring low dew points and for other methods of dehumidification, see Chapter 24.

Commercial applications for mechanical dehumidifiers include the following:

- Dedicated outdoor air systems
- Controlled environment agriculture
- Indoor swimming pools
- Makeup air treatment
- Ice rinks
- Dry storage
- Schools
- Hospitals
- Office buildings
- Museums, libraries, and archives
- Restaurants
- Hotels and motels
- Assisted living facilities
- Supermarkets
- Manufacturing plants and processes
- Water making
- Industrial drying

In addition, an air-to-air heat exchanger (e.g., heat pipe, coil runaround loop, fixed-plate heat exchanger, rotary heat exchanger) may be used to enhance moisture removal by a mechanical dehumidifier or air conditioner. The section on wraparound heat exchangers discusses how dehumidification processes can be improved by using such a device. Other uses of air-to-air heat exchangers are covered in Chapter 26.

1. MECHANICAL DEHUMIDIFIERS

Mechanical dehumidifiers remove moisture by passing air over a surface that has been cooled below the air's dew point. This cold surface may be the exterior of a chilled-water coil or a direct-expansion refrigerant coil. To prevent overcooling the space (and avoid the need to add heat energy from another source), a mechanical dehumidifier also usually has means to reheat the air, normally using recovered and recycled energy (e.g., recovering heat from hot refrigerant vapor in the refrigeration circuit) or, in the case of a chilled-water dehumidifying system, using wrap around heat exchangers to absorb heat energy from incoming air then passively transferring it around the cooling coil into the leaving air). Using external energy input for reheat is wasteful and is prohibited or limited in many countries (see ASHRAE *Standard* 90.1).

A mechanical dehumidifier differs from a typical off-the-shelf air conditioner in that the dehumidifier usually has a much lower sensible heat ratio (SHR). The dehumidifier starts the compressor on a call for dehumidification, whereas an air conditioner starts the compressor on a call for sensible cooling. Typically, a room dehumidifier has an SHR of 0.6 or less, compared to a standard air-conditioning system of 0.8 SHR. Dehumidifiers must also allow condensation from the cooling coil to drain easily from the coils. They may need air velocities over the cooling coil lower than those for a typical air conditioner, to improve moisture runoff and minimize carryover of condensed moisture.

In addition, the need to introduce code-mandated ventilation air may require that outdoor air be treated to avoid introducing excessive moisture. Basic strategies include precooling outdoor air entering the air-conditioning evaporator coil, or providing a separate system to provide properly conditioned outdoor air. For some low-dew-point (below 7°C) applications, mechanical dehumidification may be used as the first stage, with desiccant dehumidification for the final stage to maximize efficiency and minimize installed cost.

Although the main purpose of a mechanical dehumidifier is to remove moisture from the air, many features can be incorporated for various applications, such as

- Dehumidifying and cooling (no reheat)
- Dehumidifying with partial reheat (leaving dry-bulb temperature is cooler than with a dehumidifier with full reheat)
- Dehumidifying with full reheat
- Dehumidifying with heat recovery to various heat sinks
- Dehumidification capacity modulation
- Reheat capacity modulation
- Ventilation air introduction
- Auxiliary space or water heating

Often, mechanical dehumidifiers can be incorporated in a system to use waste heat from mechanical cooling (e.g., heat rejection to a swimming pool, whirlpool, domestic hot water, heat pump loop, chilled-water loop, or remote air-cooled condenser).

Outdoor dehumidifiers should be protected against internal moisture condensation when winter conditions are severe, because of the higher dew-point temperature of air circulating in the unit.

Psychrometrics of Dehumidification

Figures 1 and 2 show the process of air moving over the dehumidifying coil and being reheated. Many manufacturers size the dehumidifying coil for only part of the unit total airflow. This allows them to introduce outdoor air after the dehumidifying coil and allows more unit airflow for the condenser reheat coil to maintain

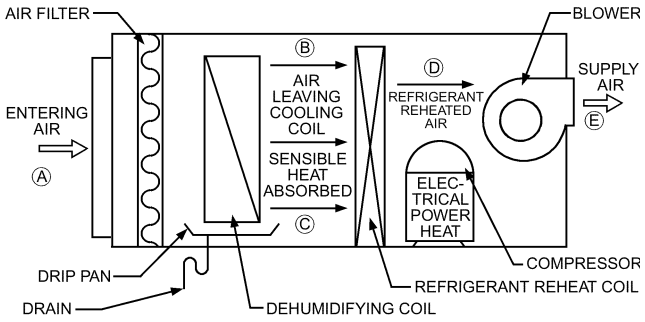

Fig. 1 Dehumidification Process Points

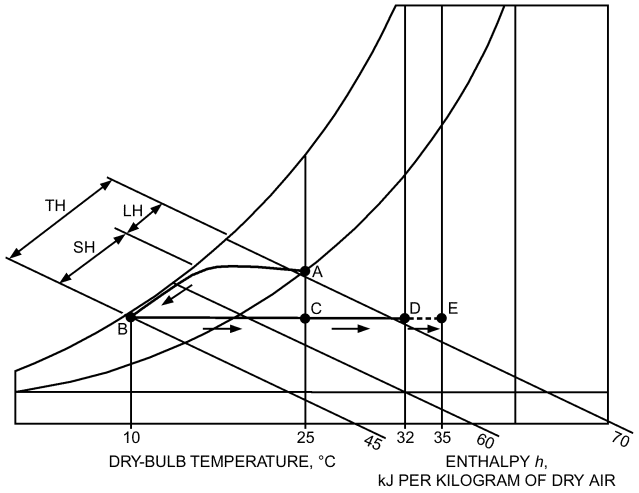

Fig. 2 Psychrometric Diagram of Typical Dehumidification Process

proper system refrigeration pressures when rejecting refrigerant heat to the airstream. Figures 3 and 4 show a bypass air process.

In Figures 1 and 2, air enters the dehumidifying coil at point A. The dehumidifying coil removes sensible heat (SH) and latent heat (LH) from the airstream. The dehumidified, cooled air leaves the coil at its saturation temperature at point B. The total heat removed (TH) is the net cooling capacity of the system.

In reheating, the refrigerant (hot gas) rejects heat it has obtained from multiple sources. Sensible heat absorbed in the air-cooling process is rejected to air leaving the cooling coil. This air is at point C, which is the same dry-bulb temperature as the entering air minus the moisture content. This heat is also rejected into the airstream, raising the air temperature to point D. Also, nearly all electric power required to drive the refrigeration cycle is converted to heat. This portion of heat rejection raises the air leaving temperature to point E.

This process assumes that all heat is rejected by the refrigerant reheat coil. Depending on refrigerant system complexity, any part of the total heat rejection can be diverted to other heat exchangers (condensers/desuperheaters).

Dehumidifier supply air temperatures can be controlled between 10 and 35°C. However, system design should not rely on a mechanical dehumidifier as a dependable heat source for space heating, because heat is only available when the unit is operating.

In Figures 3 and 4, air enters the dehumidifying coil at point A. The dehumidifying coil removes sensible heat (SH) and latent heat (LH) from the airstream. The dehumidified, cooled air leaves the coil at its saturation temperature at point B. The total heat removed (TH) is the net cooling capacity of the system.

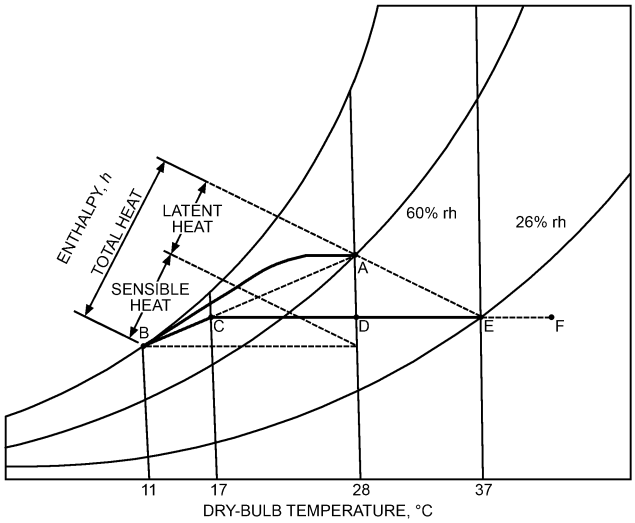

Fig. 3 Psychrometric Diagram of Typical Dehumidification Process with Bypass Air

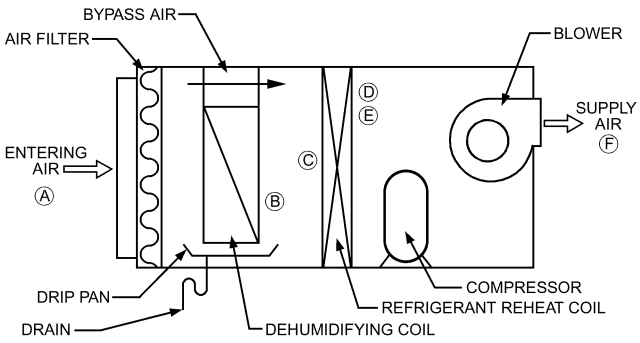

Fig. 4 Dehumidification Process Points with Bypass Air

In Figure 3, the air at B mixes with the bypass air to get to point C. In reheating, the refrigerant (hot gas) rejects heat it has obtained from three sources. First, sensible heat absorbed in the air-cooling process is rejected to air leaving the cooling coil. This air is at point D, which is the same dry-bulb temperature as the entering air minus the moisture content. Next, the latent heat removal that causes the moisture to condense also adds heat to the hot refrigerant gas. This heat is also rejected into the airstream, raising the air temperature to point E. Finally, nearly all electric power required to drive the refrigeration cycle is converted to heat. This portion of heat rejection raises the air's leaving temperature to point F.

This process assumes that all heat is rejected by the refrigerant reheat coil. Depending on refrigerant system complexity, any part of the total heat rejection can be diverted to other heat exchangers (condensers/desuperheaters).

Dehumidifier supply air temperatures can be controlled between 18 and 40°C. However, system design should not rely on a mechanical dehumidifier as a dependable heat source for space heating, because heat is only available when the unit is operating.

Residential Dehumidifiers

Portable Dehumidifiers. These are smaller (usually less than 3.5 kW), simpler versions of commercial dehumidifiers. They are self-contained and easily movable. They are designed to be used in localized areas, such as basements or other high-moisture areas.

As shown in Figure 5, a single fan draws humid room air through the cold coil, removing moisture that either drains into the water receptacle or passes through the cabinet into some other means of disposal. The cooled air passes through the condenser, reheating the air.

Portable dehumidifiers ordinarily maintain satisfactory humidity levels in an enclosed space when the airflow rate and unit placement move the entire air volume of the space through the dehumidifier once an hour.

Design and Construction. Portable dehumidifiers use hermetic motor-compressors; the refrigerant condenser is usually conventional finned tube. Refrigerant flow is usually controlled by a capillary tube, although some high-capacity dehumidifiers use an expansion valve. A propeller fan moves air through the unit at typical airflows of 70 to 120 L/s.

The refrigerated surface (evaporator) is usually a bare-tube coil, although finned-tube coils can be used if they are spaced to allow rapid runoff of water droplets. Vertically disposed bare-tube coils tend to collect smaller drops of water, promote quicker runoff, and result in less condensate reevaporation compared to finned-tube or horizontally arranged bare-tube coils. Continuous bare-tube coils, wound in a flat circular spiral (sometimes with two coil layers) and mounted with the flat dimension of the coil in the vertical plane, are a good design compromise because they have most of the advantages of the vertical bare-tube coil.

Evaporators are protected against corrosion by finishes such as waxing, painting, or anodizing (on aluminum). Waxing reduces the wetting effect that promotes condensate formation; however, tests on waxed versus nonwaxed evaporator surfaces show negligible loss of capacity. Thin paint films do not have an appreciable effect on capacity.

Removable water receptacles, provided with most dehumidifiers, hold 7.5 to 11 L and are usually made of plastic to withstand corrosion. Easy removal and handling without spillage are important. Most dehumidifiers also provide either a means of attaching a flexible hose to the water receptacle or a fitting provided specially for that purpose, allowing direct gravity drainage to another means of disposal external to the cabinet.

An adjustable humidistat (30 to 80%) automatically cycles the unit to maintain a preselected relative humidity. The humidistat may also provide a detent setting for continuous operation. Some models also include a sensing and switching device that automatically turns the unit off when the water receptacle is full.

Dehumidifiers are designed to provide optimum performance at standard rating conditions of 27°C db room temperature and 60% rh. When the room is less than 18°C db and 60% rh, the evaporator may freeze. This effect is especially noticeable on units with a capillary tube.

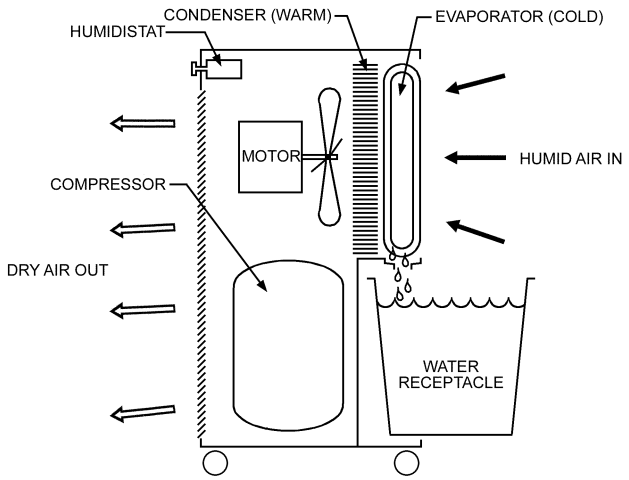

Fig. 5 Typical Portable Dehumidifier

Some dehumidifiers are equipped with defrost controls that cycle the compressor off under frosting conditions. This control is generally a bimetal thermostat attached to the evaporator tubing, allowing dehumidification to continue at a reduced rate when frosting conditions exist. The humidistat can sometimes be adjusted to a higher relative humidity setting, which reduces the number and duration of running cycles and allows satisfactory operation at low-load conditions. Often, especially in the late fall and early spring, supplemental heat must be provided from other sources to maintain above-frosting temperatures in the space.

Capacity and Performance Rating. Portable dehumidifiers are available with moisture removal capacities of 5 to 30 L per 24 h, and are operable from ordinary household electrical outlets (115 or 230 V, single-phase, 60 Hz). Input varies from 200 to 800 W, depending on the output capacity rating.

AHAM *Standard* DH-1 establishes a uniform procedure for determining the rated capacity of dehumidifiers under specified test conditions and establishes other recommended performance characteristics. An industry certification program sponsored by AHAM covers the great majority of portable dehumidifiers and certifies dehumidification capacity.

The U.S. Environmental Protection Agency (EPA) qualifies dehumidifiers to carry its ENERGY STAR® label if they remove the same amount of moisture as similarly sized standard units, but use at least 10% less energy. The EPA's ENERGY STAR website provides additional information on qualifying products (EPA 2020).

Whole-House Dehumidifiers. Whole-house dehumidifiers have higher moisture removal capacity than portable dehumidifiers. Blowers in whole-house dehumidifiers are typically more powerful because they draw air through the unit at higher external static pressures as compared to portable dehumidifiers. The design allows for connection of ductwork to the unit's inlet and outlet. Moist air is typically drawn from either the return plenum of the HVAC system ductwork (Figure 6) or from a centrally located register. The air is dehumidified and then discharged into the supply ductwork of the HVAC system for distribution. To prevent reevaporation of moisture from the HVAC system evaporator coil, the dry air enters the system downstream of the coil.

Whole-house dehumidifiers typically integrate controls to allow operation of the HVAC system blower while dehumidifying the air; this allows the dry air to be distributed throughout the home. Some dehumidifiers are equipped with controls to bring in outdoor air, which can then be run through the dehumidifier before being distributed to the rest of the home. Sensors are typically located inside the dehumidifier to measure the temperature and relative humidity of air passing through the unit as opposed to the surrounding air. Controls on some models may provide for installation of a remote humidistat or humidity sensor. Drain tubing must typically be installed on the dehumidifier and routed to the nearest floor drain. Most models include an internal condensate overflow switch or provide for the installation of a field-installed overflow switch that will turn the unit off if it overflows.

Units are typically sheltered from the elements and should not be installed in locations that can experience freezing temperatures. Whole-house dehumidifiers are typically located near the HVAC system for convenient access to the supply and return plenums and to drains. Systems may be installed in basements, closets, crawlspaces, or attics, so dehumidifier cabinets are typically insulated. When units are installed over a finished area, drain pans are commonly installed under the unit.

Codes. Domestic dehumidifiers are designed to meet the safety requirements of UL *Standard* 474, *Canadian Electrical Code*, and ASHRAE *Standard* 15. UL-listed and CSA-approved equipment have a label or data plate indicating approval. UL also publishes the

Electrical Appliance and Utilization Equipment Directory, which covers this type of appliance.

General-Purpose Dehumidifiers

Basic components of general-purpose dehumidifiers are shown in Figure 7. An air filter is required to protect the evaporator. Dehumidifying coils, because of their depth and thoroughly wetted surfaces, are excellent dust collectors and not as easily cleanable as much thinner air-conditioning evaporator coils. However, the large amount of condensate has a self-cleaning effect. A bypass damper at the evaporator coil allows airflow adjustments for the evaporator without decreasing airflow for the reheat coil. Dehumidifying and reheat coils may operate at different airflows.

The compressor may be isolated from the airstream or located in it. Locating the compressor in the airstream may make service more difficult, but this arrangement allows heat lost through the compressor casing to be provided to the conditioned space while reducing the size of the enclosure. During the cooling season, this compressor location reduces the unit's sensible cooling capacity.

Code-required outdoor air may be introduced between the evaporator and reheat coil. The amount of outdoor air should be controlled to not adversely affect the refrigeration system's operation.

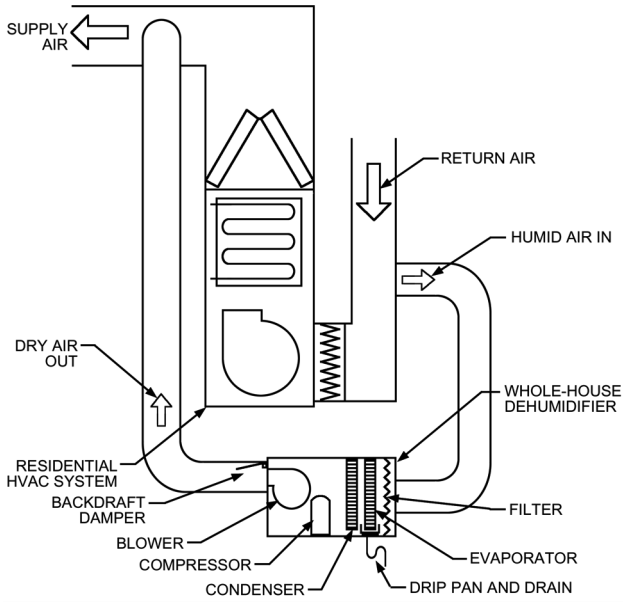

Fig. 6 Typical Whole-House Dehumidifier Installation

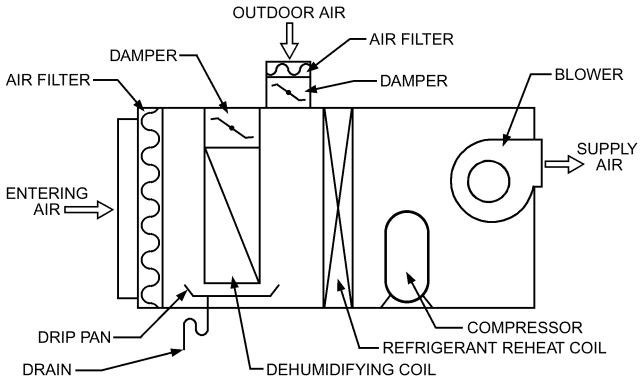

Fig. 7 Typical General-Purpose Dehumidifier

Preheating outdoor air may be required in colder climates. Use caution when introducing outdoor air before the evaporator coil. Some applications (e.g., indoor swimming pools) have a constant moisture load year round. The dehumidifier's performance is based on the conditions of the air moving across the evaporator coil. Mixing outdoor air with space return air before the evaporator coil changes the dehumidifier's performance to latent removal, which may be less than the space load and result in the inability to maintain the original design conditions. The unit's latent capacity can be significantly reduced when outdoor air is introduced before the evaporator coil.

Computerized controls can sense return air temperature and relative humidity. Remote wall-mounted sensors are also available. More sophisticated controls are desirable to regulate dew-point temperature and maintain the desired relative humidity in the space.

General Considerations. Before considering installation of any type of dehumidification equipment, all latent loads should be identified and quantified. In many cases, this might lead to decisions that reduce the latent load. For example, a storage facility that does not have an adequate vapor retarder in the building envelope should be retrofitted before attempting to calculate the amount of moisture migration through the structure. The same approach should be taken to reduce the amount of uncontrolled air infiltration.

Consider covering large water surfaces, such as vats, and/or providing a local exhaust hood to evacuate concentrated water vapor from where it is generated. Although these corrections seem to add cost to a project, the resulting reduced size of the dehumidifier and its lower operating cost often result in an attractive financial payback.

Other special considerations include the following:

- **High volumes of outdoor air.** A project may start out as suitable for a general-purpose dehumidifier. However, once outdoor air requirements are quantified to compensate for exhaust and to pressurize the facility, a general-purpose dehumidifier may no longer be applicable. The maximum acceptable portion of outdoor air for general-purpose dehumidifiers is limited, and depends on climatic conditions and the desired indoor conditions to be maintained. As a general rule, when outdoor air requirements exceed 20% of the dehumidifier's total airflow, the manufacturer should be consulted to determine whether the equipment is suitable for the application. In many cases, a direct-exchange (DX) dedicated outdoor air system unit should be considered instead.
- **Low-return-air-temperature applications.** When the return air temperature is below 18°C, consult the dehumidifier manufacturer to determine whether the equipment is suitable for the application. Recognize that defrost control might be required.

DX Dedicated Outdoor Air System (DOAS) Units

A **DX dedicated outdoor air system (DX-DOAS)** unit is used to separately condition outdoor air brought into the building for ventilation or to replace air that is being exhausted. (As such, select a DX-DOAS unit based on its latent dehumidification capacity, not necessarily on its total air-conditioning capacity.) This conditioned outdoor air is then delivered either directly to each occupied space, to small HVAC units located in or near the space, or to a central air handler serving the spaces. Meanwhile, the local or central HVAC equipment is used to maintain space temperature. Treating outdoor air separately from recirculated return air makes it more straightforward to verify sufficient ventilation airflow and enables humidity control in the occupied spaces. Decoupling the latent load from the sensible using a DX-DOAS can make both the dehumidifier and sensible cooling equipment more efficient.

DX-DOAS units use a vapor compression refrigeration cycle as part of the system to cool the air below its dew point and condense the moisture on a dehumidifying coil.

AHRI *Standard* 921 establishes requirements for the testing and rating of moisture removal capacity and moisture removal effi-

ciency of DX-DOAS units. ASHRAE *Standard* 198 prescribes test methods for rating DX-DOAS units.

DX-DOAS units may require simultaneous heat rejection to the reheat coil and/or another condenser (air- or water-cooled), because it may not always be possible or warranted in the application to reject the total heat of rejection from the dehumidifying coil to the conditioned airstream. A rainproof air intake and cooling capacity modulation (or staging) are important. With constantly changing weather conditions, even throughout the day, compressor capacity must be adjusted to prevent coil freeze-ups. Basic components are shown in Figure 8.

Auxiliary heating may be required for year-round operation in some climates. Water- and steam-heating coils should have freeze protection features. When using indirect-fired gas heaters, the combustion chamber should be resistant to condensation.

DX-DOAS units may be interfaced with a building automation system (BAS) to control the unit's on/off status and operating mode, because most spaces do not require continuous ventilation or replacement air. Air exhaust systems must also be synchronized with the DX-DOAS unit to maintain proper building pressurization.

The inclusion of exhaust air energy recovery within DX-DOAS units provides the opportunity to transfer energy between the two airstreams. A typical arrangement is shown in Figure 9.

For more information on DOAS, see Chapter 51.

Indoor Swimming Pool Dehumidifiers

Indoor pools (natatoriums) are an efficient application for mechanical dehumidifiers. Humidity control is required 24 h a day, year-round. Dehumidifiers are available as single- and double-blower units (see Figures 10 to 13). AHRI *Standard* 911 establishes requirements for testing and rating moisture removal capacity and moisture removal efficiency of indoor pool dehumidifiers. ASHRAE *Standard* 190 prescribes test methods for rating these units.

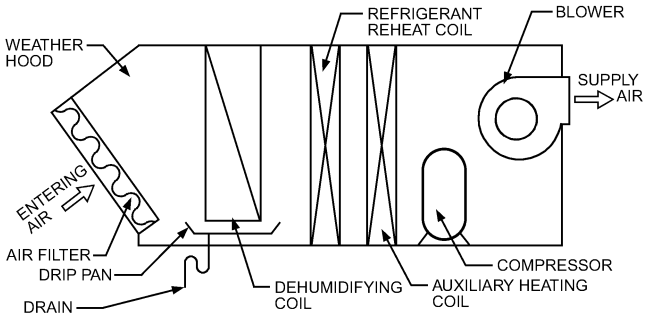

Fig. 8 DX-DOAS Unit

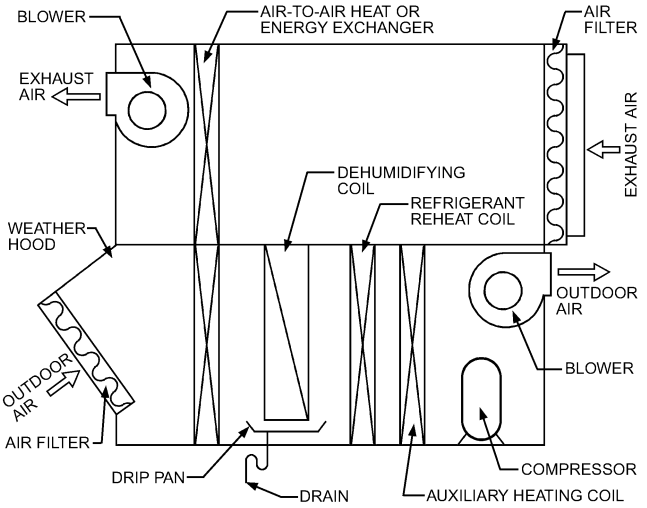

Fig. 9 DX-DOAS Unit with Exhaust Air Heat/Energy

The latent heat (LH) from dehumidification (see Figure 2) comes nearly exclusively from pool water (excluding humidity from makeup air and latent heat from large spectator areas). Loss of evaporation heat cools the pool water. By returning evaporation heat losses to the pool water, the sensible heat between points C and D of Figure 2 is not rejected into the supply air, which can reduce supply air temperature by approximately 8 K. ASHRAE *Standard* 90.1 requires that heated pools be provided with a vapor-retardant pool cover unless 60% of their energy for heating is site recovered. Use of compressor waste heat for pool water heating may satisfy this requirement.

Energy Considerations. The pool water temperature, space temperature, and relative humidity conditions maintained at a facility directly affect occupant comfort, dehumidifier size, and operating costs. It is important that the design engineer understand the effects of changes to these conditions to properly establish realistic operating conditions for a given project. Operating temperatures can change dramatically, depending on the type of pool being designed. See Table 2 in Chapter 6 of the 2023 *ASHRAE Handbook—HVAC Applications* for additional information.

The peak dehumidification load and peak energy conditions may not be concurrent in a natatorium. The peak dehumidification load generally occurs on a summer design day where the latent load from ventilation air is at its peak. The peak energy condition often is in the winter, when cold, dry ventilation air is a significant heating load and dehumidification credit to the space. In addition to extra heating costs, introducing more outdoor air than required by code in winter increases operating costs by driving space relative humidity levels down. This increases pool water evaporation and, consequently, pool water heating, makeup water, and pool chemical costs. Low humidity levels also increase bather discomfort through the evaporation effect across the surface of bathers' skin, causing a chilling effect on leaving the pool.

Fan energy can be a significant portion of the total energy consumed by a natatorium dehumidifier because the supply air fan operates constantly and delivers relatively high amounts of air.

Many dehumidifiers have exhaust fans to maintain the natatorium at a negative pressure. This exhaust air is energy rich, and heat recovery should be considered. Dehumidifiers are available with heat recovery such as heat pipes, glycol-runaround loops, compressorized heat pumps, and plate heat exchangers that transfer heat from the energy-rich exhaust air to cold incoming ventilation air (see Chapter 26).

Condensation. Note that the space dew point in most pools is above 17°C. Even when space conditions are properly maintained, there is still a significantly higher chance, compared to traditional conditioned spaces, that condensation might occur in the space or within the HVAC system. Condensation is possible in winter or summer.

Most codes have adopted ASHRAE *Standard* 62.1 to determine the amount of outdoor air required for acceptable indoor air quality. Introducing outdoor air that is cooler than the room dew-point temperature could lead to condensation. This is especially important in areas that experience cold winters. If condensation might occur, preheating the outdoor air is required.

Most dehumidifiers have a cooling mode. The units are generally designed to ensure supply air to the space is warmer than the space dew point. When adding additional cooling capacity to a dehumidifier, summer condensation is a concern if supply air could be cooled below the dew point of either the outdoor air or the space.

Designers are encouraged to verify that all necessary measures to avoid condensation have been taken, especially when modifying or customizing standard products from manufacturers. Discharge air must always be supplied at a temperature higher than the room dew-point temperature. Similarly, blended airstreams must not be allowed to result in temperatures cooler than the space dew point.

Single-blower pool dehumidifiers (Figure 10) are similar to general-purpose dehumidifiers (see Figure 4), with the following exceptions:

- Recovered heat from the refrigeration circuit can be used to provide heating to one or more pools or for domestic water preheat.
- All components in the airstream must be corrosion-resistant to chloramine-laden air. Electrical panels must be fully isolated from the chloramine-laden airstream.
- The pool water heater must be resistant to chlorinated water.
- Cross-contamination prevention features in the pool water heater are not required, but should be considered to prevent introducing refrigerant oil to the pool water if a breach occurred.
- Polyol ester (POE) refrigerant oil will damage polyvinyl chloride (PVC) piping.

Figure 11 shows a double-blower pool dehumidifier with economizer dampers and a full-sized return fan located upstream of the evaporator coil. This configuration can provide up to 100% makeup air to maintain humidity levels, which can be attractive when the outdoor dew point is below the required indoor dew point during mild weather, or in climates when enough hours of dry- and wet-bulb conditions are below the level to be maintained. Preheating outdoor air may be required to prevent condensation inside the mixing box. Also, this configuration does not recover energy from the warm, moist exhaust air. During dehumidifying coil operation, the amount of makeup and exhaust air is limited by outdoor conditions, especially during the heating season. Cold makeup air may lower the mixed-air temperature to the point where the dehumidifying coil cannot extract any moisture. Be careful during economizer operation to not introduce more outdoor air than required by code, so as not to lower the space humidity below design levels, as discussed in the section on Energy Considerations.

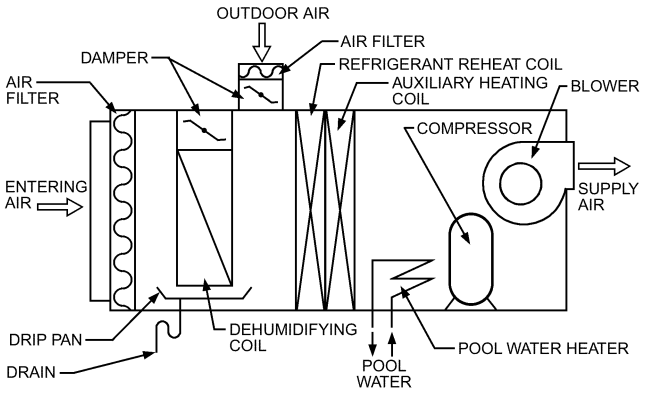

Fig. 10 Typical Single-Blower Pool Dehumidifier

In some regions, it is economically attractive to remove moisture from the exhaust air to recover its latent heat. In this case, the dehumidifying coil is installed in the return air section. Figure 12 shows a double-blower pool dehumidifier with economizer dampers and return fan located downstream of the evaporator coil. A damper system can also be incorporated to exhaust before the evaporator coil during colder conditions and after the evaporator during warmer conditions. This configuration recovers energy from the warm, moist exhaust air; however, exhausting air from downstream of the evaporator coil also reduces the unit's sensible capacity by the amount of the exhaust air. The ratio of return air to exhaust air must be considered to determine the unit's capacity to remove moisture from the conditioned space.

Figure 13 shows a different unit configuration that addresses concerns related to blower energy use during the various operating modes. This unit can operate with the supply blower only, or with the addition of one or two exhaust blowers.

Most manufacturers also offer some means of air-to-air heat recovery between the exhaust and makeup airstreams (see Chapter 26). During cold weather, this arrangement preheats entering makeup air with heat recovered from the exhaust airstream. Latent heat recovery may not be practical, however, because it transfers moisture to the entering air, thus possibly increasing dehumidification requirements.

Control systems should be compatible with building automation systems; however, the BAS must not disable dehumidifier operation because indoor pools always need some dehumidification, regardless of occupancy, and require specialized control sequences.

General Considerations. The primary function of an indoor swimming pool dehumidifier is to maintain the space dew-point temperature at the design level year round and to provide adequate air circulation to comply with minimum air change rates.

For more information on indoor swimming pool (natatorium) applications, see Chapter 6 of the 2023 *ASHRAE Handbook—HVAC Applications*.

Types of Equipment. Indoor swimming pool dehumidifiers are available in single- and double-blower configurations (see Figures 10 to 13). Heat from the refrigeration circuit can be (1) used to reheat supply air, (2) used to heat pool water, or (3) rejected to the

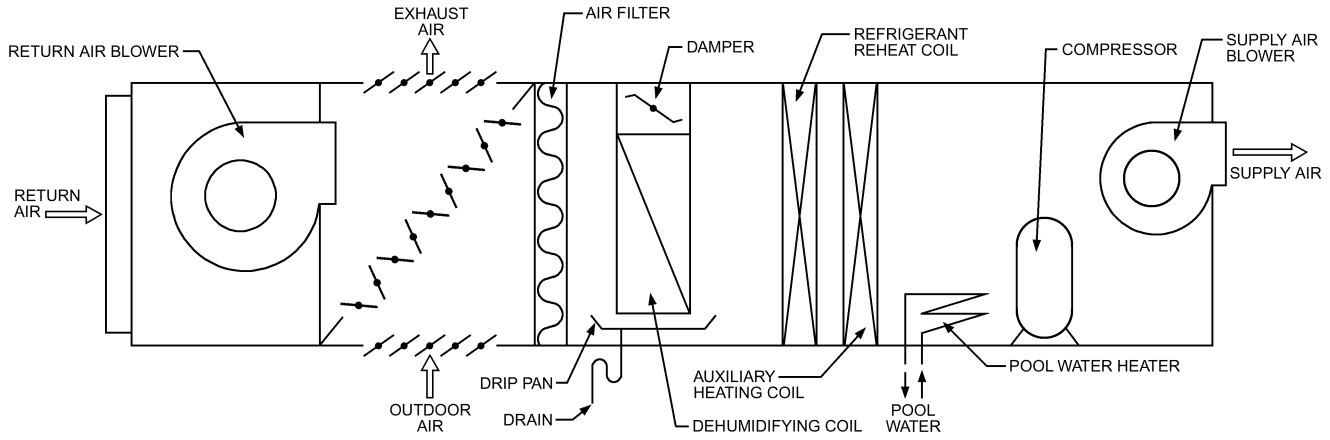

Fig. 11 Typical Double-Blower Pool Dehumidifier with DX Coil in Supply Air Section

outdoors by an optional air- or water-cooled condenser. Equipment configurations are available to use the heat for any combination of these three purposes.

The equipment can be located indoors or outdoors, and may be manufactured as a single package or as a split system with a remote condenser. Avoiding remote condensers with long refrigerant lines reduces refrigerant charge. Indoor, air-cooled condensers are typically equipped with a blower-type fan suitable for duct connections. An optional economizer allows for introduction of up to 100% of outdoor air (turning off the compressors) when conditions are appropriate.

When selecting a dehumidifier for an indoor swimming pool application, several questions need to be addressed to ensure that the dehumidifier can maintain the space conditions:

- In what mode of operation is the dehumidifier rated?
- Does the rating include ventilation air, and what effect, if any, does it have on dehumidifier performance?
- Does the unit include exhaust air, and what effect, if any, does it have on dehumidifier performance?
- Does the cost of running a second fan offset the energy saved by the economizer?
- Will the dehumidifier maintain the desired space conditions during all modes of operation?

Ice Rink Dehumidifiers

Design for ice rink dehumidifiers is similar to that of general-purpose dehumidifiers (see Figure 4). However, because of the lower temperatures, airflow and dehumidifying and reheat coils are selected in accordance with the following conditions:

- The dehumidifying coil may or may not have an air bypass, depending on the location of makeup air intake and/or coil selection.
- The dehumidifying coil may have means to defrost or to prevent frost formation.
- Makeup air treatment is limited.

For large spectator areas, special makeup air dehumidifiers may be required.

General Considerations. For community ice rinks with small spectator areas (or none), it is customary to install two small dehumidifiers over the dasher boards in a diagonal arrangement, 3.7 to 4.6 m above the ice surface (Figure 14). Take care that discharge air from dehumidifiers is not directed toward the ice surface. Forced airflow at any temperature may damage the ice surface. Ice rinks with large spectator areas have different requirements.

The spectator area is typically maintained at 21°C. To limit moisture migration to the ice sheet, space conditions must be maintained at 50% rh or less. The resulting dew-point temperature is then 10°C or less. The air temperature over the ice sheet in the dasher boards, however, is approximately 3 K lower than the air in the spectator area. With an air temperature of 18°C and a dew-point temperature

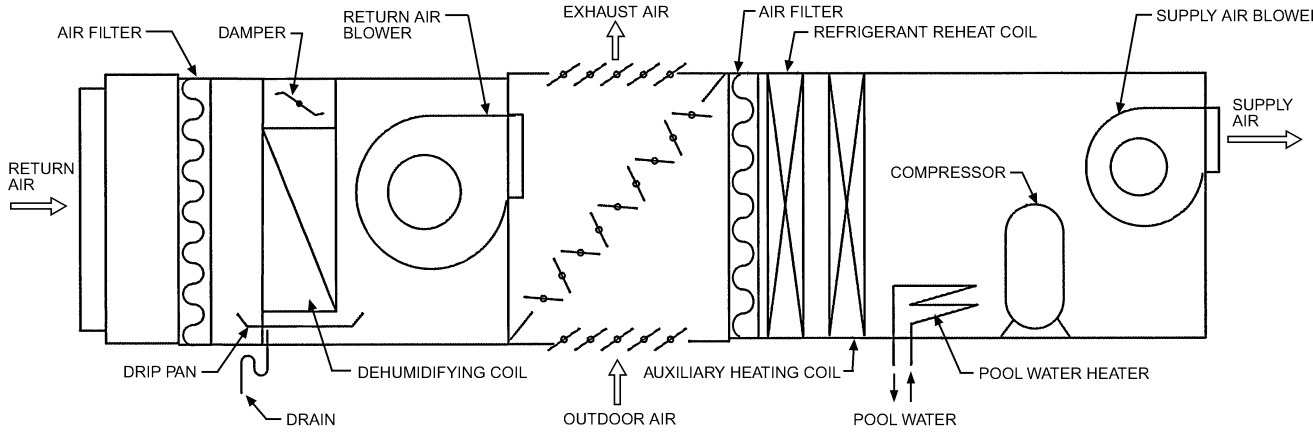

Fig. 12 Typical Double-Blower Pool Dehumidifier with DX Coil in Return Air Section

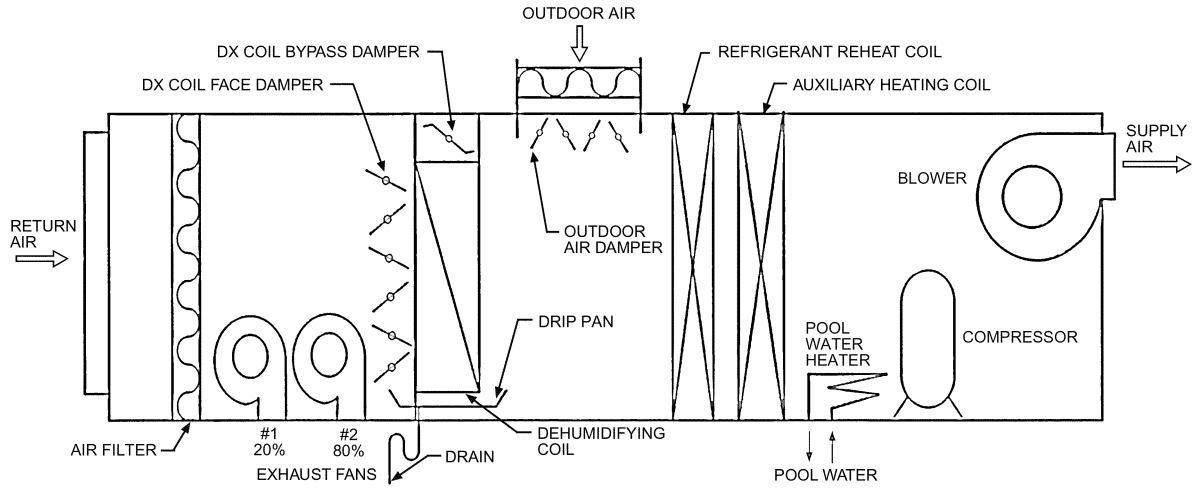

Fig. 13 Supply Blower and Double Exhaust Blower Pool Dehumidifier

of 10°C or less, fog over the ice sheet cannot develop. As a general rule, mechanical ice rink dehumidifiers are most effective for condensation and fog control when dry-bulb space temperature is at least 8 K above the dew point. For additional fog and condensation prevention methods, see Chapter 44 of the 2022 *ASHRAE Handbook—Refrigeration*.

Industrial Dehumidifiers

Industrial products and surfaces can sweat, causing corrosion, dimensional distortions, and other deterioration from excess humidity in the air. In some cases, this humidity is caused by leakage or infiltration; in other cases, it may be from indoor storage or processes. Normal air conditioning is not always adequate to control excess humidity, leading to material or structural damages and cool but damp working conditions. Industrial dehumidifiers use direct-expansion refrigeration coils to remove moisture and thus lower the supply air dew point to

- Prevent undesirable condensing or sweating on products and surfaces
- Improve product/process quality
- Help reduce building repair and maintenance costs
- Provide a comfortably dry working environment (max. 60% rh)
- Minimize biological pollutants such as mold spores

Some mechanical dehumidifiers may also contribute to space heating and/or cooling, recover heat energy for processes, and/or recover water for allowable purposes.

Sources of Humidity. Indoor air quality is affected by several key factors, which vary in importance depending on the location of the building and on the activity for which a building is designed. Relative humidity is usually a critical air quality factor, with high indoor relative humidity resulting from the following sources of moisture:

- Increased quantities of humid outdoor air brought in to improve air quality
- Openings, infiltration and permeation
- Moisture produced by occupants
- Moisture released by products or processes

Moisture migrates from areas of high vapor pressure to areas of low vapor pressure. In the summer, when the outdoor air is warm and humid, moisture can find a path to the interior of a cooler or drier structure. This could be from openings in the building such as doors, infiltration through cracks and poorly sealed joints, or permeation in the case of low-quality or nonexistent vapor retarders. In many instances, the primary source of humidity is from outdoor air purposely brought into the structure to meet air quality standards, or to replace air being exhausted because of contamination.

Occupants contribute to the moisture load through respiration and perspiration; amounts depend on the number of people and their activities. A worker involved in heavy lifting can generate seven times the moisture of a co-worker seated at rest. In agricultural or laboratory structures, animals also produce a moisture load.

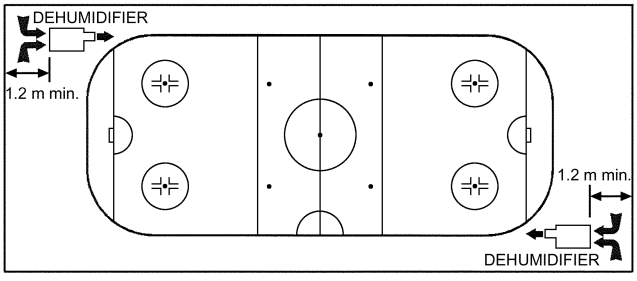

Fig. 14 Typical Installation of Ice Rink Dehumidifiers

Indoor materials or processes may give off moisture. Storing or cooking fruits, vegetables, or other foodstuffs may release moisture indoors. The presence of open tanks of water or the storing or handling of wet materials, such as wood, may also release moisture indoors.

Moisture dissolved in indoor air will condense onto any surface that is at a temperature lower than the room air's dew-point temperature. This can lead to quality and productivity problems or even to damage to the building and plant equipment. Rust and corrosion can affect metal surfaces, electrical controls and contacts, etc., which can lead to increased costs and even to potentially hazardous conditions.

For typical conditions (temperatures and relative humidities) of industrial applications, see Table 1 of Chapter 15 of the 2023 *ASHRAE Handbook—HVAC Applications*.

Dehumidifiers for Controlled Environment Agriculture (CEA)

If the main conditioning system is not selected to handle the high dehumidification load of a grow or drying space, the engineer may use a combination of a primary cooling air-handling system combined with in-room or ducted dehumidifiers to support the main cooling system for the water load in these rooms. Dehumidifiers for controlled environment agriculture share many of the characteristics of general-purpose dehumidifiers (see Figures 4 and 7), but may have a few additional design considerations because of the specialized nature of their application:

- Dehumidifiers can be the primary total environmental control or used in conjunction with a primary cooling system.
  - Care must be taken in the engineering calculations of load to ensure that the combined systems can address the loads for the entire duration of the plant's life cycle, day and night, and all associated transition periods.
  - The watering rate can vary widely between growing recipes; a thorough discussion with the grower must be had to understand the water and lighting loads for each stage of life of the plant when that plant enters and leaves that room.
  - The capacity of dehumidifiers is typically reported on a litres-per-day rate. Careful consideration of the calculations should be undertaken for the hourly water removal rate, calculated at the actual room conditions at the time and additional sensible heat component added by the dehumidification units.
- Air distribution is of critical importance in grow rooms, especially when using unitary dehumidification units with ducted primary conditioning systems. Dehumidification outlets provide warm or hot very dry air, and if that air is directed at the plants in either grow rooms or drying rooms, the plants will realize localized microclimates.
  - In a grow room, this causes these plants to dry out more quickly. In some cases this will cause these plants to grow faster than the rest of the room, eventually running short of water, exposing them to risk of failure. Should the grower increase the amount of watering, then the balance of plants will be exposed to overwatering, and cause failure as well.
  - In drying rooms, product can be damaged from drying too quickly or by over-drying causing damage to the plant material and decreasing product quality.
- Dehumidifiers for growing rooms in CEA are typically much larger than general-purpose or portable dehumidifiers, with 240 to 2300 L/day (10 to 90 kg/h) capacities
  - Great care must be taken with respect to placement with the maintenance of these units in mind. The larger dehumidification systems can weigh hundreds of kilograms and require gantries or trolleys to move when they require replacement.

  - Dehumidifiers of this type are still under severe duty loading and will have abbreviated service lives when compared to dehumidifiers in more conventional applications. As such, maintenance access and ease of unit "swapping" is crucial to the successful future operation of these systems.
  - Keep in mind that replacement of units is preferable upon component failure to reduce the downtime impact on the rooms and keep the rooms clear of debris associated with maintenance activities.
- Use an evaporator bypass damper, variable airflow rate, and/or defrost cycle to ensure operation during cooler lights-off or end-of-grow-cycle conditions, which can be as low as 18°C at 40% rh (4°C dp).
  - Careful consideration must be made with regard to the derating of the capacity of the dehumidifiers in reduced temperature environments, such as nighttime use and more prevalently drying room use.
  - Dry rooms may have significant initial water vapor loading for the first two days of the dry period to reach 50% weight goals to reduce the potential propagation of molds within the harvested materials.
  - The transition from day to night in a grow room is the largest water removal rate ratio, effectively a negative sensible heat ratio where the combined HVAC system should only be dehumidifying and warming the room with basically neutral air. This period is generally more than 30 min and less than an hour, depending upon the size of plants. This period, if not properly addressed, exposes the plants to very high relative humidity, both choking the plants ability to transpire, causing condensation, and propagation of fungus and bacteria.
- Use minimum efficiency reporting value (MERV) 13 filters or better to provide adequate mold spore reducing filtration (see ASHRAE *Standard* 52.2 for details on MERV filters)
  - Many times the dehumidifiers cannot be equipped with proper filters. In this case, using ducted dehumidifiers as a sidestream to the main cooling equipment can be arranged to provide filtered air to the dehumidifier.
- Controls integration between the dehumidification units and the primary cooling/conditioning system is required to eliminate hunting of the room. Typical on-board controls for unitary dehumidifiers reference local relative humidity, and that sensor will be affected by changes in the room temperature.
  - For instance, cycling DX type systems can cause run away hunting between the primary cooling and the dehumidification systems, causing over drying of the room, or over heating of the room.
  - Most dehumidification units are fitted with remote relays to trigger their stages, and those should be tied into an electronic controls system so that the dehumidification units may be staged appropriately along with the cooling and reheat provided by the main conditioning system.
  - Many rooms require multiple dehumidifiers to address the water load. By not interconnecting them, large swings in humidity will be experienced, even if using staggered set points between the units.

General Considerations. Because most grow rooms are sensible cooling primary load facilities, care is needed to ensure that heat gain from the dehumidification process can be managed by the existing or designed sensible cooling devices. A CEA dehumidifier can be selected with remote heat rejection to provide some or all of the sensible cooling required. This approach may achieve better energy management by ensuring that the facility is not forced to oversize or overuse sensible cooling devices to counter heat gain from dehumidification equipment in the space.

Grow rooms can require washdown cycles. Ensure that selected equipment has washdown capabilities to reduce pathogen and mold growth, and that filters are easily accessible for regular replacement.

CEA rooms should be considered process air and handled appropriately as such. The typical relative humidity excursions from set point that are typically acceptable in a comfort cooling environment are not acceptable for grow rooms.

Dehumidification of grow rooms is a wildly variable application of HVAC equipment. The room calculations should be made for selections of the equipment in an all-sensible environment: lights and fans on, but no plants. They should also be made for the heaviest day condition: lights on and loaded with plants transpiring at the maximum expected amount. What is commonly missed is calculating the day-night transition and the steady-state night conditions. All four of these major load cases must be satisfied successfully by the combination of central cooling and unitary dehumidification units. Further, these load cases should be calculated for young plants entering rooms that can be over-dried with systems that cannot be turned down or bypassed to reduce the water removal rate.

When looking at the calculations for the sensible and latent heat loads within the room, the engineer should be mindful that the plants themselves do not constitute a latent load as they are not a heat source. The plants will take the energy from the lights, and as long as the vapor pressure deficit is correct for them to transpire, the transpiration will convert the sensible load from the room into a latent load through the latent heat of evaporation. With this in mind, the calculations can be made for the maximum sensible load (lights on, no plants) and the maximum water removal rate, which can actually require more energy than the sensible case, making the SHR of the total system effectively 0 or negative.

The calculations should not add the calculated sensible and latent loads. The calculation should start with the total sensible energy gain into the room as case 1. This is very easily addressed by the main cooling system. Then, the watering recipes should be examined to find the steady state transpiration load into the room. This transpiration converts sensible heat into latent heat through adiabatic cooling. When looking at case 2 (lights on/ heavy plants), the engineer may find that the water load going into the room creates a latent load that exceeds the lighting power. This is often the case in nurseries where there can be heavy young, non-flowering plants, within a space with nursery-level lighting. The engineer should then select dehumidification equipment to address the water load, taking into consideration the contribution from the main cooling equipment, and then recalculating the main cooling equipment with the dehumidification heat rejection taken into consideration. In many cases, the reheat provided by the dehumidification equipment can make up for the sensible shortfall, allowing the main cooling equipment to be roughly equivalent size as the sensible case. In many existing installations, Engineers have made the mistake of adding the sensible and latent loads together.

Then, the selected equipment should be calculated against the two final operating conditions: case 3 (lights off/plants transpiring) and case 4 (lights off/plants asleep). Case 3 represents a pure dehumidification operation case. The sensible heating elements are all shut down, while the plants continue to transpire at the same rate they had during the day for a period of about 40 minutes (±15 min). However, the systems should not immediately decrease the temperature set point at the same time, or there will be an over-cooling (further pressure on relative humidity) followed by an over-drying condition when the plants go to sleep. Case 4 represents the lights off hours where the plants have gone to sleep. The transpiration load typically decreases to about 5 to 10% of the daytime rate and there is no real sensible loads aside from circulation fans and the building envelope.

The issue here is that the equipment will not be sized appropriately (oversized) and cause short cycling. This short cycling not

only leads to shorter equipment life, but it causes severe control excursions with respect to room humidity. The classic example is a dry room served by a two stage direct-expansion packaged HVAC unit when the DX coils both cycle off. The wet coil allows the discharge air humidity to spike and it takes some time for the system to cycle back on. This can cause excessive condensation within the supply ducts, water intrusion into the rooms, etc.

Dehumidification for CEA rooms is crucial to maintaining the water vapor levels, and what growers call **vapor pressure deficit (VPD)**. This is simply the concept of relative humidity (rh) with a specific bent towards the vapor pressure of water rather than just a percent of total carrying capacity. The plants are able to transpire when the vapor pressure deficit is ideal across the stomata. Growers target different VPDs for different parts of the plant's life, the type or strain of plant, and what they are trying to achieve with that plant.

Maintenance of VPD is more important than maintaining temperature. If the plant can continue to transpire, even in over- or under-temperature excursions, there will not likely be damage to the plants. In this way, dehumidification equipment becomes the driving factor in the system design. Over-temperature conditions of a space is OK, as long as it is not too dry. However, allowing a space to get overly wet in order to maintain the space temperature is a recipe for fungus and poor plant health, even for short periods of time. Very great care should be taken when considering equipment to eliminate short cycling, maintenance of off-cycle conditions, etc.

VPD, like relative humidity, is based on temperature. So, it is possible to achieve the proper VPD at any given operating temperature. Because of this, it should be assumed that the plant can and will transpire water into the space at the given watering rates, no matter the temperature within the room. It also means, that great care should be taken when transitioning set points and operating conditions.

The largest example of this is the change from day mode to night mode. Day mode set points can generally be in the upper 20s or over 30°C with relative humidity in the 55 to 65% range. By the end of the day, the plants are transpiring at their steady day awake levels, and then the lights are either dimmed and turned off or just shut off quickly. In this event, it is critical to keep the night set point from being a double-step-change on the control systems because the lights have gone out, the sensible load in the room has all but been eliminated and the plants continue to transpire. It is very typical to see relative humidity spike out after the lights shut off in conventionally constructed grow rooms. When this happens, damage can occur to the plants as they suffocate in this condition. The propagation of fungus is also typically associated with this transition period.

In addition to the above conditions, it should be noted that grow rooms are to be considered harsh environments. There is dust and intense UV light, and the space is typically cleaned with strong chemicals between harvests to eliminate pests, fungus, bacteria, etc. Ensure that the equipment, ductwork, filters, etc., have been selected to give long service life even if treated with chemicals such as chlorine dioxide, hydrogen peroxide, etc. Further, the operators may use a wash-down approach to these spaces. Investigate the intended cleaning standard operating procedures or consider signage on the equipment if it might be susceptible to certain chemicals or conditions.

Tunnel Dryer Dehumidifier

A general-purpose dehumidifier system removes moisture from a product inside the drying tunnel. Air at the desired temperature and humidity constantly recirculates around the product, continuously removing moisture. Tunnel dryer dehumidifier design is similar to that of a general-purpose dehumidifier (see Figure 4). Because of the closely controlled space humidity, temperature, and airflow, select the dehumidifying and reheat coils in accordance with the following conditions:

- The dehumidifying coil must have variable apparatus dew-point control; it might also have an air bypass, depending on coil selection.
- The reheat coil needs variable reheat control.
- A means of external heat rejection is required (e.g., heat rejection to a heat pump loop, chilled-water loop, fluid cooler, or remote air-cooled condenser).

Process Considerations. A precision control system is required to prevent overdrying by automatically shutting off or by reducing capacity when the moisture content in the product has reached the desired level. Continuous control of temperature and relative humidity improves the drying process and maintains product quality, and potentially can reduce operating cost compared to ventilation only. Users should be able to specify drying temperature to best preserve initial product quality.

Design Considerations. The usual operating range for tunnel dryer dehumidifiers is 15 to 38°C db and 10 to 38°C dew point. An average air velocity of 2.54 m/s across the tunnel net free area is recommended for effective drying.

Tunnels should be no longer than 9 m, to prevent saturated air at the tunnel's end. Construction must be air- and vaportight to prevent moisture infiltration from surrounding spaces.

Some products may produce corrosive contaminants, so tunnel dryer dehumidifier components should be corrosion resistant.

For a typical installation of a tunnel dryer dehumidifier, see Figure 15.

2. CONTROLS AND SENSORS

Care is needed when locating the humidity-sensing device that triggers compressor operation. A poorly located sensor results in failure of the system to properly control the humidity levels. The sensor must be located in an area that gives an accurate reading and feedback of the conditions needing control. In larger-volume areas, multiple sensors with an averaging algorithm might provide the best result. Consider the following when selecting sensor locations:

- If the supply fan cycles on/off with compressor operation, this scenario is likely to produce the least accurate sensor reading. Unless the sensor can be located in an area where the humidity

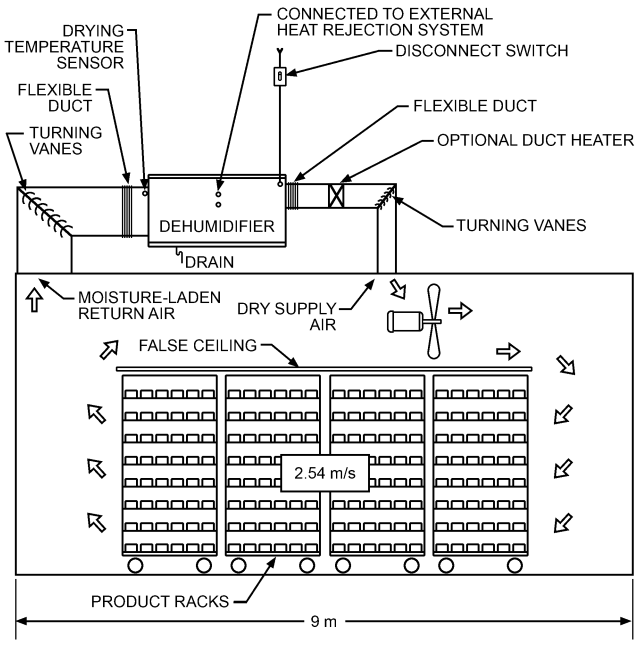

Fig. 15 Typical Tunnel Dryer Dehumidifier

levels are representative of the space when there is no air circulation, the supply fan should be set on a timer to operate on a regular cycle. This ensures air turnover and better monitoring and control of the conditioned space.

- Natatorium dehumidifiers usually have sensors mounted on the unit because of the space high air turnover rate and continuous fan operation. Ensure that the air distribution system does not introduce dry supply air into the return; otherwise, the control system might incorrectly sense that the space is satisfied.
- DOAS units typically have all sensors mounted on the unit and are configured to deliver neutral air. Some units have space-mounted temperature sensors to trigger a full cooling mode (no reheat) to contribute to the space's sensible cooling requirements. This operational mode requires a space-mounted thermostat.
- DOAS units are often configured with 100% recirculation or a percentage of recirculation mode operation, and are tasked for space cooling, heating, and humidity control. Proper location of these space-mounted temperature and humidity sensors is vital for the equipment to provide proper space control.

Heat recovery devices require additional sensors for proper operation.

3. INSTALLATION AND SERVICE CONSIDERATIONS

Equipment and sensors must be installed properly so that they function in accordance with manufacturers' specifications. Interconnecting diagrams for the low-voltage control system should be documented for proper future servicing. Planning is important for installing large, roof-mounted equipment because special rigging is frequently required.

The refrigerant circuit must be clean, dry, and leak-free. An advantage of packaged equipment is that proper installation minimizes the risk of field contamination of the circuit. Take care to properly install split-system interconnecting tubing (e.g., proper cleanliness, brazing, evacuation to remove moisture). Charge split systems according to the manufacturer's instructions.

Equipment must be located to avoid noise and vibration problems. Mount single-package equipment of over 70 kW capacity on concrete pads if vibration control is a concern. Large-capacity equipment should be roof mounted only after the roof's structural adequacy has been evaluated. Additional installation guidelines include the following:

- In general, install products containing compressors on solid, level surfaces.
- Avoid mounting products containing compressors (e.g., remote units) on or touching the foundation of a building. A separate pad that does not touch the foundation is recommended to reduce noise and vibration transmission through the slab.
- Do not box in outdoor air-cooled units with fences, walls, overhangs, or bushes. Doing so reduces the unit's air-moving ability, reducing efficiency.
- For a split-system remote unit, choose an installation site that is close to the indoor part of the system to minimize refrigerant charge and pressure drop in the connecting refrigerant tubing.
- Contact the equipment manufacturer or consult the installation instructions for further information on installation procedures.

Equipment should be listed or certified by nationally recognized testing laboratories to ensure safe operation and compliance with government and utility regulations. Equipment should also be installed to comply with agency standards' rating and application requirements to ensure that it performs according to industry criteria. Larger and more specialized equipment often does not carry agency labeling. However, power and control wiring practices should comply with the *National Electrical Code*® (NFPA *Standard* 70). Consult local codes before design, and consult local inspectors before installation.

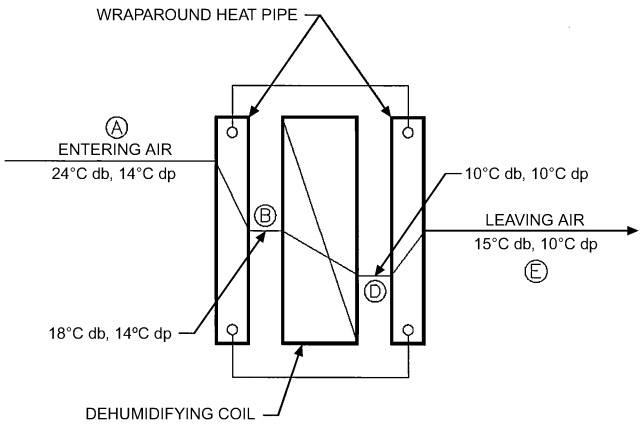

Fig. 16 Schematic of Dehumidification Enhancement with Wraparound Heat Pipe

A clear, accurate wiring diagram and well-written service manual are essential to the installer and service personnel. Easy, safe service access must be provided for cleaning, lubrication, and periodic maintenance of filters and belts. In addition, access for replacement of major components must be provided and preserved.

Service personnel must be qualified to repair or replace mechanical and electrical components and to recover and properly recycle or dispose of any refrigerant removed from a system. They must also understand the importance of controlling moisture and other contaminants in the refrigerant circuit; they should know how to clean a hermetic system if it has been opened for service (see Chapter 7 of the 2022 *ASHRAE Handbook—Refrigeration*). Proper service procedures help ensure that the equipment continues operating efficiently for its expected life.

4. WRAPAROUND HEAT EXCHANGERS

An air-to-air heat exchanger (heat pipe, coil runaround loop, fixed-plate heat exchanger, or rotary heat exchanger) in a series (or wraparound) configuration can be used to enhance moisture removal by a mechanical dehumidifier, improving efficiency, and possibly allowing reduced refrigeration capacity in new systems. Other uses of air-to-air heat exchangers are covered in Chapter 26.

Air-to-air heat exchangers are used with a mechanical dehumidification system to passively move heat from one place to another. The most common configuration used for dehumidification is the **runaround** (or **wraparound**) configuration (Figure 16), which removes sensible heat from the entering airstream and passively transfers it to the leaving airstream. (Points A to E correspond to points labeled in Figure 17.) This improves the cooling coil's latent dehumidification capacity. This method can be applied if design calculations have accounted for the condition of air entering the evaporator coil.

In the runaround or wraparound configuration (Figure 16), one section of the air-to-air heat exchanger is placed upstream of the cooling coil and the other section is placed downstream of the cooling coil. The air is precooled before entering the cooling coil. Heat absorbed by the upstream section of the air-to-air heat exchanger is then passively transferred to air leaving the cooling coil (or supply airstream) by the downstream heat exchanger.

Sensible precooling by the air-to-air heat exchanger reduces the sensible load on the cooling coil, allowing an increase in its latent capacity (Figure 17). The combination of these two effects lowers the system SHR, much like the process described in the Mechani-

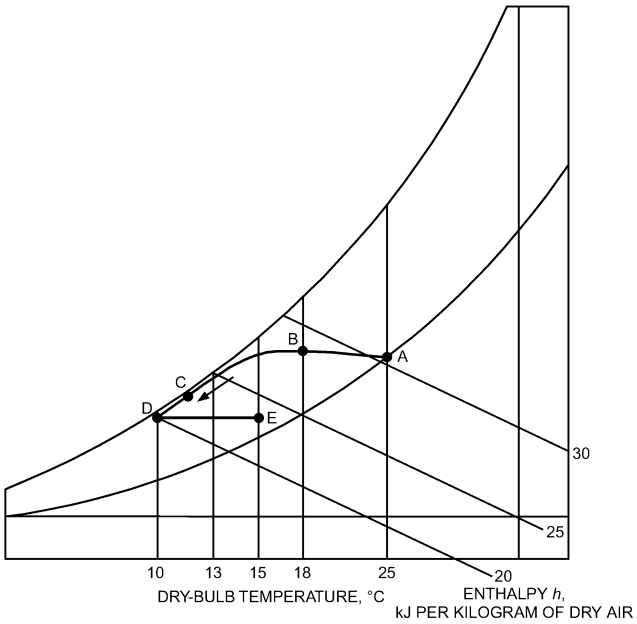

Fig. 17 Enhanced Dehumidification Process with Wraparound Heat Pipe

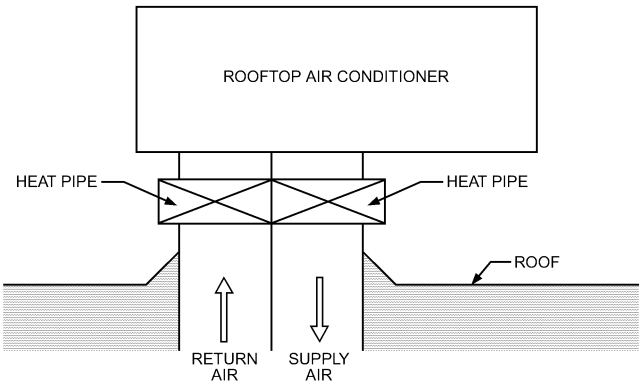

Fig. 18 Slide-in Heat Pipe for Rooftop Air Conditioner Refit

(Kittler 1996)

cal Dehumidifiers section. Adding the air-to-air heat exchanger brings the condition of air entering the evaporator coil closer to the saturation line on the psychrometric chart (A to B). In new installations, this requires careful evaporator coil design that accounts for the actual range of air conditions after the air-to-air heat exchanger, which may differ significantly from the return air conditions.

In retrofits, the **duct-to-duct** (or **slide-in**) configuration (Figure 18) is sometimes used. One section of the air-to-air heat exchanger is placed in the return airstream, and the other section in the supply airstream. This configuration, however, may not provide as much benefit as the wraparound configuration (Figure 16), when (1) the upstream side of the heat exchanger is located upstream of where outdoor air enters the system, (2) smaller duct sizes result in higher air velocity reducing the effectiveness and increases the air-side pressure drop of the heat exchanger, and (3) it requires an additional filter upstream of the air-to-air heat exchanger.

In retrofits, the lower entering-air temperature at the evaporator coil lowers the temperature of air leaving the evaporator coil. Evaporator coil capacity is reduced because of the lower entering wet-bulb temperature, changing the system's operating point. This must be analyzed to ensure that the mechanical refrigeration system still operates correctly. If evaporator coil freeze-up is possible, the system must include some means to modulate the capacity of (or deactivate) the air-to-air heat exchanger or bypass airflow to prevent evaporator freezing. Having the ability to modulate the air-to-air heat exchanger's capacity may be incorporated to better meet the load requirement of the mechanical dehumidifier.

Adding an air-to-air heat exchanger typically improves the moisture removal capacity of an existing mechanical dehumidification system by creating a lower supply air dew point, while providing some reheat without additional energy use. Proper design practices are necessary to ensure that the unit's mechanical refrigeration system still operates efficiently with the new entering air conditions and additional air-side pressure drop. Also, the added pressure drop of the air-to-air heat exchanger is likely to reduce the airflow delivered, unless fan speed in increased. If increasing fan speed is necessary, verify that the fan motor can handle the added load.

Figure 17 shows the dehumidification process when a wraparound heat pipe is added to an existing evaporator coil. Point A to C shows the cooling and dehumidification process of an existing DX evaporator coil, without the wraparound heat pipe. Point A to B shows precooling by the upstream section of heat pipe. The process line from B to D (versus B to C, without the wraparound heat pipe) shows how the evaporator coil's dehumidification performance improves (lowering leaving air dew point, from C to D) if a wraparound heat pipe is added to the existing system, because the enthalpy of the air entering the evaporator is lowered. Point D to E illustrates that the heat removed from air upstream of the evaporator (A to B) is added back into air leaving the evaporator. The total amount of heat energy (enthalpy) removed in section A-B is equal to the amount of heat added in section D-E.

Economic Considerations 26.31
Energy and/or Mass Recovery Calculation Procedure 26.32
Symbols 26.36

AIR-TO-AIR energy recovery is the process of recovering heat and/or moisture between two airstreams at different temperatures and humidities. This process is important in maintaining acceptable indoor air quality (IAQ) while keeping energy costs low and reducing overall energy consumption and carbon dioxide emission. This chapter describes various technologies for air-to-air energy recovery. Thermal and economic performance, maintenance, and related operational issues are presented, with emphasis on energy recovery for ventilation.

Air-to-air energy recovery should be considered for every building in which energy is used to condition the air. This is consistent with ASHRAE's strategic plan to support a sustainable built environment, and aligns with the United Nations International Panel for Climate Change's call for action to reduce the emissions of carbon dioxide related to energy use.

Energy can be recovered either in its sensible (temperature only) or latent (moisture) form, or a combination of both from multiple sources. Sensible energy can be extracted, for example, from outgoing airstreams in dryers, ovens, furnaces, combustion chambers, and gas turbine exhaust gases to heat supply air. Units used for this purpose are called **sensible heat exchange devices** or **heat recovery ventilators (HRVs)**. Devices that transfer both heat and moisture are known as **energy** or **enthalpy devices** or **energy recovery ventilators (ERVs)**. HRVs and ERVs are available for commercial and industrial applications as well as for residential and small-scale commercial uses.

Air conditioners use significant energy to dehumidify moist airstreams. Excessive moisture in the air of a building can result in mold, allergies, and bacterial growth. ERVs can enhance dehumidification with packaged unitary air conditioners. Introducing outdoor or ventilation air is the primary means of diluting air contaminants to achieve acceptable indoor air quality. ERVs can cost-effectively provide large amounts of outdoor air to meet a building's minimum ventilation requirements as prescribed in ASHRAE *Standards* 62.1 and 62.2.

Types of HRV/ERVs include fixed-plate heat (or enthalpy) exchangers, rotary wheels, heat pipes, runaround loops, thermosiphons, fixed-bed regenerators, and twin-tower enthalpy recovery loops. Performance is typically characterized by effectiveness; pressure drop, pumping, or fan power of fluids; cross leakage (i.e., amount of air leakage from one stream to the other); and frost control (used to prevent frosting on the heat exchanger). **Recovery efficiency ratio (RER)**, the ratio of output of a device to its input, is also often considered. In energy recovery ventilators, effectiveness refers to the ratio of actual energy or moisture recovered to the maximum possible amount of energy and/or moisture that can be recovered.

Fluid stream pressure drops because of the friction between the fluid and solid surface, and because of the geometrical complexity of the flow passages. Pumping or fan power is the product of the fluid volume flow rate and pressure drop. Economic factors such as cost of energy recovered and capital and maintenance cost (including pumping power cost) play a vital role in determining the economic feasibility of recovery ventilators for a given application.

The preparation of this chapter is assigned to TC 5.5, Air-to-Air Energy Recovery.

Table 1 Typical Applications for Air-to-Air Energy Recovery

Method	Application

	Burners
	Furnaces
	Incinerators
	Paint exhaust
	Welding exhaust

1. APPLICATIONS

Air-to-air energy recovery systems may be categorized according to their application as (1) process-to-process, (2) process-to-comfort, or (3) comfort-to-comfort. Some typical air-to-air energy recovery applications are listed in Table 1.

In **comfort-to-comfort** applications, the energy recovery device lowers the enthalpy of the building supply air during warm weather and raises it during cold weather by transferring energy between the ventilation air supply and exhaust airstreams.

Air-to-air energy recovery devices for comfort-to-comfort applications may be sensible heat exchange devices (i.e., transferring sensible energy only) or energy exchange devices (i.e., transferring both sensible energy and moisture). These devices are discussed further in the section on Additional Technical Considerations.

When outdoor air humidity is low and the building space has an appreciable latent load, an ERV can recover sensible energy while possibly slightly increasing the latent space load because of water vapor transfer within the ERV. It is therefore important to determine whether the given application calls for HRV or ERV.

HRVs are suitable in applications when outdoor air humidity is low and latent space loads are moderate or high for most of the year, and also for use with high-indoor-humidity and hazardous-exhaust applications such as swimming pools, chemical exhaust, paint booths, and indirect evaporative coolers.

ERVs are suitable for moderate- to high-outdoor-humidity applications and those that require year-round economical preheating and/or precooling of outdoor supply air.

In **process-to-process** applications, heat is captured from the process exhaust stream and transferred to the process supply airstream. Equipment is available to handle process exhaust temperatures as high as 870°C.

Process-to-process recovery devices generally recover only sensible heat and do not transfer latent heat, because moisture transfer is usually detrimental to the process. In cases involving condensable gases, less recovery may be desired to prevent condensation and possible corrosion.

In **process-to-comfort** applications, waste heat captured from process exhaust heats building makeup air during winter. Typical applications include foundries, strip-coating plants, can plants, plating operations, pulp and paper plants, and other processing areas with heated process exhaust and large makeup air volume requirements.

Although full recovery is usually desired in process-to-process applications, recovery for process-to-comfort applications must be modulated during warm weather to prevent overheating the makeup air. During summer, no recovery is required. Because energy is saved only in the winter and recovery is modulated during moderate weather, process-to-comfort applications save less energy annually than do process-to-process applications.

Process-to-comfort recovery devices generally recover sensible heat only and do not transfer moisture between airstreams.

2. BASIC HEAT OR HEAT AND WATER VAPOR TRANSFER RELATIONS

The second law of thermodynamics states that heat energy always transfers from a region of high temperature to one of low temperature. This law can be extended to say that mass transfer always occurs from a region of high vapor pressure to one of low vapor pressure. The conceptual energy recovery exchanger in Figure 1 facilitates this transfer (without mixing supply and exhaust airstreams) across a separating wall (shown by a thick horizontal line in Figure 1) made of a material that conducts heat and is permeable to water vapor. Heat is transferred when there is a difference in temperature between the two airstreams. Moisture is transferred when there is a difference in vapor pressure between the two airstreams.

On a typical summer day, supply air at temperature, humidity, or enthalpy of x_1 and mass flow rate m_s enters the ERV, while exhaust air from the conditioned space enters at conditions x_3 and m_3. Because conditions at x_3 are lower than conditions at x_1, heat and mass transfer from the supply airstream to the exhaust airstream because of differences in temperature and vapor pressures across the separating wall. Consequently, the supply air exit properties decrease, while those of the exhaust air increase.

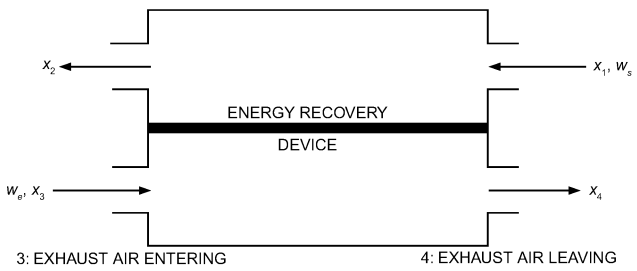

Fig. 1 Airstream Numbering Convention

Effectiveness

When mass flow rates, temperatures, and humidities of the inlets and outlets are known, the sensible, latent, or total effectiveness of the exchanger for those operating conditions can be determined.

Conversely, if the respective effectiveness of the exchanger at specific mass flow rates is known or rated, and the temperatures and humidities of the inlets are specified, it is possible to estimate conditions at the outlets, as long as confounding variables such as occurrence of condensation or internal leakages are insignificant.

The general definition of transfer effectiveness ε, on which ASHRAE *Standard* 84 bases its definitions of effectiveness, is

$$\varepsilon = \frac{\text{Actual transfer of moisture and/or energy}}{\text{Maximum possible transfer between airstreams}} \quad (1)$$

Referring to Figure 1, the gross sensible effectiveness ε_s or $\varepsilon_{sensible}$ of an energy recovery ventilator is given as

$$\varepsilon_{sensible} = \frac{\dot{m}_2(c_{p,1}T_1 - c_{p,2}T_2)}{\dot{m}_{min}(c_{p,1}T_1 - c_{p,3}T_3)} \quad (2a)$$

Referring to Figure 1, the gross latent effectiveness ε_L or ε_{latent} of an energy recovery ventilator is given as

$$\varepsilon_{latent} = \frac{\dot{m}_2(h_{fg,1}W_1 - h_{fg,2}W_2)}{\dot{m}_{min}(h_{fg,1}W_1 - h_{fg,3}W_3)} \quad (2b)$$

Referring to Figure 1, the gross total effectiveness ε_T or ε_{total} of an energy recovery ventilator is given as

$$\varepsilon_{total} = \frac{\dot{m}_2(h_1 - h_2)}{\dot{m}_{min}(h_1 - h_3)} \quad (2c)$$

where

$\dot{m}_n$ = mass flow rate at station n, kg/s
$\dot{m}_{min}$ = minimum of $\dot{m}_2$ and $\dot{m}_3$, kg/s
$c_{p,n}$ = specific heat of dry air at station n, kJ/(kg·K)
h_{fg} = heat of vaporization of water, kJ/(kg·K)
T_n = dry-bulb temperature at station n, °C
W_n = humidity at station n, kg_w/kg_{da}
h_n = enthalpy at station n, kJ/kg

Note that in Equations (2a), (2b), and (2c), the denominators express the theoretical maximum sensible, latent, or total energy transfer.

An additional figure of merit, which characterizes the reduction in heating or cooling load associated with the supply air, is the **enthalpy recovery ratio**, given by

$$\text{Enthalpy recovery ratio} = \frac{h_1 - h_2}{h_1 - h_3} \quad (3)$$

where h is enthalpy at station n, in kJ/kg.

Equation (3) bears a superficial resemblance to Equation (2c) which defines gross total effectiveness, but when the supply and exhaust mass flows through the exchanger are different, the two metrics may have different values. Using the enthalpy recovery ratio when designing HVAC systems for compliance with ASHRAE *Standard* 90.1 is detailed in the section on Performance Ratings.

The leaving supply air conditions and heat transfer rates easily can be estimated under ideal conditions: steady-state operation; no heat or moisture transfer between the heat exchanger and its surroundings; no cross-leakage; and no energy gains or losses from motors, fans, or frost control devices, with negligible condensation or frosting. Under such ideal conditions, the leaving supply temperature is

$$T_2 = \frac{\dot{m}_2 c_{p,1} T_1 - \varepsilon_{sensible} \dot{m}_{min} (c_{p,1} T_1 - c_{p,3} T_3)}{\dot{m}_2 c_{p,2}} \quad (4a)$$

and the exhaust air temperature is

$$T_4 = \frac{\dot{m}_2 c_{p,3} T_3 + \varepsilon_{sensible} \dot{m}_{min} (c_{p,1} T_1 - c_{p,3} T_3)}{\dot{m}_2 c_{p,2}} \quad (4b)$$

The leaving supply air humidity is

$$W_2 = \frac{\dot{m}_2 h_{fg,1} W_1 - \varepsilon_{latent} \dot{m}_{min} (h_{fg,1} W_1 - h_{fg,1} W_3)}{\dot{m}_2 h_{fg,2}} \quad (4c)$$

And the exhaust air humidity is

$$W_4 = \frac{\dot{m}_2 h_{fg,3} W_3 + \varepsilon_{latent} \dot{m}_{min} (h_{fg,1} W_1 - h_{fg,3} W_3)}{\dot{m}_2 h_{fg,2}} \quad (4d)$$

The leaving supply air enthalpy is

$$h_2 = h_1 - \varepsilon_{total} \frac{\dot{m}_{min}}{\dot{m}_s} (h_1 - h_3) \quad (4e)$$

And the exhaust air enthalpy is

$$h_4 = h_3 - \varepsilon_{total} \frac{\dot{m}_{min}}{\dot{m}_s} (h_1 - h_3) \quad (4f)$$

Use Equations (4e) and (4f) with caution. When the enthalpies of the entering airstreams are very close but the temperatures and humidities are not, it is possible for the calculated total effectiveness to be greater than or less than both of the sensible or latent effectivenesses, or even to be greater than 100% or less than 0%. For example, in some conditions, the supply airstream flowing through an ERV may gain heat energy ($+q_s$) from the adjoining stream but lose latent energy ($-q_L$) if it transfers the water vapor to the adjoining stream. Therefore, it is generally best to determine the expected enthalpy of leaving air by first calculating the expected temperature and humidity of the leaving air.

The sensible heat energy transfer q_s in the energy recovery exchanger can be estimated from

$$q_s = \dot{m}_2 (c_{p,1} T_1 - c_{p,2} T_2) = Q_2 \rho_2 (c_{p,1} T_1 - c_{p,2} T_2) \quad (5a)$$

where

q_s = sensible heat transfer, kW
c_p = specific heat of air, kJ/(kg·K)
Q_2 = volume flow rate of supply outlet air, m^3/s
ρ_2 = density of dry outlet supply air, kg/m^3
t_1, t_2, t_3 = inlet and exit temperatures of supply inlet, supply outlet, and exhaust inlet airstreams, respectively, K
$\dot{m}_2$ = mass flow rate of supply air inlet, kg/s

The latent heat transfer q_L in the energy recovery exchanger can be estimated from

$$q_L = \dot{m}_2 (h_{fg,1} W_1 - h_{fg,2} W_2) = Q_2 \rho_2 (h_{fg,1} W_1 - h_{fg,2} W_2) \quad (5b)$$

where

q_L = latent heat transfer, kW
h_{fg} = enthalpy or heat of vaporization of water, kJ/kg
W_1, W_2, W_3=inlet and exit humidity ratios of the supply inlet, supply outlet, and exhaust inlet airstreams, respectively, kg_w/kg_{da}

Similarly, humidity transfer q_w in the ERV can be estimated from

$$q_w = \dot{m}_2 (W_1 - W_2) = Q_2 \rho_2 (W_1 - W_2) \quad (5c)$$

where q_w is humidity transfer, in kg_w/s

In some cases, the total energy transfer q_T or q_{total} can be estimated from

$$q_{total} = \dot{m}_2 (h_1 - h_2) = Q_2 \rho_2 (h_1 - h_2) \quad (5d)$$

where q_h is total energy transfer, kilowatts

However, in the somewhat unusual case when the supply airstream gains sensible energy but loses water content, q_{total} is best estimated from

$$q_{total} = q_s + q_L \quad (5e)$$

Heat or energy exchange effectiveness as defined in Equations (1), (2a), (2b), and (2c) is used to characterize each type of energy transfer in air-to-air exchangers. For a given set of inlet properties and flow rates, knowledge of each effectiveness allows the designer to calculate the sensible, latent, and total energy transfer rates using Equations (5a), (5b), and (5d), respectively. These effectiveness values can be determined either from measured test data or using correlations that have been verified in the peer-reviewed engineering literature. These correlations can also be used to predict energy transfer rates and outlet air properties for operating conditions different from those used for certification purposes. Predicting effectiveness for noncertified operating conditions using certified test data is the most common use of correlations for HVAC designs, though the practice is less necessary since AHRI *Standard* 1060 revised certification requirements requiring manufacturers to certify AAERV selection software that can predict performance at a range of operating conditions. AAERV performance for entering air conditions outside of certified mapped performance ranges must still be extrapolated based on tested and/or certified values. Although correlations are not available for all types of air-to-air exchangers under all operating conditions, they are available for the most common types of air-to-air exchanger under operating conditions which have no condensation or frosting.

Rate of Energy Transfer

The rate of energy transfer depends on the operating conditions and the intrinsic characteristics of the energy exchanger, such as the geometry of the exchanger (parallel flow/counterflow/ cross-flow, number of passes, fins), thermal conductivity of walls separating the streams, and permeability of walls to various gases. As in a conventional heat exchanger, energy transfer between the airstreams is driven by cross-stream dry-bulb temperature differences. Energy is also transported piggyback-style between the streams by cross-stream mass transfer, which may include air, gases, and water vapor. In another mode of energy transfer, water vapor condenses into liquid in one of the two airstreams of the exchanger. The condensation process liberates the latent heat of condensation, which is transferred to the other stream as sensible heat; this two-step process is also called **latent heat transfer**.

Latent energy transfer between airstreams occurs only when moisture is transferred from one airstream to another without condensation, thereby maintaining the latent heat of condensation. Once moisture has crossed from one airstream to the other, it may

either remain in the vapor state or condense in the second stream, depending on the temperature of that stream.

Rotating-wheel and fixed-plate enthalpy exchangers are used because of their moisture exchange function. Some cross-stream mass transfer may also occur through leakage even when such transfer is unintended. This may alter exchanger performance from its design value, but for most HVAC applications with exhaust air from occupied spaces, small transfers to the supply air are not important. However, these transfers can and should be evaluated during design, and in many cases can be controlled.

Heat transfer differs in principle from mass transfer. Heat transfer only occurs when there is a temperature difference. In the case of air-to-air exchange between the supply and exhaust airflow, heat transfer by conduction and convection only occurs when there is a temperature difference between these airstreams. Remember the following facts about heat/mass exchanger performance:

- Effectiveness for moisture transfer may not equal the effectiveness for heat transfer.
- Total energy effectiveness may not equal either the sensible or latent effectiveness.

Net total energy transfer and effectiveness need careful examination when the direction of sensible (temperature-driven) transfer is opposite to that of latent (moisture or water vapor) transfer.

ERV performance is expressed by the magnitudes of pumping power and sensible, latent, or total energy recovered. The energy recovered is estimated from the exit temperatures or humidity ratios, which are directly related to the effectiveness. Effectiveness is a function of two parameters: the number of transfer units (NTU) and thermal flow capacity ratio C_r.

$$\text{NTU} = UA/C_{min} \tag{6}$$

$$C_r = C_{min}/C_{max} \tag{7}$$

where

U = overall heat transfer coefficient, related to flow rates and dimensions of fluid flow path in heat exchanger, kW/(m^2·K)
A = area of heat exchanger, m^2
C_{min}, C_{max} = minimum and maximum capacity rates, expressed for sensible as $m_s c_{p,s}$ and $m_e c_{p,e}$

See Figure 8 for the variation of effectiveness with NTU for a rotary heat wheel. Variation of effectiveness is similar for plate exchangers.

Example 1. Inlet supply air enters an ERV with a flow rate of 4.41 m^3/s at 35°C and 20% rh. Inlet exhaust air enters with a flow rate of 4.27 m^3/s at 24°C and 50% rh. Assume that the energy exchanger was tested under ASHRAE *Standard* 84, which rated the sensible heat transfer effectiveness at 50% and the latent (water vapor) transfer effectiveness at 50%. With the simplifying assumptions that the specific heat of air is 1 kJ/(kg·K) and the latent heat of vaporization is 2560 kJ/kg, determine the sensible, latent, and net energy transferred in the exchanger.

Solution:

From the psychrometric chart, the properties of air at 35°C and 20% rh are

$V_1 = 0.8825$ m^3/kg $\quad h_1 = 54.2$ kJ/kg $\quad w_1 = 0.0071$ kg/kg of dry air

and the properties of air at 24°C and 50% rh are

$V_3 = 0.854$ m^3/kg $\quad h_3 = 48$ kJ/kg $\quad w_3 = 0.0093$ kg/kg of dry air

The mass flow rate at state 1 is obtained from

$$\{m_1 = \frac{Q_1}{v_1} = \frac{4.41 \text{ m}^3/\text{s}}{0.8825 \text{ m}^3/\text{kg}} = 5.0 \text{ kg/s}\}$$

Similarly, the mass flow rate at state 3 is obtained from

$$m_3 = \frac{Q_3}{v_3} = \frac{4.27 \text{ m}^3/\text{s}}{0.854 \text{ m}^3/\text{kg}} = 5.0 \text{ kg/s}$$

Exit temperatures of the supply airstream can be obtained from Equation (4a):

$$t_2 = \frac{50(1)35 - 0.50(50)\{(1)35 - (1)24\}}{(50)1} = 29.5°\text{C}$$

The exit humidity of the supply airstream is found from Equation (4c):

$$w_2 = \{5.0(2560)0.0071 - 0.50(5.0)[(2560)0.0071 - (2560)0.0093]\}/[(5.0)(2560)] = 0.0080 \text{ kg}_w/\text{kg}_{da}$$

The sensible heat transfer q_s in the exchanger is found from Equation (5a):

$$q_s = 5.0(1 \times 35 - 1 \times 29.5) = 27.5 \text{ kW}$$

The latent heat transfer q_L in the exchanger is found from Equation (5b):

$$q_L = 5.0[(2560)(0.0071) - (2560)(0.0080)] = -11.52 \text{ kW}$$

The net heat energy transfer q_s in the exchanger is found from Equation (5d):

$$q = q_s + q_L = 27.5 - 11.52 = 15.98 \text{ kW}$$

If the incoming outdoor air conditions had been at 35°C and 14% rh, then the net energy gained by the exhaust airstream would have been zero.

Fan Power

It is important to estimate the fan power required to move the supply and exhaust airstream through the exchanger.

The fan power P_s required by the supply air is estimated from

$$P_s = \frac{Q_s \, \Delta p_s}{\eta_f}\} \tag{8}$$

The fan power P_e required by the exhaust air is estimated from

$$P_e = \frac{Q_e \, \Delta p_e}{\eta_f} p\} \tag{9}$$

where

P_s = fan power for supply air, W
P_e = fan power for exhaust air, W
Q_s = supply volume flow rate, m^3/s
Q_e = exhaust volume flow rate, m^3/s
Δp_s = pressure drop of supply air caused by fluid friction, Pa
Δp_e = pressure drop of exhaust air caused by fluid friction, Pa
η_f = overall efficiency of fan and motor or product of fan and motor efficiencies

If pressure drops through the exchanger are not known at the operating conditions, they may be estimated from a standard pressure drop rating at a reference condition. Ideally, the density, viscosity, and Reynolds number of the air are known, which allows use of the following approach to estimate operating pressure drops.

The density and viscosity of air vary with temperature, and therefore pressure drop through the exchanger varies with temperature as well as flow rate. The variation of viscosity with temperature is given by the Sutherland law as

$$\frac{\mu}{\mu_o} = \left(\frac{T}{T_o}\right)^{3/2}\left(\frac{T_o + S}{T + S}\right) \quad (10)$$

where

μ = dynamic viscosity, kg/(m·s)
μ_o = dynamic viscosity at the reference temperature, kg/(m·s)
T = absolute temperature, K
T_o = reference temperature, K
S = constant = 110.4 K

The Reynolds number can be estimated from

$$Re_D = \frac{(\rho V)_{av} D_h}{\mu T} \quad (11)$$

where

ρ = air density, kg/m^3
V = average velocity in flow channels, m/s
D_h = hydraulic diameter of flow channels, m
μ_T = dynamic viscosity at average temperature T, kg/(m·s)

When flow through the exchanger is transitional or turbulent (i.e., when the Reynolds number Re_D for airflow through the exchanger is in the range $5 \times 10^3 \le Re_D \le 10^5$), then, treating air as an ideal gas, the pressure drop Δp at any temperature T is related to the pressure drop Δp_o at reference temperature T_o and is expressed as

$$\frac{\Delta p}{\Delta p_o} = \left(\frac{m}{m_o}\right)^{1.75}\left(\frac{T}{T_o}\right)^{1.375}\left(\frac{T_o + S}{T + S}\right)^{0.25} \quad (12)$$

where

Δp = pressure drop, Pa
Δp_o = pressure drop at reference temperature, Pa
m = mass flow rate at operating condition, kg/s
m_o = mass flow rate at rating condition, kg/s

For fully developed laminar flow through an energy exchanger, i.e. where $Re_D < 2000$, the corresponding dimensionless pressure drop relation similar to Equation (12) is given as

$$\frac{\Delta p}{\Delta p_o} = \left(\frac{m}{m_o}\right)\left(\frac{T}{T_o}\right)^{3/2}\left(\frac{1 + C/T_o}{1 + C/T}\right) \quad (13)$$

The equations above cannot be used in the case of (1) flow channels that are not reasonably smooth; (2) flow Reynolds numbers that are out of range; (3) significant exchanger fouling caused by condensation, frost, or dust; (4) excessive nonuniform property distributions inside the exchanger; or (5) significant pressure deformation of the flow channels (e.g., some plate cross-flow exchangers).

The total pumping power P of the ERV can be given as

$$P = P_s + P_e \quad (14)$$

3. TYPES OF AIR-TO-AIR HEAT EXCHANGERS

Ideal Air-to-Air Energy Exchange

An ideal air-to-air energy exchanger

- Allows temperature-driven heat transfer between participating airstreams
- Allows partial-pressure-driven moisture transfer between the two streams
- Minimizes cross-stream transfer of air, other gases (e.g., pollutants), biological contaminants, and particulates
- Optimizes energy recovery performance to minimize pressure drop while providing reasonable cost, dimensions, and mass

Heat transfer is an important energy recovery vehicle from airstreams that carry waste heat. The role of moisture transfer as an energy recovery process is less well known and merits explanation.

Consider an air-to-air energy exchanger operating in a hot, humid climate in a comfort air-conditioning application. If the energy exchanger exchanges heat but not moisture, it cools outdoor ventilation air as it passes through the exchanger to the indoor space. Heat flows from the incoming outdoor air to the outgoing (and cooler) exhaust air drawn from the indoor conditioned space. This does very little to mitigate the high humidity carried into the indoor space by the outdoor ventilation air and may even increase the relative humidity in the conditioned space, resulting in increased refrigeration and/or reheat to dehumidify the air and achieve acceptable comfort conditions. On the other hand, if the energy exchanger transfers both heat and moisture, the humid outdoor supply air transfers moisture to the less-humid inside exhaust air as the streams pass through the energy exchanger. The lower humidity of the entering ventilation air requires less energy input for comfort conditioning.

Fixed-Plate Heat Exchangers

Plate exchangers are available in many configurations, materials, sizes, and flow patterns. Many have modules that can be arranged to handle almost any airflow, effectiveness, and pressure drop requirement. Plates are formed with spacers or separators (e.g., ribs, dimples, ovals) constructed into the plates or with external separators (e.g., supports, braces, corrugations). Airstream separations are sealed by folding, multiple folding, gluing, cementing, welding, or any combination of these, depending on the application and manufacturer. Ease of access for examining and cleaning heat transfer surfaces depends on the configuration and installation.

Heat transfer resistance through the plates is small compared to the airstream boundary layer resistance on each side of the plates. Heat transfer efficiency is not substantially affected by the heat transfer coefficient of the plates. Aluminum is the most popular plate construction material because of its nonflammability and durability. Polymer plate exchangers may improve heat transfer by causing some turbulence in the channel flow, and are popular because of their corrosion resistance and cost-effectiveness. Steel alloys are used for temperatures over 200°C and for specialized applications where cost is not a key factor. Plate exchangers normally conduct sensible heat only; however, water-vapor-permeable materials, such as treated paper and microporous polymeric membranes, may be used to transfer moisture, thus providing total (enthalpy) energy exchange.

Most manufacturers offer modular plate exchangers. Modules range in capacity from 0.01 to 5 m^3/s and can be arranged into configurations exceeding 50 m^3/s. Multiple sizes and configurations allow selections to meet space and performance requirements.

Plate spacing ranges from 2.5 to 12.5 mm, depending on the design and application. Heat is transferred directly from the warm airstreams through the separating plates into the cool airstreams. Usually design, construction, and cost restrictions result in the selection of cross-flow exchangers, but additional counterflow patterns can increase heat transfer effectiveness.

Normally, both latent heat of condensation (from moisture condensed as the temperature of the warm exhaust airstream drops below its dew point) and sensible heat are conducted through the separating plates into the cool supply airstream. Thus, energy is transferred but moisture is not. Recovering 80% or more of the available waste exhaust heat is possible.

Fixed-plate heat exchangers can achieve high sensible heat recovery and total energy effectiveness because they have only a

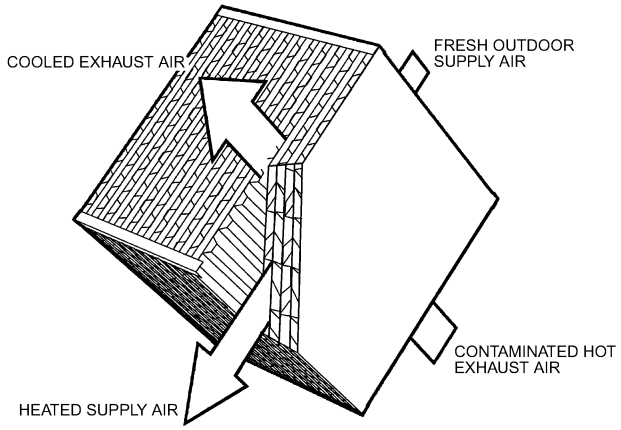

Fig. 2 Fixed-Plate Cross-Flow Heat Exchanger

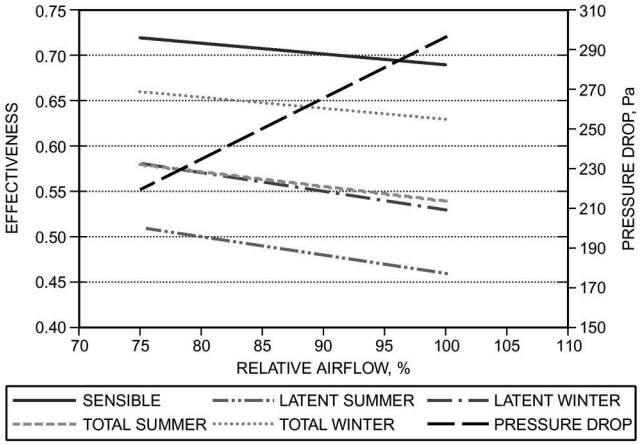

Fig. 3 Variation of Pressure Drop and Effectiveness with Airflow Rates for Membrane Plate Exchanger

(Dhamshala, 2016)

primary heat transfer surface area separating the airstreams and are therefore not inhibited by the additional secondary resistance (e.g., pumping liquid, in runaround systems or transporting a heat transfer medium) inherent in some other exchanger types. In a cross-flow arrangement (Figure 2), they usually do not have sensible effectiveness greater than 75% unless two devices are used in series as shown in Figure 3.

One advantage of the plate exchanger is that it is a static device with little or no leakage between airstreams. As velocity increases, the pressure difference between the two airstreams increases. High differential pressures may deform the separating plates and, if excessive, can permanently damage the exchanger, significantly reducing the airflow rate on the low-pressure side as well as the effectiveness and possibly causing excessive air leakage. This is not normally a problem because differential pressures in most applications are less than 1 kPa. In applications requiring high air velocities, high static pressures, or both, plate exchangers built to withstand these conditions are available and should be specified.

Most sensible plate exchangers have condensate drains, which remove condensate and also wastewater in water-wash systems. Heat recovered from a high-humidity exhaust is better returned to a building or process by a sensible heat exchanger rather than an enthalpy exchanger if humidity transfer is not desired.

Frosting can be controlled by preheating incoming supply air, bypassing part of the incoming air, recirculating supply air through the exhaust side of the exchanger, or temporarily interrupting supply air while maintaining exhaust. However, frost on cross-flow heat exchangers is less likely to block the exhaust airflow completely than with other types of exchangers. Generally, frost should be avoided unless a defrost cycle is included.

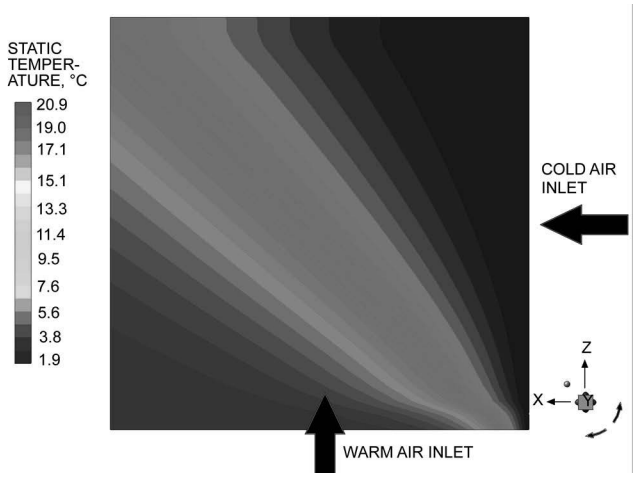

Fig. 4 Typical Temperature Stratification at Outlets of Cross-Flow Heat Exchanger

Fixed-plate heat exchangers can be made from permeable membranes designed to maximize moisture and energy transfer between airstreams while minimizing air transfer. Suitable permeable microporous membranes for this emerging technology include cellulose, polymers, and other synthetic materials such as hydrophilic electrolyte. Hydrophilic electrolytes are made from, for example, sulphonation chemistry techniques and contain charged ions that attract polar water molecules; adsorption and desorption of water occur in vapor state.

Airstreams exiting a cross-flow plate exchanger display temperature stratification when there is a temperature difference between the two airstreams (Figure 4). Enthalpy plate exchangers will also display humidity stratification. This should be considered if the temperature of one of these airstreams is to be measured (e.g., to control operation of downstream conditioning equipment or of a defrost mechanism).

Heat exchanger effectiveness depends heavily on the airflow direction and pattern of the supply and exhaust airstreams. Parallel-flow exchangers (Figure 5A), in which both airstreams move along heat exchange surfaces in the same direction, have a theoretical maximum effectiveness of 50%. Counterflow exchangers (Figure 5B), in which airstreams move in opposite directions, can have a theoretical effectiveness approaching 100%, but typical units have an effectiveness closer to 80%. Theoretical effectiveness for cross-flow heat exchangers is somewhat lower than for counterflow, and typical units have effectiveness of 50 to 70% (Figure 5C) and 60 to 85% for multiple-pass exchangers (Figure 5D).

In practice, construction limitations favor designs that use transverse flow (or cross-flow) over much of the heat exchange surface (Figures 5C and 5D).

Rotary Air-to-Air Energy Exchangers

A rotary air-to-air energy exchanger, or **rotary energy recovery wheel**, has a revolving cylinder filled with an air-permeable medium having a large internal surface area designed to absorb heat and/or moisture. Adjacent supply and exhaust airstreams each flow through half the exchanger in a counterflow pattern (Figure 6). Heat transfer media may be selected to recover sensible heat only or total (sensible plus latent) heat.

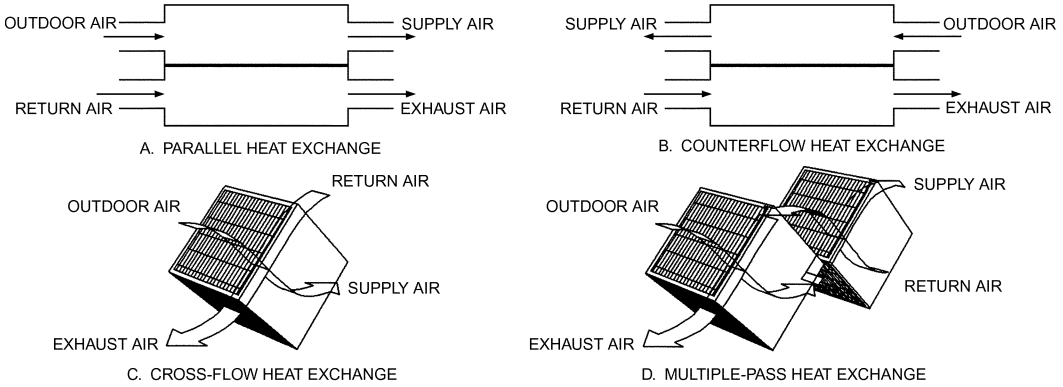

Fig. 5 Plate Heat or Heat and Mass Exchanger Airflow Configurations

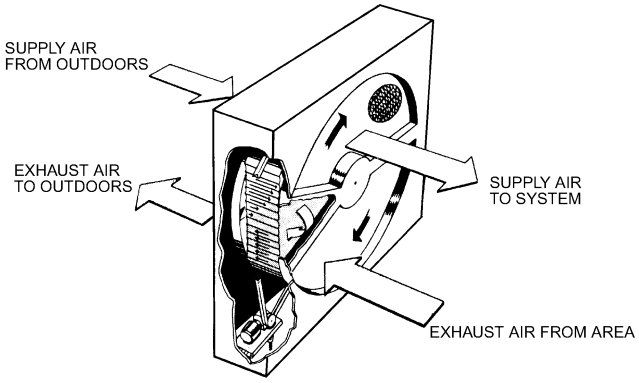

Fig. 6 Rotary Air-to-Air Energy Exchanger

Sensible Versus Enthalpy Recovery. Sensible heat is transferred as the medium stores heat from the hot airstream and releases it to the cold one. Latent heat is transferred as the medium adsorbs water vapor from the higher-humidity airstream and desorbs moisture into the lower-humidity airstream, driven in each case by the vapor pressure difference between the airstream and energy exchange medium. Thus, the moist air is dried while the drier air is humidified. In total energy transfer, both sensible and latent heat transfer occur simultaneously. Sensible-only wheels (not coated with desiccant) can also transfer moisture via a mechanism of condensation and reevaporation driven by dew point and vapor pressure; the latent effectiveness is typically lower than that of enthalpy wheels and varies strongly with conditions.

Because rotary exchangers have a counterflow configuration and normally use small-diameter flow passages, they are quite compact and can achieve high sensible or enthalpy transfer effectiveness. When compared to fixed-plate exchangers, rotary energy recovery wheels are much more compact when treating the same airflow.

Media Selection. Air contaminants, dew point, exhaust air temperature, and supply air properties influence the choice of materials for the casing, rotor structure, and medium of a rotary energy exchanger. Aluminum, steel, and polymers are the usual structural, casing, and rotor materials for normal comfort ventilating systems. Exchanger media are fabricated from metal, mineral, or synthetic materials and provide either random or directionally oriented flow through their structures.

Random-flow media are made by knitting wire into an open woven cloth or corrugated mesh, which is layered to the desired configuration. Aluminum mesh is packed in pie-shaped wheel segments. Stainless steel and monel mesh are used for high-temperature and corrosive applications. These media should only be used with clean, filtered airstreams because they plug easily. Random-flow media also require a significantly larger face area than directionally oriented media for a given airflow and pressure drop.

Directionally oriented media are available in various geometric configurations. The most common consist of small (1.5 to 2 mm) air passages parallel to the direction of airflow. Air passages are very similar in performance regardless of their shape (triangular, hexagonal, parallel plate, or other). Aluminum foil, paper, plastic, and synthetic materials are used for low and medium temperatures. Stainless steel and ceramics are used for high temperatures and corrosive atmospheres.

Media surface areas exposed to airflow vary from 300 to over 4000 m^2/m^3, depending on the type of medium and physical configuration. Media may also be classified by their ability to recover sensible heat only or total heat. Media for sensible heat recovery are made of aluminum, copper, stainless steel, and monel. Media for total heat recovery can be from any of a number of materials and treated with a desiccant (typically zeolites, molecular sieves, silica gels, activated alumina, titanium silicate, synthetic polymers, lithium chloride, or aluminum oxide) to have specific moisture recovery characteristics.

Cross-Leakage. Cross-leakage (mixing between supply and exhaust airstreams) can occur in all rotary energy exchangers by two mechanisms: carryover and seal leakage. Refer to the Air Leakage section of this chapter for more detail on these two methods of leakage and description of how to measure and rate cross-leakage.

Measures can be taken to reduce cross-leakage, though reduction may result in an energy penalty to process additional outdoor air. Cross leakage can be reduced by placing the blowers to maintain at least 125 Pa greater static pressure in the leaving supply airstream than the entering exhaust airstream, thereby promoting leakage of outdoor air to the exhaust airstream. A purge section also can be installed on the heat exchanger to reduce exhaust air leakage from carryover. A purge section is a section of wheel that directs outdoor air through the wheel and into the exhaust air outlet to remove any entrained exhaust air before rotating back into the supply airstream.

In many applications, some air recirculation due to cross-leakage is not a concern. However, critical applications such as hospital operating rooms, laboratories, and cleanrooms require stringent control of carryover. Carryover can be reduced to less than 0.1% of the exhaust airflow with a purge section but cannot be completely eliminated.

The theoretical carryover of a wheel without a purge section is directly proportional to the speed of the wheel and the void volume of the medium (75 to 95% void, depending on type and configuration). For example, a 3 m diameter, 200 mm deep wheel with a 90% void volume operating at 14 rpm has a carryover volumetric flow of

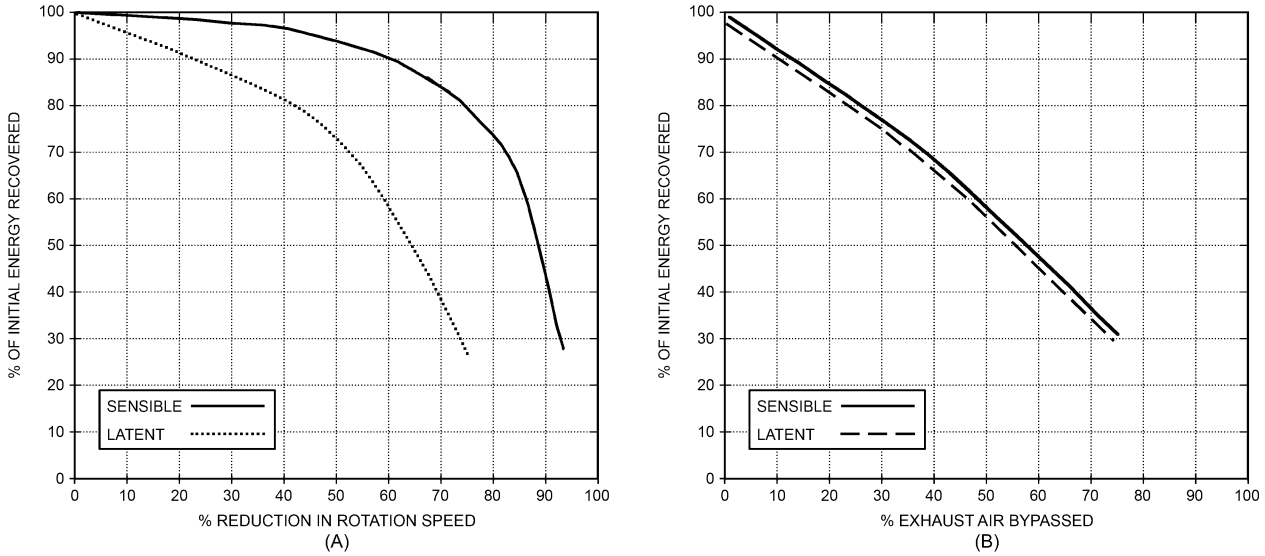

Fig. 7 Latent and Sensible Effectiveness Versus (A) Wheel Speed and (B) Bypassed Air

(Moffitt 2010)

$$\pi(3/2)^2(0.2)(0.9)(14/60) = 0.3 \text{ m}^3/\text{s}$$

If the wheel is handling a 9 m^3/s balanced flow, the percentage carryover is

$$\frac{0.3}{9} \times 100 = 3.3\%$$

The exhaust fan, which is usually located at the exit of the exchanger, should be sized to include leakage and purge airflows. The supply fan should be sized to account for any outdoor air correction factor of the rotary exchanger.

Modulating Energy Recovery. Two control methods are commonly used to regulate wheel energy recovery: supply or return air bypass and variation of the wheel rotation speed. These methods may be used to limit heat exchange when it is not beneficial. See the Controls and Defrost Control sections for additional detail on specific energy recovery control measures.

In **supply** or **exhaust air bypass** control, the amount of supply air allowed to pass through the wheel establishes the supply air temperature. An air bypass damper, controlled by a wheel supply air discharge temperature sensor, regulates the proportion of supply air permitted to bypass the exchanger.

The second method regulates the energy recovery rate by varying wheel rotational speed. The most frequently used **variable-speed drives** are (1) a silicon controlled rectifier (SCR) with variable-speed dc motor, (2) a constant-speed AC motor with hysteresis coupling, and (3) an AC frequency inverter with an AC induction motor. The dehumidification capacity and reheating effectiveness of a energy wheel can be varied by changing the wheel speed (Figure 7A) or by bypassing air around the wheel (Figure 7B) (Moffitt 2010). Figure 7A is a typical capacity curve for varying the wheel's rotation speed when the outdoor air is cooler and drier than the exhaust air; when outdoor air conditions are cooler and more humid, capacity may increase at low speeds (Simonson et al. 2000).

Figure 8 shows the effectiveness ε, sensible heat transfer only, with balanced airflow, convection/conduction ratio less than 4, and no leakage or cross-flow, of a regenerative counterflow heat wheel versus number of transfer units (NTU). This simple example of a regenerative wheel also shows that regenerative counterflow rotary effectiveness increases with wheel speed (C_r is proportional to wheel speed), but there is no advantage in going beyond C_r/C_{min} = 5

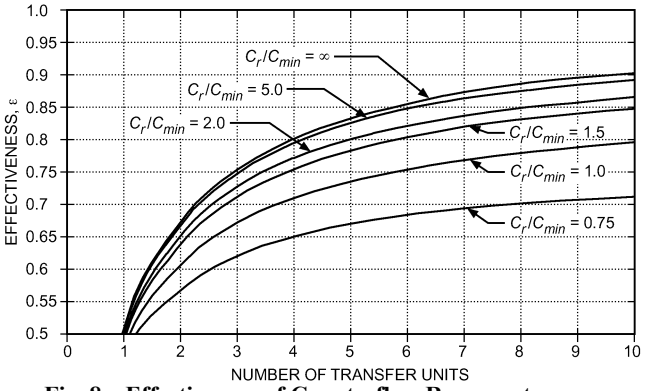

Fig. 8 Effectiveness of Counterflow Regenerator as a Function of NTU

(Shah 1981)

because the carryover of contaminants increases with wheel speed. See Kays and Crawford (1993) or Shah (1981) for details.

Rotary energy or enthalpy wheels are more complex than sensible wheels, but recent research has characterized their behavior using laboratory and field data (Johnson et al. 1998).

A dead band control, which stops or limits the exchanger, may be necessary when no recovery is desired (e.g., when outdoor air temperature is higher than the required supply air temperature but below the exhaust inlet air temperature). When outdoor air temperature is above the exhaust air temperature, the equipment operates at full capacity to cool incoming air. During very cold weather, it may be necessary to heat the supply air, stop the wheel, or, in small systems, use a defrost cycle for frost control.

Maintenance and Operation. Rotary energy recovery wheels require little maintenance and tend to be self-cleaning because the airflow direction is reversed for each rotation of the wheel. The following maintenance procedures ensure best performance:

- At commissioning of the rotary exchanger, inspect seals and set purge angle if purge section is included. Verify direction of wheel rotation.
- Clean the medium when lint, dust, or other foreign materials build up, following the manufacturer's instructions.

- Maintain drive motor and train according to the manufacturer's recommendations. Speed-control motors that have commutators and brushes require more frequent inspection and maintenance than induction motors. Brushes should be replaced, and the commutator should be periodically turned and undercut.
- Inspect wheels regularly for proper belt or chain tension. Inspect seals regularly for signs of wear and replace if necessary.
- Refer to the manufacturer's recommendations for spare and replacement parts.

Coil Energy Recovery (Runaround) Loops

A typical coil energy recovery loop (Figure 9) places extended-surface, finned-tube water coils in the supply and exhaust airstreams of a building or process. The coils are connected in a closed loop by counterflow piping through which an intermediate heat transfer fluid or a working fluid (typically water mixed with ethylene or propelyne glycol) is pumped. Coil energy recovery loops are highly flexible. The loop accommodates remote supply and exhaust ducts and allows simultaneous transfer of energy between multiple sources with zero cross contamination between airstreams. This makes them well suited to renovation, industrial applications, laboratories, and hospitals. In critical environments, the system is equipped with *N*+1 redundancy on pumps so, if one fails, the system can continue to run at 100% output.

As with other sensible recovery technologies, some means of frost control should be applied in very cold climates, to avoid condensation forming on the exhaust coil and freezing. By maintaining an exhaust leaving air temperature above freezing (e.g., 2°C) any condensation formed on the fins will not freeze. This is achieved by reducing energy recovery performance, through either reducing working fluid flow in the system (i.e., pump speed), or partially bypassing the supply coils (bypass valve). Controlling pump speeds and valve positions can also be used to maintain the supply air leaving temperature. When the system is not required to recover energy (e.g. economizer mode), then the pumps can be turned off altogether.

An expansion tank must be included to allow fluid expansion and contraction. A closed expansion tank minimizes oxidation when ethylene glycol is used.

Standard finned-tube water coils may be used; however, these need to be selected using an accurate simulation model if high effectiveness and low costs are needed (Johnson et al. 1995). Integrating runaround loops in buildings with variable loads to achieve maximum benefits may require combining the runaround simulation with building energy simulation (Dhital et al. 1995). Manufacturers' design curves and performance data should be used when selecting coils, face velocities, and pressure drops, but only when the design data are for the same temperature and operating conditions as in the runaround loop.

When testing chilled-water coils for certification, AHRI *Standard* 410 requires testing in the range of 1.7 to 12.8°C. Care should be taken when using manufacturers' selection programs for sizing coils for runaround loops. It is common to use a cooling coil design for these systems, but average water temperatures can vary outside the range for which these coils are typically used. For example, in commercial comfort conditioning, average water temperatures in a runaround loop can range from –4°C (–29°C outdoors, 21°C return) to 27°C (35°C outdoors, 24°C return) in a single application, whereas cooling coils are normally applied using a steady chilled-water supply designed from a narrower range.

The coil energy recovery loop cannot transfer moisture between airstreams; however, indirect evaporative cooling can reduce the exhaust air temperature, which significantly reduces cooling loads. For the most cost-effective operation, with equal airflow rates and no condensation, typical effectiveness values range from 45 to 65%.

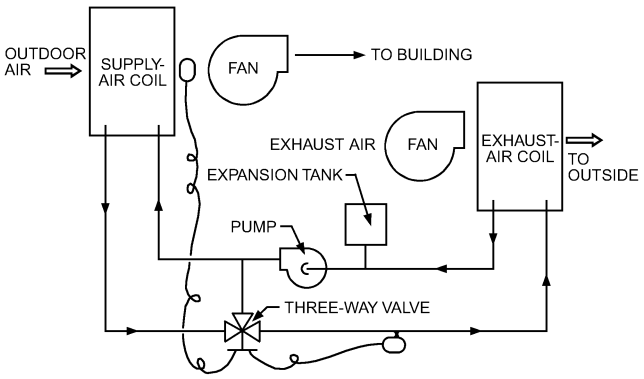

Fig. 9 Coil Energy Recovery Loop

The highest effectiveness does not necessarily give the greatest net life-cycle cost saving.

Typically, the sensible heat effectiveness of a coil energy recovery loop is independent of the outdoor air temperature. However, when the capacity is controlled, the sensible heat effectiveness decreases.

Coil energy recovery loops use coils constructed to suit their environment and operating conditions. For typical comfort-to-comfort applications, standard coil construction usually suffices. In process-to-process and process-to-comfort applications, the effect of high temperature, condensable gases, corrosives, and contaminants on the coil(s) must be considered. Above 200°C, special construction may be required to ensure a permanent fin-to-tube bond. The effects of condensable gases and other adverse factors may require special coil construction and/or coatings. Chapters 23 and 27 discuss the construction and selection of coils in more detail.

Complete separation of the airstreams eliminates cross-contamination between the supply and exhaust air.

Coil energy recovery loops require little maintenance. The only moving parts are the circulation pump and three-way control valve. However, to ensure optimum operation, the air should be filtered, the coil surface cleaned regularly, the pump and valve maintained, and the transfer fluid refilled or replaced periodically. Fluid manufacturers or their representatives should be contacted for specific recommendations.

The thermal transfer fluid selected for a closed-loop exchanger depends on the application and on the temperatures of the two airstreams. An inhibited ethylene glycol solution in water is common when freeze protection is required. These solutions break down to an acidic sludge at temperatures above 135°C. If freeze protection is needed and exhaust air temperatures exceed 135°C, a nonaqueous synthetic heat transfer fluid should be used. Heat transfer fluid manufacturers and chemical suppliers should recommend appropriate fluids.

Due to the flexibility of the runaround loop, systems can incorporate an array of features:

- Multiple airstreams with a unique supply leaving temperature set point for each airstream
- Many-to-one airstreams (e.g., many exhaust ducts to a common supply duct)
- Heat injection, where hot water or steam supplies heat to the working fluid directly, eliminating the need for hot-water coils in the air-handling unit(s) (Figure 10)
- Precool-reheat, placing two supply coils in a supply airstream, one upstream of the cooling coil and one downstream, to further improve energy recovery when dehumidification is required (Figure 11)

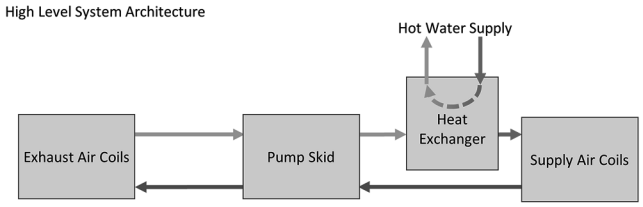

Fig. 10 Adding Supplemental Heat to the System

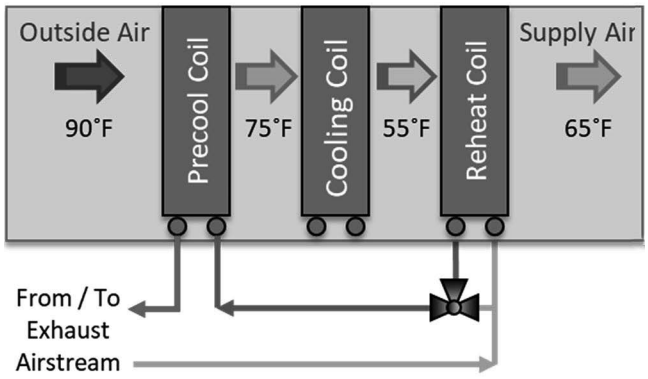

Fig. 11 Coil Energy Recovery Loop

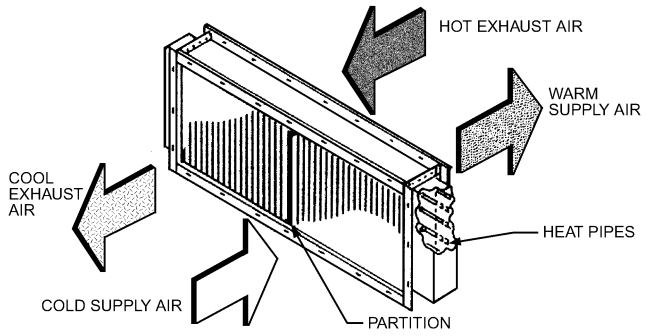

Fig. 12 Heat Pipe Assembly

Heat Pipe Heat Exchangers

Figure 12 shows a typical heat pipe assembly. Hot air flowing over the evaporator end of the heat pipe vaporizes the working fluid. A vapor pressure gradient drives the vapor to the condenser end of the heat pipe tube, where the vapor condenses, releasing the latent energy of vaporization (Figure 13). The condensed fluid is wicked or flows back to the evaporator, where it is revaporized, thus completing the cycle. Thus the heat pipe's working fluid operates in a closed-loop evaporation/condensation cycle that continues as long as there is a temperature difference to drive the process. Using this mechanism, the heat transfer rate along a heat pipe is up to 1000 times greater than through copper (Ruch 1976).

Energy transfer in heat pipes is often considered isothermal. However, there is a small temperature drop through the tube wall, wick, and fluid medium. Heat pipes have a finite heat transfer capacity that is affected by factors such as wick design, tube diameter, working fluid, and tube (heat pipe) orientation relative to horizontal. In current designs, a wick is replaced by circumferential grooves that facilitate capillary-action flow of condensed refrigerant back to the evaporator section.

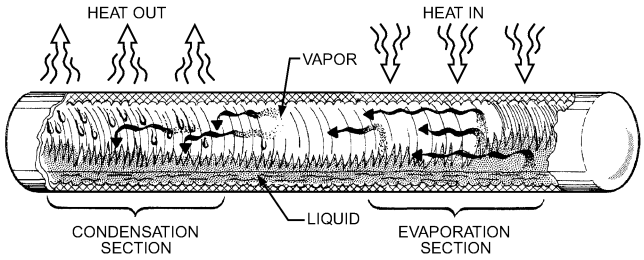

Fig. 13 Heat Pipe Operation

HVAC systems use copper or aluminum heat pipe tubes with aluminum or copper fins. Fin designs include continuous corrugated plate, continuous plain, and spiral. Modifying fin design and tube spacing changes pressure drop at a given face velocity.

For process-to-comfort applications with large temperature changes, tubes and fins are usually constructed of the same material to avoid problems with different thermal expansions of materials. Heat pipe heat exchangers for exhaust temperatures below 220°C are most often constructed with aluminum or copper tubes and fins. Protective coatings allow inexpensive aluminum to replace exotic metals in corrosive atmospheres; these coatings have a minimal effect on thermal performance.

Heat pipe heat exchangers for use above 220°C are generally constructed with steel tubes and fins. The fins are often aluminized to prevent rusting. Composite systems for special applications may be created by assembling units with different materials and/or different working fluids.

Selecting the proper working fluid for a heat pipe is critical to long-term operation. The working fluid should have high latent heat of vaporization, a high surface tension, and a low liquid viscosity over the operating range; it must be thermally stable at operating temperatures. Decomposition of the thermal fluids can form noncondensable gases that deteriorate performance. For low-temperature applications, gases such as helium can be used as working fluid; for moderate temperatures, commercial refrigerants and liquids such as water can be used; and for high temperatures, liquid metals such as sodium or mercury can be used.

Heat pipe heat exchangers typically have no cross-contamination for pressure differentials between airstreams of up to 12 kPa. A vented double-wall partition between the airstreams can provide additional protection against cross contamination. If an exhaust duct is attached to the partition space, any leakage is usually withdrawn and exhausted from the space between the two ducts. Similarly, an extended space can be created between the airstreams, where the space around the pipes is packed, or sealed, with an expanding foam.

Heat pipe heat transfer capacity depends on design and orientation. Figure 14 shows a typical effectiveness curves for various face velocities and rows of tubes. As the number of rows increases, effectiveness increases at a decreasing rate. For example, doubling the number of rows of tubes in a 60% effective heat exchanger increases the effectiveness to 75%. The effectiveness of a counterflow heat pipe heat exchanger depends on the total number of rows such that two units in series yield the same effectiveness as a single unit of the same total number of rows. Series units are often used to facilitate handling, cleaning, and maintenance. Effectiveness also depends on outdoor air temperature and the ratio of mass flow rates of the airstreams. Typically, heat capacity in the cooling season increases with a rise in outdoor air temperature. It has an opposite effect during the heating season. Effectiveness typically increases with the ratio of mass flow rates of the fluids (flow rate of the fluid with warmer entering temperature over that of cooler entering fluid temperature).

The heat transfer capacity of a heat pipe increases roughly with the square of the inside diameter of the pipe. For example, at a given tilt angle, a 25 mm inside diameter heat pipe will transfer roughly 2.5 times as much energy as a 16 mm inside diameter pipe. Consequently, heat pipes with large diameters, or tubes joined into a circuit, are used for larger-airflow applications and where level installation is required to accommodate both summer and winter operation.

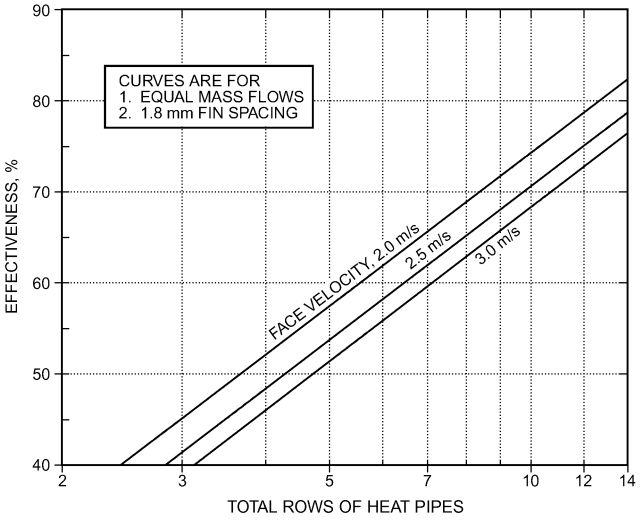

Fig. 14 Heat Pipe Exchanger Effectiveness

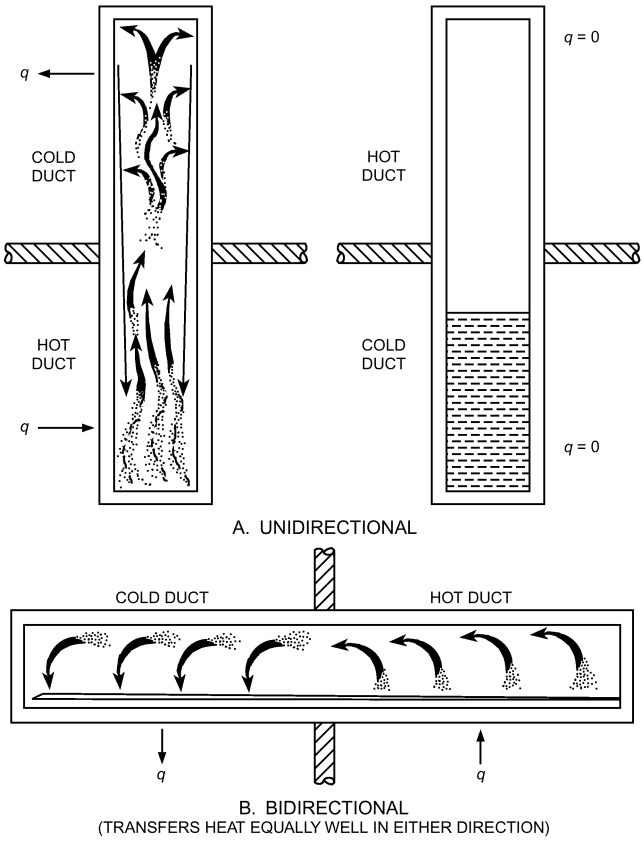

Fig. 15 Sealed-Tube Thermosiphons

Heat transfer capacity is virtually independent of heat pipe length, except for very short heat pipes. A system can be reconfigured to a taller face height and more numerous but shorter heat pipes to yield the same airflow face area while improving system performance. Also, under limiting conditions, adding rows increases performance more proportionally. In typical HVAC comfort applications, the heat pipe capacity is not reached, and longer heat pipes can be used to recover more energy. The limit for a level (two-season) 12.7 mm-diameter heat pipe, using R-410A and six rows deep, is 5080 mm in most HVAC comfort applications.

The selection of fin design and spacing should be based on the dirtiness of the two airstreams and the resulting cleaning and maintenance required. For HVAC applications, fin spacing of 1.8 to 2.3 mm is common. Wider spacing (2.5 to 3.2 mm) is usually used for industrial applications. Plate-fin heat pipe heat exchangers can easily be constructed with different fin spacing for the exhaust and supply airstreams, allowing wider fin spacing on the dirty exhaust side. This increases design flexibility where pressure drop constraints exist and also prevents deterioration of performance caused by dirt build-up on the exhaust side surface.

Changing the tilt of a heat pipe controls the amount of heat it transfers. Operating the heat pipe on a slope with the hot end below (or above) the horizontal improves (or retards) condensate flow back to the evaporator end of the heat pipe. This feature can be used to improve performance in one season over another. For example, in much of North America there is more sensible energy recovery opportunity in winter than in summer, due to both the number of hours the heat pipe is in heating mode and the difference in temperatures between outdoor air and return air.

Tilting can also be used to control heat pipe performance, by pivoting the heat pipe with an actuator around a fulcrum. This is typically not used in zero-cross-contamination applications because the airstreams are separated by a flexible interface and it is difficult to maintain an acceptable seal over years of service.

Capacity and frost control can also be achieved through bypassing airflow over the heat pipes, as for air coils. Bypassing airflow is

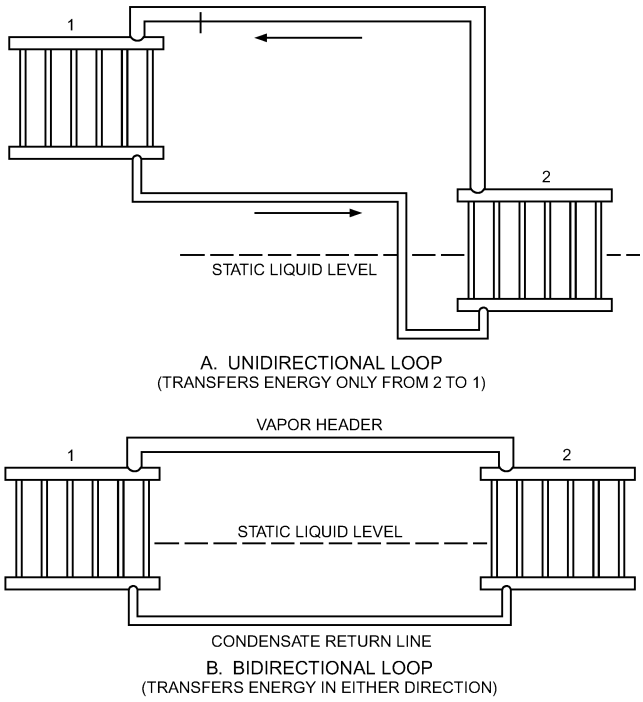

Fig. 16 Coil-Type Thermosiphon Loops

the preferred method of control in applications where the average (annual) recovery efficiency ratio (RER) is important, because the reduced airflow through the heat pipe results in reduced air pressure losses during periods of modulation.

Thermosiphon Heat Exchangers

Two-phase thermosiphon heat exchangers are sealed systems that consist of an evaporator, a condenser, interconnecting piping, and an intermediate working fluid that is present in both liquid and vapor phases. Two types of thermosiphon are used: a sealed tube (Figure 15) and a coil type (Figure 16). In the sealed-tube thermosiphon, the evaporator and the condenser are usually at opposite ends of a bundle of straight, individual thermosiphon tubes, and the exhaust and supply ducts are adjacent to each other (this arrangement is similar to that in a heat pipe system). In coil-type thermosiphons, evaporator and condenser coils are installed independently in the ducts and are interconnected by the working fluid piping (this configuration is similar to that of a coil energy recovery loop). A thermosiphon is a sealed system containing a two-phase working fluid. Because part of the system contains vapor and part contains liquid, the pressure in a thermosiphon is governed by the liquid temperature at the liquid/vapor interface. If the surroundings cause a temperature difference between the regions where liquid and vapor interfaces are present, the resulting vapor pressure difference causes vapor to flow from the warmer to the colder region. The flow is sustained by condensation in the cooler region and by evaporation in the warmer region. The condenser and evaporator must be oriented so that the condensate can return to the evaporator by gravity (Figures 15 and 16). For coil-type thermosiphon loops (Figure 16), static liquid level or refrigerant charge has a significant effect on system performance. The static charge should be optimized: a low static charge leads to dryout in the evaporator and reduced system performance, and a high charge suppresses condensation in the condenser. When the coils are on the same vertical level, as in Figure 15B, a certain amount of suppressed condensation in the condenser is inevitable because a certain static liquid head is required in the bottom of the condenser to drive liquid through the loop into the evaporator (Wei Qu 2010). Figure 17A shows a typical temperature change profile along the vertical section of a condenser, where lower ΔT indicates loss of energy recovery potential, and the thermosiphon manufacturer should quote performance as an average across the whole airstream. Wei Qu (2010) found that the condenser need not be placed much higher than the evaporator to reach full potential; Figure 17B shows that raising the condenser 25 to 30% of the coil face height above the evaporator can result in negligible variation in the temperature profile.

In thermosiphon systems, a temperature difference and gravity force are required for the working fluid to circulate between the evaporator and condenser. As a result, thermosiphons may be designed to transfer heat equally in either direction (bidirectional), in one direction only (unidirectional), or in both directions unequally. In many applications in North America, designing for both directions unequally will produce the most annual energy savings, with a focus on the heating season, where (1) there are more hours during heating and the driving difference in temperatures are greater, and (2) there is still reasonable energy recovery available in cooling mode.

Although similar in form and operation to heat pipes, thermosiphon tubes are different in two ways: (1) they have no wicks and hence rely only on gravity to return condensate to the evaporator, whereas heat pipes use capillary forces; and (2) they depend, at least initially, on nucleate boiling, whereas heat pipes vaporize the fluid from a large, ever-present liquid/vapor interface. Thus, thermosiphon heat exchangers may require a significant temperature difference to initiate boiling (Mathur and McDonald 1987; McDonald and Shivprasad 1989). Thermosiphon tubes require no pump to circulate the working fluid. However, the geometric configuration must be such that liquid working fluid is always present in the evaporator section of the heat exchanger.

Thermosiphon loops differ from other coil energy recovery loop systems in that they require no pumps and hence no external power supply, and the coils must be appropriate for evaporation and condensation. Two-phase thermosiphon loops are used for solar water heating (Mathur 1990a) and for performance enhancement of existing (i.e., retrofit applications) air-conditioning systems (Mathur 1997a, 1997b, 1997c, 1997d). Two-phase thermosiphon loops can be used to downsize new air-conditioning systems and thus reduce the overall project costs. Figures 18 and 19 shows thermosiphon loop performance (Mathur and McDonald 1986) for an eight-row, system with 2 mm fin spacing in unidirectional mode. shows the performance of the same system as a function of percent static charge for an overall temperature difference of XX. Contemporary commercial systems are designed with commercial refrigerants. Lower-pressure refrigerants, such as R-134a, are usually chosen to keep the larger-diameter transfer tubes within a safe working pressure, compared to smaller-diameter heat pipes. These systems have been designed with various working fluids like *n*-pentene and R-134a (Samba et al. 2013) with lower saturation pressures at atmospheric pressure, water (Mathur 1994) at negative operating pressures at typical ambient condition, and napthalene for high-temperature applications (Orr et al. 2016).

These energy recovery systems are available to enhance system performance (similar to heat pipe heat exchangers) of existing systems (Cieslinski and Fiuk 2013; Mathur 1994; Yau 2007) or to downsize new equipment. Using two-phase thermosiphon loop systems or other energy recovery systems can improve the overall EERs of the systems and can earn significant LEED® points. These systems are also used for exhaust heat recovery for automotive application (Orr et al. 2016) and for cooling telecommunications systems (Samba et al. 2013).

Example 2. Sensible Heat Energy Recovery in Two-Phase Thermosiphon Loop. Outdoor air at –12°C enters an eight-row. two-phase thermosiphon loop with a face area of 0.2 m at a face velocity of 2.2 m/s. Exhaust air enters the two-phase thermosiphon loop with the same velocity with same face area at _24°C. Pressure drop across the heat pipe is 0.18 kPa. The supply air density is 1.35 kg/m^3. Efficiencies of the electric motor and connected fan are 90 and 75%, respectively. Assuming the performance characteristics of the two-phase thermosiphon as shown in Figure 26, determine the sensible effectiveness $\varepsilon_{sensible}$, exit temperature of supply air to the space T_2, sensible energy recovered q_s, and power supplied to the fan motor p_s.

Solution:

From the data given, the overall temperature difference between supply and exhaust airstreams is 36 K [i.e., 24 – (–12) = 36]. From Figure 17, at face velocity of 2.2 m/s and with eight rows, the effectiveness is about 52.5%. Because the mass flow rate of the airstreams is the same, and, for simplification, assuming specific heat is constant at 1.0 kJ/(kg·K), then the exit temperature of the supply air to the space can be obtained as follows:

$$t_2 = -12 + 0.525[24 - (-12)] = 6.9°C$$

The sensible energy recovered can be obtained from a variation of Equation (5a) as

$$q_s = (2.2)(0.2)(1.35)(1.0)[6.9 - (-12)] = 11.2 \text{ kW}$$

The supply air fan power can be obtained using Equation (8) as

$$Q_s = (2.2)(0.2) = 0.44 \text{ m}^3/\text{s}$$

$$P_s = [(0.44)(0.18)]/[(0.9)(0.75)] = 117 \text{ W}$$

Because there are two airstreams, the total pumping power of the two-phase thermosiphon loop (neglecting the differences in air den-

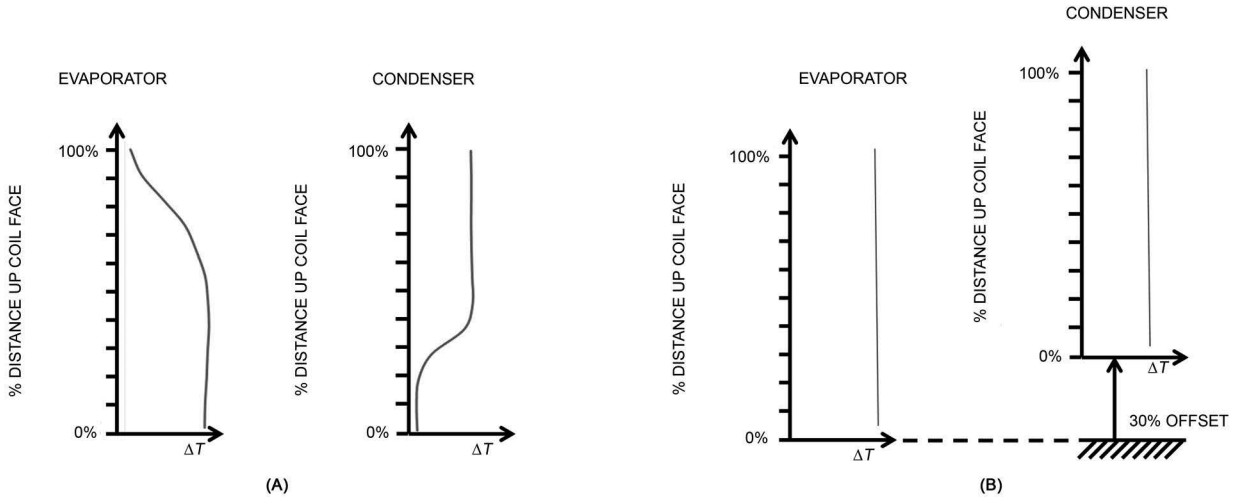

Fig. 17 Heat Recovered Across Evaporator and Condenser Coils for (A) Level Thermosiphon and (B) Thermosiphon with Elevated Condenser

sity between the airstreams) is approximately twice the value of P_s (i.e., 234 W).

Liquid-Desiccant Cooling Systems

Liquid-desiccant cooling systems (LDCSs) have great potential in reducing energy costs associated with meeting latent loads in high-occupancy commercial building applications. An LDCS can produce very dry air as long as the desiccant solution is supplied to its dehumidifier at low temperatures. However, an LDCS requires additional components: two or three plate-to-plate heat exchangers, a separate cooling tower, pump, fan, and a packed-bed humidifier and regenerator.

When exposed to moist air at the proper temperature and concentration, some chemical solutions (e.g., lithium chloride, lithium bromide, calcium chloride, triethylene glycol) can either absorb water vapor from, or release water vapor to, the airstream. These chemicals, known as liquid desiccants, are used to dehumidify air with significantly less energy consumption than by a mechanical refrigeration system. Liquid desiccants also have the advantage of removing bacteria and dust from the air compared to solid desiccant wheels or mechanical vapor compression systems. It requires a lower-temperature (less than 82°C) heat source for regeneration, which can be provided by solar energy or waste heat from local equipment. Moisture transfer between the desiccant solution and process air is caused by the difference in vapor pressures at the desiccant surface and that of the air passing over it. The desiccant collects moisture when its vapor pressure is lower than that of the water vapor in the air, and releases it when its vapor pressure is higher. Absorption of water vapor releases heat energy, including the heat of vaporization and, in some cases, additional heat. After absorbing water vapor from the processes air, the solution temperature increases slightly, and its concentration drops as absorbed water vapor becomes part of the solvent of the solution. For cyclic operation, the desiccant solution is regenerated to restore its original concentration; this involves heating the solution with a low-grade heat source and exposing the heated solution to an airstream, as shown in Figure 20 (Williams 2007). Often, outdoor air is used as a scavenging airstream in regeneration. Heat added to the desiccant solution for regeneration is of low grade and can be obtained from a source at no more than 71°C. Such low-temperature energy sources are often available as waste heat in many applications.

As seen in Figure 20, the hot, humid process air to be dehumidified enters the packed-bed dehumidifier or absorber at state 1 and leaves at state 2. The concentrated desiccant solution enters the absorber at state 5 and leaves at state 6 as dilute solution after absorbing water vapor from the process airstream. The dilute solution now passes through a liquid-to-liquid plate heat exchanger to recover some of the heat energy from the concentrated solution exiting the regenerator. The dilute solution is heated further to the required temperature in the desiccant solution heating coil and is sprayed over the incoming outdoor scavenging air passing through the regenerator. For air-to-air energy recovery purposes, the exhaust air from the space can be used for greater effectiveness in place of outdoor scavenging air. Because of the high inlet temperature of the desiccant solution, its vapor pressure is relatively higher than that of the incoming air, causing moisture transfer from the solution to the air. The inlet temperature of the desiccant solution to the regenerator for the given state of the air at state 8 is such that the desiccant concentration is restored to its value at state 6 as it exits the regenerator. The concentrated desiccant solution leaving the regenerator transfers heat energy to the incoming dilute solution exiting the packed-bed dehumidifier, in the liquid-to-liquid plate heat exchanger. Further temperature reduction of the desiccant solution, if required before it enters the absorber, can be accomplished by using cooling water from a cooling tower in the desiccant cooling coil. During extreme high-latent-load conditions, chilled water, rather than water from a cooling tower, may be necessary to cool the desiccant solution before it enters the absorber. The temperature of the solution at the inlet of the absorber strongly influences the air-dehumidifying capacity. The higher the concentration and lower the temperature of the solution, the higher the moisture absorbed and lower the humidity of the exiting air from the absorber.

Types of Desiccant Solutions. Desiccant solutions used by different investigators, as well as their key features, are shown in Table 2. Lithium chloride (LiCl) is a good candidate material because it has good desiccant characteristics and does not vaporize in air at ambient temperature, but it is corrosive. Calcium chloride ($CaCl_2$) is an equally good candidate for desiccant choice and is less expensive than LiCl. A 50%/50% combination of LiCl and $CaCl_2$ is also being investigated. Triethylene glycol (TEG) has a low vapor pressure that enables effective dehumidification in the absorber, but it also makes it vulnerable to evaporation. Special coatings may be

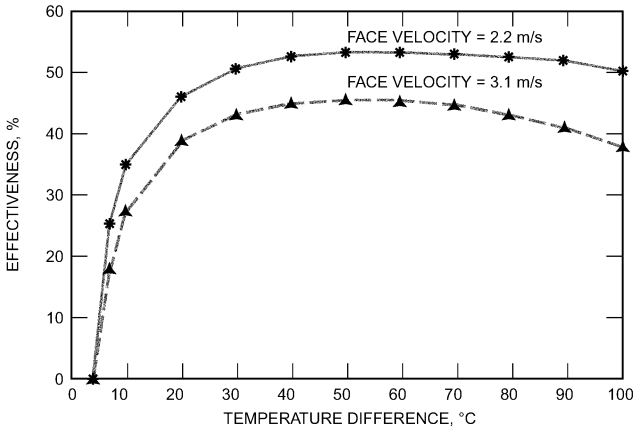

Fig. 18 Eight-Row, Unidirectional System with 2 mm Fin Spacing; Static Charge of 80%

(Mathur and McDonald 1986)

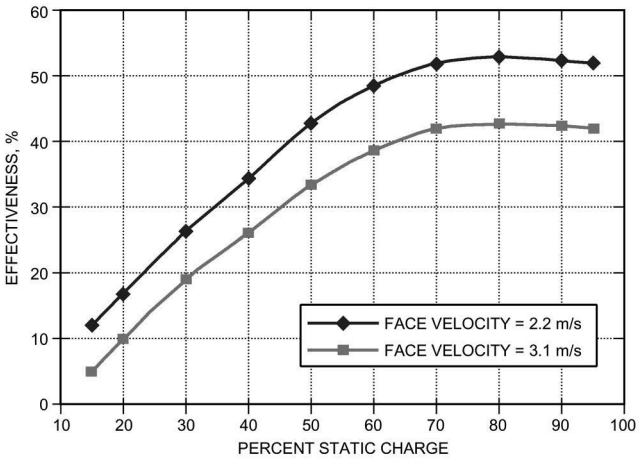

Fig. 19 Typical Performance of Two-Phase Thermosiphon Loop as Function of Percent Static Charge: Eight Rows, Unidirectional System with 2 mm Fin Spacing; Overall Temperature Difference of 35 K

(Mathur and McDonald 1986)

required to avoid corrosion, and efficient absorber design may be needed to prevent liquid or desiccant carryover.

Fluid Flow Configuration. Four different types of fluid flow configurations are used by different investigators in the packed beds for absorbers and regenerators.

- Counter flow
- Parallel flow
- Cross flow
- Falling film

Most applications are counter flow, because it provides the maximum enthalpy and humidity effectiveness for the packed beds.

Types of Packing. Packing arrangements are basically either structured or random types. In some cases, vertical surfaces or tubes are used, over which the desiccant solution falls as a thin film. The purpose of packing is to provide the maximum surface area for the desiccant solution to come in contact with the process air. The greater the area, the greater the dehumidification. The main parameters affecting bed arrangement are the enhancement of heat and mass transfer, air pressure drop, and pumping power to circulate the fluids through the bed. The main advantage of structured packing is the low pressure drop, whereas that of random packing is high heat and mass transfer but with high pressure drop. Packing compactness is typically expressed in terms of packing density a_t, in units of m^2/m^3. Typically, packing densities exceeding 200 m^2/m^3 have been achieved in the field. A higher packing density allows for more dehumidification but also produces greater pressure drop for the fluid streams. In random packing arrangements, packing is made up of Berl saddles, Raschig rings, and saddles of various trademarked designs, whereas in structured packing, the packing consists of cellulose rigid media pads, wood grids, expanded metal lash packing, or double spiral rings.

Table 2 Types of Liquid-Desiccant Solutions

Desiccant Type	Typical Concentration Range, %	Operating Temperatures, °C
LiCl	34 to 43	25 to 27
TEG	92 to 98	20.2 to 45.5
LiBr	42.6 to 57	20.1 to 34.1
$CaCl_2$	40 to 43	27.0
KCOOH	72.8 to 74	21.9 to 24.8

Twin-Tower Enthalpy Recovery Loops

One method of ventilation air enthalpy recovery is liquid desiccant twin-tower systems. In this air-to-liquid, liquid-to-air enthalpy recovery system, sorbent liquid circulates continuously between supply and exhaust airstreams, alternately contacting both airstreams directly in contactor towers (Figure 21). This liquid transports water vapor and heat. The sorbent solution is usually a halogen salt solution such as lithium chloride, calcium chloride, and water. Pumps circulate the solution between supply and exhaust contactor towers.

Both vertical and horizontal airflow contactor towers are available, and both types can be combined in a common system. Contactor towers of both configurations are commonly available with airflow capacities of up to 40 m^3/s.

In the vertical configuration, the supply or exhaust air passes vertically through the contact surface counterflow to the sorbent liquid to achieve high contact efficiency. In the horizontal configuration, air passes horizontally through the contact surface cross flow to the sorbent liquid, yielding a slightly lower contact efficiency.

The contactor surface is usually made of nonmetallic materials. Air leaving the contactor tower passes through demister pads, which remove any entrained sorbent solution. The halogen salt solution does not offgas or vaporize.

Design Considerations. Twin-tower enthalpy recovery systems operate primarily in the comfort conditioning range; they are not suitable for high-temperature applications. During summer, these systems operate efficiently with building supply outdoor air temperatures as high as 46°C. Winter supply air temperatures as low as –40°C can be tolerated without freezing or frosting problems because the sorbent solution is an effective antifreeze at all useful concentrations. During weather conditions that are not advantageous for energy recovery, the system automatically shuts down the pump(s), thereby saving operating power. When outdoor conditions warrant energy recovery, the system restarts automatically. Because contactor supply and exhaust air towers are independent units connected only by piping, supply and exhaust air fans can be located wherever desired. Contactor towers can operate with air inlet static pressure from –1.5 to 1.5 kPa, but require less than 0.4 kPa air-side pressure drop. The exhaust contactor tower may operate at a higher internal static pressure than the supply contactor tower without danger of exhaust-to-supply cross contamination.

Particulate cross contamination does not occur because wetted particulates remain in the sorbent solution until they are filtered. Limited gaseous cross contamination may occur, depending on the

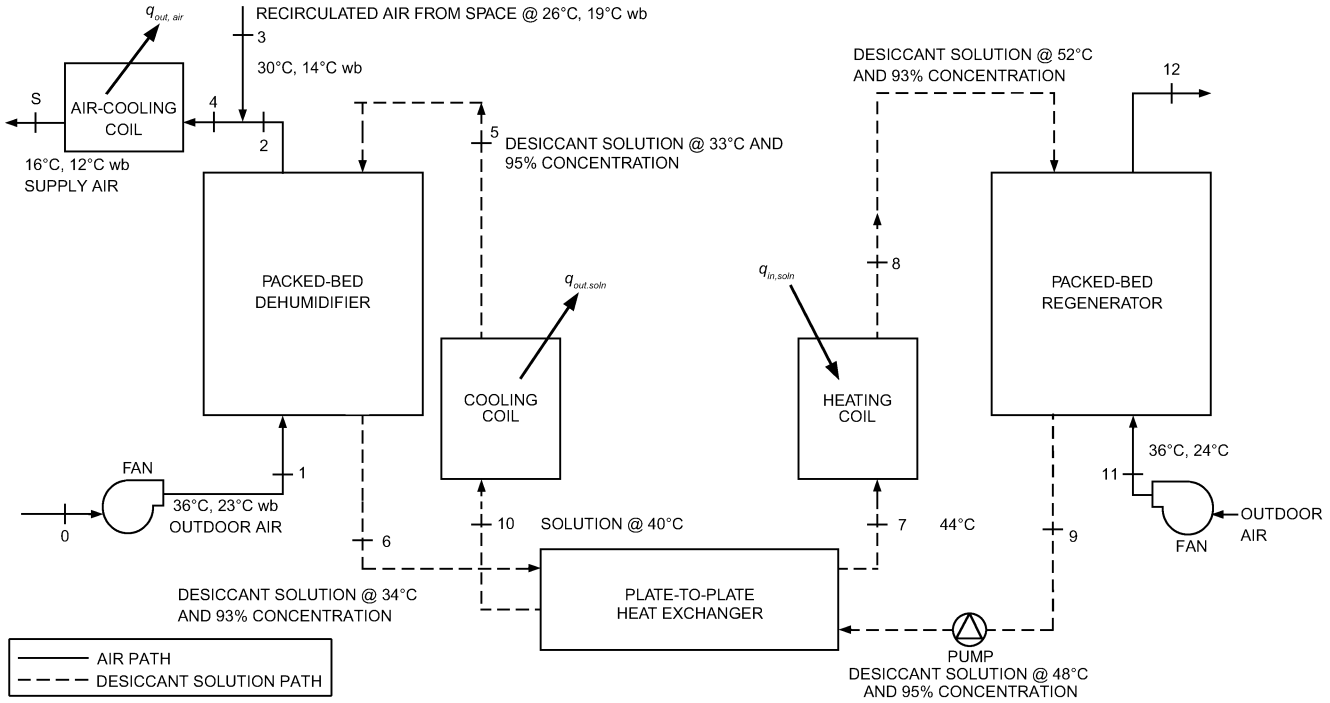

Fig. 20 Typical Dehumidification of Outdoor Air by Liquid-Desiccant System

(Williams 2007)

solubility of the gas in the sorbent solution. Sorbent solutions, especially halide brines, are bactericidal. Lithium or calcium chloride as used in twin-tower systems is viricidal against all viruses.

If the building or process exhaust contains large amounts of lint, animal hair, or other solids, filters should be placed upstream of the exhaust air contactor tower; if it contains large amounts of gaseous contaminants, such as chemical fumes and hydrocarbons, investigate the possibility of cross contamination as well as the possible effects of contaminants on the sorbent solution. When using twin-tower systems in controlled-humidity applications in colder climates, saturation effects (which can cause condensation, frosting, and icing in other types of equipment) may overdilute the twin towers' sorbent solution. Heating the sorbent liquid supplied to the supply air contactor tower can prevent dilution, as shown in Figure 21A. Heating raises the discharge temperature and humidity of air leaving the supply contactor tower, thus balancing the humidity of the system and preventing overdilution.

A thermostat sensing the leaving air temperature from the supply air contactor tower is commonly used to control the solution heater to deliver constant-temperature air regardless of outdoor temperature. Automatic addition of makeup water to maintain a fixed concentration of the sorbent solution enables the twin-tower system to deliver supply air at fixed humidity during cold weather. Thus, the system provides a constant supply air temperature and humidity without preheat or reheat coils or humidifiers.

Any number of supply air towers can be combined with any number of exhaust air towers, as shown in Figure 21B. If a sufficient elevation difference exists between supply and exhaust towers, gravity may be used to return the sorbent solution from the upper tower(s) in lieu of pumped flow. Twin-tower energy recovery systems can be retrofitted to existing buildings. The towers are connected to each other with piping. The solution piping can be easily installed inside or outside the building. Twin-tower enthalpy recovery systems operate with only routine maintenance. Complete instructions on procedures as well as spare-parts lists are included in operating manuals relevant to each installation. Periodically, the circulation pumps, spray nozzles, liquid transfer controls, and mist eliminators need checking and adjusting or maintenance. Halide brine solutions are normally used as energy transfer media in twin-tower systems. Manufacturers provide technical support, including solution sampling services to monitor and report changes in concentration and pH, thus ensuring continued maximum performance.

Fixed-Bed Regenerators

Fixed-bed regenerators (FBRs) are available in many configurations, sizes, and airflow patterns. In general, FBRs contain one or two cores for the purpose of energy transfer, and some means of reversing airflow through its core(s) to alternately store and release energy.

In North America, double-core FBRs are more common; single-core FBRs are available but have not been widely adopted. Double-core FBRs are packaged with two cores and an airflow control module to alternate supply and exhaust air through each core. These units are used in large residential, commercial, and industrial applications with airflow capacity in the range of 0.025 to 50 m^3/s. Cost and physical size are the main barriers between double-core FBRs and the residential home market.

Unlike other energy recovery exchangers, in FBRs the outlet air temperatures and humidities are never steady state; instead, they rise and fall cyclically with each reversal of airflow. This poses challenges to test facilities, which generally seek to take measurement only when the device under test is operating in steady state with very small variations in outlet conditions. The latest edition of ASHRAE *Standard* 84 introduces techniques for data reduction and humidity averaging to deal with this challenge. As more manufacturers enter the market, certified performance data may become available.

Arrangement. Cores are typically split into smaller cells (Figure 22) to facilitate transportation, handling, and cleaning. Plates are formed with spacers (e.g., ribs or dimples) constructed into the

plates or by alternating corrugation angle between adjacent plates (direction of the angle spaces plates apart). Corrugation patterns and plate thickness varies depending on manufacturer. Plate spacing ranges from 2.5 to 13 mm. Aluminum cores are the most popular construction, but some manufacturers also offer polypropylene cores for corrosive or lightweight applications.

Airflow control modules consist of a single deflector plate or a multiblade damper system. Early designs included pneumatic actuators controlled by solenoids and flow valves. Electric actuators were introduced to improve synchronization and to reduce switchover time of multiblade dampers to 0.5 to 1.5 s. Rapid switchover is of key importance to minimize exhaust air transfer between recovery periods.

In Europe, various types of single-core devices are used for residential, apartment, condo, or renovation projects with limited ceiling space. Often, the only option is a room-based decentralized ductless ventilation system, which consists of several single-core FBRs installed in the exterior walls of a space. The individual devices are synchronized via interconnecting wiring or wireless communication to alternately store and release energy from a single honeycomb-shaped, ceramic core.

Operation. Typically, the devices are staggered so half of the ventilation system is exhausting while the other half is bringing tempered outside air into the space. After a certain period of time, called the recovery period, the system switches direction to recharge the devices that have been in the outside airstream. The other half of the system now transfers energy to the outside air stream until the next recovery period.

Many single-core FBRs are equipped with a relatively small fan, capable of changing its direction at the end of each recovery period to supply air to, or exhaust air from, the space. Depending on the manufacturer, the device is designed with two opposite fans in adjacent channels, airflow deflectors, and/or backdraft flaps to alternate exhaust and supply air through the core. Performance curves of the fan must be considered for high-rise buildings and locations with high winds. Stack effect and wind direction can be detrimental to supply airflow rate or effectiveness of single-core FBRs (Figure 23).

Recovery periods in the range of 50 to 70 s are common to both single-core and double-core FBRs. Manufacturers report sensible effectiveness typically in the range of 80 to 90%. Latent recovery is also possible. With sensible-only FBRs, latent recovery can occur in condensing conditions (i.e., heating mode). FBRs also can be manufactured with desiccant treatment providing latent recovery in all conditions. Manufacturers report latent effectiveness in desiccant-treated FBRs in the 60 to 80% range, and in non-desiccant-treated FBRs, as high as 70% (depending on conditions). Longer recovery periods up to 3 h are used for free cooling mode. Some manufacturers vary the recovery period between 20 to 120 s to control discharge air temperature and/or humidity. Shorter recovery periods improve effectiveness, but the drawback is a higher exhaust air transfer ratio (Figure 24).

Exhaust air transfer for outdoor double-core FBRs is reported by manufacturers to be in the range of 3 to 5%. Indoor applications with long ducts connecting the unit to the ambient suffer from higher exhaust transfer rates due to the volume of exhaust air drawn

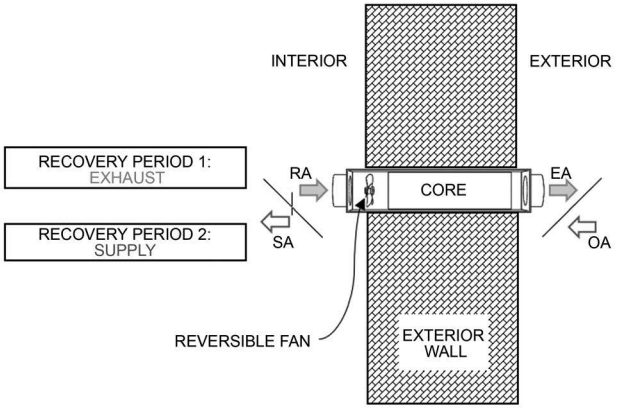

Fig. 24 Single-Core Fixed-Bed Regenerator

back from these ducts. Generally, duct length is kept under 8 m to limit increase in pressure drop and exhaust air transfer.

An advantage of FBRs is the repeated exhaust regeneration, which allows this technology to operate in extremely cold climates below –40°C without the need of auxiliary defrost strategies. Typically, discharge air from a double-core FBR is condition by a heater, or an interlocked air handling unit before entering the space.

4. PERFORMANCE RATINGS

Performance ratings should be based on tests performed in qualified laboratories that are staffed and instrumented to meet requirements of ASHRAE *Standard* 84 and AHRI *Standard* 1061.It may be very difficult to adhere to any standard when field tests are made.

Performance Ratings for Air-to-Air Heat or Heat and Mass Exchangers

ASHRAE *Standard* 84 (1) establishes a uniform method of testing for obtaining performance data; (2) specifies the data required, calculations to be used, and reporting procedures for testing each of seven independent performance factors and their uncertainty limits; and (3) guides selection of test equipment. The independent performance factors are sensible, latent, and total effectivenesses e_s, e_l, and e_t; the enthalpy recovery ratio; supply and exhaust air pressure drops ΔP_s and ΔP_e; exhaust air transfer ratio (EATR), which characterizes the fraction of exhaust air transferred to the supply air; and outdoor air correction factor (OACF), which is the ratio of supply inlet to outlet airflow. An additional useful parameter, which can be evaluated only when fan efficiency is known or assumed, is the recovery efficiency ratio.

AHRI *Standard* 1061 is an industry-established standard for rating air-to-air heat/energy exchanger performance for use in energy recovery ventilation equipment. This standard, based on ASHRAE *Standard* 84, establishes definitions, requirements for marking and nameplate data, and conformance conditions intended for the industry, including manufacturers, engineers, installers, contractors, and users. Standard temperature and humidity conditions at which equipment tests are to be conducted are specified for summer and winter conditions. Published ratings must be reported for the performance factors specified in ASHRAE *Standard* 84. The AHRI certification program using *Standard* 1061 is used to verify ratings published by manufacturers. At this time the scope of the certification program includes plate, rotary, and heat pipe exchangers. Coil energy recovery systems, twin-tower enthalpy recovery loops, and fixed-bed regenerators are not in the scope of the certification program.

Before 2020, AHRI *Standard* 1060 required the publication of ratings based on performance of the rated exchanger at two balanced airflow rates selected by the manufacturer, at standard winter and summer conditions:

Winter: Outdoor air at $t_1 = 1.7°C$ and $t_{w1} = 0.6°C$
Indoor (room) air at $t_3 = 21.1°C$ and $t_{w3} = 14.4°C$ and $p_2 - p_3 = 0$

Summer: Outdoor air at $t_1 = 35°C$ and $t_{w1} = 25.6°C$
Indoor (room) air at $t_3 = 23.9°C$ and $t_{w3} = 17.2°C$ and $p_2 - p_3 = 0$

These ratings applied to operation with the static pressure at supply air outlet equal to the static pressure at the exhaust air inlet. Ratings for the leakage metrics EATR and OACF also were to be provided at these static pressure conditions, as well as at two additional static pressure conditions selected by the manufacturer.

As of 2020, the AHRI certification program verifies ratings generated by a manufacturer's prediction software across a broad psychrometric range, at any combination of airflows and static pressures supported by the software. The program also verifies that all of the ratings required for a complete characterization of exchanger performance are provided.

Some metrics can be provided optionally. The new **energy recovery ratio** (Equation [3]) is used to characterize the performance of the exchanger in relation to its use in a system. This metric is important because, as of 2019, ASHRAE *Standard* 90.1 requires that energy recovery systems have an enthalpy recovery ratio of at least 50% (i.e., a change in enthalpy of outdoor air supply equal to 50% of the difference between outdoor air and entering exhaust air enthalpies at design conditions).

Standard 90.1 previously used 50% effectiveness at design conditions, but this metric measures performance of the exchanger and is less relevant when defining the performance of an enthalpy recovery system.

It is more difficult to measure performance of a heat or heat/mass exchanger when condensation occurs. ASHRAE *Standard* 84 provides theoretical approaches, but in practice it is challenging to measure the rate at which condensate is generated, which is required to confirm the test meets steady-state requirements. CSA *Standard* C439-2018 provides a method to measure some energy and ventilation parameters of a complete ventilating unit equipped with heat or heat and mass recovery and active frost prevention or recovery means. However, this is intended for use with packaged ventilating units, and is not intended to characterize the conditions under which frost occurs in the exchanger itself.

Performance Ratings for Residential Ventilators with Air-to-Air Heat or Heat and Mass Exchangers

Residential ventilation products are certified by the Home Ventilating Institute (HVI 2015). Heat recovery ventilators and energy recovery ventilators (H/ERVs) are certified for their ventilation performance at high speed and for their energy recovery performance at manufacturer's selected airflows. The *HVI Certified Products Directory* (www.hvi.org/proddirectory) is useful for comparing product performance on a level playing field. H/ERVs must be tested at prescribed conditions in accordance with CSA *Standard* C439 at an HVI-designated laboratory to be eligible for HVI certification.

HVI issues certified ratings for H/ERVs for airflow (net supply, gross exhaust, gross supply) and for energy recovery performance parameters include the following:

- Sensible recovery efficiency (SRE)
- Adjusted sensible recovery efficiency (ASRE)
- Total sensible recovery efficiency (TRE) in cooling modes
- Adjusted total sensible recovery efficiency (ATRE) in cooling modes
- Latent recovery moisture transfer
- Very-low-temperature ventilation reductions

Note that ratings for ASRE are to be used in energy-modeling software where fan power is a separate modeling input, to avoid counting fan power twice. Residential H/ERVs are certified as a packaged unit, whereas larger commercial H/ERVs typically carry certified ratings for energy recovery performance of just the core. Products must be listed in the online directory to be considered HVI certified (i.e., not listed means not certified).

5. ADDITIONAL TECHNICAL CONSIDERATIONS

The rated effectiveness of energy recovery units is obtained under balanced flow conditions (i.e., the flow rates of supply and exhaust airstreams are the same). However, these ideal conditions do not always exist, because of design for positive building pressure, air leakage, fouling, condensation, or frosting, and the following other factors.

Air Leakage

Air leakage refers to any air that enters or leaves the supply or exhaust airstreams. Zero air leakage in either airstream would require m_1 to equal m_2 and m_3 to equal m_4. External air leakage occurs when the ambient air surrounding the energy recovery system leaks into (or exits) either or both airstreams. Internal air leakage occurs when holes or passages are open to the other airstream. Internal air leakage occurs when heat or energy exchanger design allows (1) tangential air movement in the wheel's rotational direction and (2) air movement through holes in the barrier between airstreams. Under some pressure differentials, air leaks in and out of each airstream in nearly equal amounts, giving the illusion that there is no air leakage. Heat and water vapor transfer could appear to be greater than it is in reality.

Leakage varies with heat exchanger type and design, airstream static pressure differences, and the physical condition of the heat exchanger (see Table 3). Air leakage is seldom zero because external and internal air pressures are usually different, causing air to leak from areas of higher pressure to those of lower pressure. Cross-leakage, cross-contamination, or mixing between supply and exhaust airstreams may occur in air-to-air heat exchangers and may be a significant problem if exhaust gases are toxic or odorous.

Cross-leakage between incoming fresh air and outgoing exhaust air can be classified into two mechanisms: seal leakage and carryover.

Cross-leakage is caused primarily by difference in static pressures between states 2 and 3 and/or between states 1 and 4, as shown in Figure 25. This is a major cause of cross-leakage, and underscores the importance of specifying precise locations for fans that circulate the airstreams. Seal leakage can also be caused by factors such as provisions for surging, geometrical irregularities, and local velocity distribution of the airstreams.

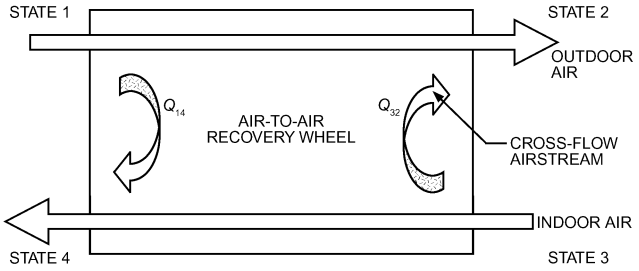

Fig. 25 Air Leakage in Energy Recovery Units

Carryover occurs in rotary recovery units because of wheel rotation out of one airstream into the other. Exhaust air trapped in cavities in the heat transfer medium is carried into the fresh airstream by the wheel's rotation. Inclusion of a purge section in a rotary energy recovery device is the best way to minimize cross-leakage due to carryover.

The test estimate of the air leakage is characterized by two dimensionless parameters: the exhaust air transfer ratio (EATR) and outdoor air correction factor (OACF). During these tests, $m_2 = m_3$, while an inert tracer gas is introduced at station 3 (Shang et al. 2001a):

$$\text{EATR} = \frac{c_2 - c_1}{c_3 - c_1} \tag{15}$$

where c_1, c_2, and c_3 are the concentrations of inert gas at states 1, 2, and 3, respectively.

EATR is the ratio of the concentration increase in supply air relative to the maximum concentration difference between stations 3 and 1. It is representative of the air mass leakage from exhaust air into supply air, when the air-to-air heat exchanger is operating at mass flow rates and static pressures equal to those at which the device was tested.

$$\text{OACF} = \frac{m_1}{m_2} \tag{16}$$

where m_1 and m_2 are the mass flow rates of incoming fresh airstream at states 1 and 2, respectively.

OACF gives the ratio of outdoor airflow required at the inlet (station 1) relative to the supply flow at 2 to compensate for air that leaks into or out of the exchanger, to meet the required net supply airflow to the building space, when the air-to-air heat exchanger is operating at mass flow rates and static pressures equal to those at which the device was tested.

Ideal operating conditions exist when there is no air leakage between the streams, EATR is close to zero, and OACF approaches 1. Deviations from ideal conditions indicate air leakage between the airstreams, which complicates the determination of accurate values for pressure drop and effectiveness. Methods to estimate actual flow rates at states 1, 2, 3, and 4 when air leakage exists and the values of the parameters EATR and OACF are known are discussed in Friedlander (2003) and Moffitt (2003). EATR and OACF must be determined when evaluating any HRV or ERV in which leakage between airstreams occurs, when evaluating the actual flow rate of outdoor

air supplied for a given ventilation requirement, and when estimating the capacity of ventilator fans, as shown by the following.

Air Capacity of Ventilator Fans

For a given ventilation requirement Q_v, the density-corrected volume flow rate capacity Q_{fan} of the supply fan is greater than Q_2 if air leakage exists (see Figure 25).

In the following calculations, be sure to obtain the value for EATR that applies to the device when it operates at the airflow volumes and static pressure that will exist in the specific application. The leakage flow rate from the exhaust to the supply air $Q_{3\text{-}2}$ can be estimated by the equation.

$$Q_3 - Q_2 = Q_2 \frac{\text{EATR}}{100} \tag{17}$$

If the ventilation requirement is Q_v, then the actual volume flow rate of supply air to the space is calculated as

$$Q_2 = Q_v + Q_{3-2} = Q_v + Q_2 \frac{\text{EATR}}{100} \tag{18}$$

This can be simplified as

$$Q_2 = \frac{Q_v}{1 - (\text{EATR}/100)} \tag{19}$$

which gives the quantity of air entering the space. Assuming steady-state conditions, and balanced flow through the energy recovery ventilator, the density corrected quantity of air leaving the building space (Q_3) should be same as air supplied to the space Q_2.

$$Q_3 = Q_2 = \frac{Q_v}{1 - (\text{EATR}/100)} \tag{20}$$

Combining Equations (16) and (20) gives the required supply air inlet volume q_1 as

$$Q_1 = Q_2(\text{OACF}) = \frac{Q_v(OACF)}{1 - (\text{EATR}/100)} \tag{21}$$

Caution should be used with Equations (20) and (21) because in many practical applications, Q_2 is not equal to Q_3.

Equation (21) gives the volume flow rate capacity of the intake, which equals the exhaust outlet for balanced airflow. (Fan capacity depends on location. This statement only applies to the supply fan at station 1 [blow-through]; its capacity would change at station 2 [draw-through].)

Pressure Drop

Pressure drop for each airstream through an energy recovery unit depends on many factors, including exchanger design, mass flow rate, temperature, moisture, and inlet and outlet air connections. The pressure drop must be overcome by fans or blowers. Because the power required for circulating airstreams through the recovery unit is directly proportional to the pressure drop, the pressure drop through the energy recovery unit at its operating conditions should be known. The pressure drop may be used with the fan efficiency to characterize the energy used by the exchanger and in turn the efficiency (not effectiveness) of an application.

Maintenance

The method used to clean a heat exchanger depends on the transfer medium or mechanism used in the energy recovery unit and on the nature of the material to be removed. Grease build-up from kitchen exhaust, for example, is often removed with an automatic water-wash system. Other kinds of dirt may be removed by vacuuming, blowing compressed air through the passages, steam cleaning, manual spray cleaning, soaking the units in soapy water or solvents, or using soot blowers. The cleaning method should be determined during design so that a compatible heat exchanger can be selected.

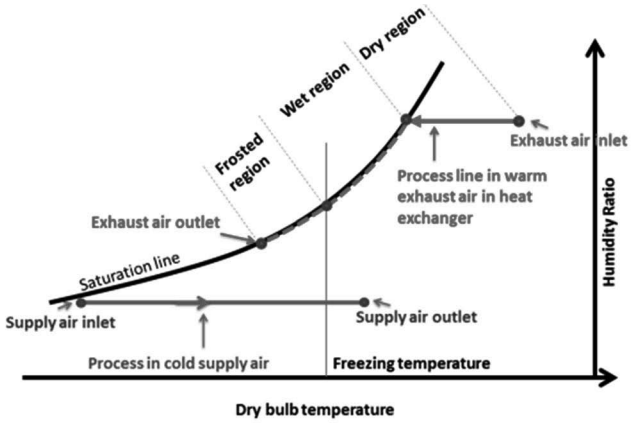

Fig. 26 Psychrometric Chart Showing the Processes in Exhaust and Supply Airstreams in Heat Exchangers

Cleaning frequency depends on the quality of the exhaust airstream. Residential and commercial HVAC systems generally require only infrequent cleaning; industrial systems, usually more. Consult equipment suppliers about the specific cleaning and maintenance requirements of systems being considered.

Filtration

Filters are recommended and should be placed in both the supply and exhaust airstreams to reduce fouling and thus the frequency of cleaning. Exhaust filters are especially important if the contaminants are sticky or greasy or if particulates can plug airflow passages in the exchanger. Supply filters eliminate insects, leaves, and other foreign materials, thus protecting both the heat exchanger and air-conditioning equipment. Snow or frost can block the air supply filter and cause severe problems. Specify steps to ensure a continuous flow of supply air.

Controls

Heat exchanger controls may control frost formation or regulate the amount of energy transferred between airstreams at specified operating conditions. For example, ventilation systems designed to maintain specific indoor conditions at extreme outdoor design conditions may require energy recovery modulation to provide an economizer function, to prevent overheating ventilation supply air during cool to moderate weather or to prevent overhumidification. Modulation methods include tilting heat pipes, changing rotational speeds of (or stopping) heat wheels, or bypassing part of one airstream around the heat exchanger using dampers (i.e., changing the supply-to-exhaust mass airflow ratio).

Fouling

Fouling, an accumulation of dust or condensates on heat exchanger surfaces, reduces heat exchanger performance by increasing resistance to airflow, interfering with mass transfer, and generally decreasing heat transfer coefficients. Increased resistance to airflow increases fan power requirements and may reduce airflow.

Increased pressure drop across the heat exchanger core can indicate fouling and, with experience, may be used to establish cleaning

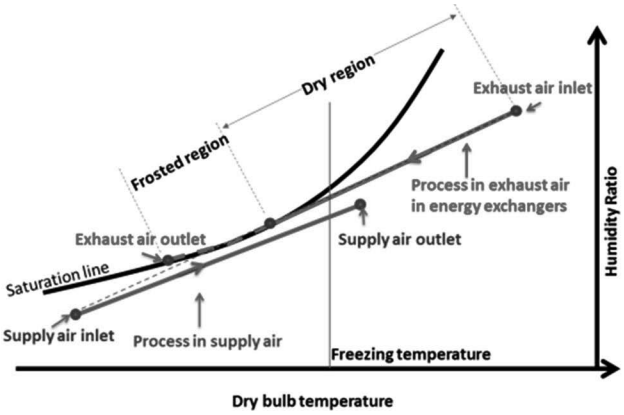

Fig. 27 Psychrometric Chart Showing the Processes in Exhaust and Supply Airstreams in Energy Exchangers

schedules. Reduced mass transfer performance (latent effectiveness) indicates fouling of permeable membranes or desiccant sorption sites. Heat exchanger surfaces must be kept clean to maximize system performance.

Corrosion

Process exhaust frequently contains corrosive substances. If it is not known which construction materials are most corrosion resistant for an application, the user and/or designer should examine on-site ductwork, review literature, and contact equipment suppliers before selecting materials. A corrosion study of heat exchanger construction materials in the proposed operating environment may be warranted if installation costs are high and the environment is corrosive. Experimental procedures for such studies are described in an ASHRAE symposium (ASHRAE 1982). Often contaminants not directly related to the process are present in the exhaust airstream (e.g., welding fumes or paint carryover from adjacent processes).

Moderate corrosion generally occurs over time, roughening metal surfaces and increasing their heat transfer coefficients. Severe corrosion reduces overall heat transfer and can cause cross-leakage between airstreams because of perforation or mechanical failure.

Condensation and Freeze-Up

Condensation, ice formation, and/or frosting may occur on heat exchange surfaces. Ignoring entrance and exit effects, four distinct air/moisture regimes may occur as the warm airstream cools from its inlet condition to its outlet condition. First, there is a dry region with no condensate. Once the warm airstream cools below its dew point, there is a condensing region, which wets the heat exchange surfaces. If the heat exchange surfaces fall below freezing, the condensation freezes. Finally, if the warm airstream temperature falls below its dew point and is also below freezing temperature, sublimation causes frost to form. The locations of these regions and rates of condensation and frosting depend on the duration of frosting conditions; airflow rates; inlet air temperature and humidity; heat exchanger core temperature; heat exchanger effectiveness; geometry, configuration, and orientation; and heat transfer coefficients. Figures 26 and 27 show the psychrometric process of the two airstreams when frosting happens for both energy exchanger and heat exchanger.

Sensible heat exchangers, which are ideally suited to applications in which heat transfer is desired but humidity transfer is not (e.g., swimming pools, kitchens, drying ovens), can benefit from the latent heat released by the exhaust gas when condensation occurs. One kilogram of moisture condensed transfers about 2440 kJ to the incoming air at room temperature. Equipment design should provide for continuous draining of the condensate from the unit. Transfer of latent heat occurs at the point of condensation, and little available energy remains in the condensate.

Condensation increases the heat transfer rate and thus the sensible effectiveness; it can also significantly increase pressure drops in heat exchangers with narrow airflow passage spacing. Frosting fouls the heat exchanger surfaces, which initially improves energy transfer but subsequently restricts the exhaust airflow, which in turn reduces the energy transfer rate. In extreme cases, the exhaust airflow (and supply, in the case of heat wheels) can become blocked. Defrosting a fully blocked heat exchanger requires that the unit be shut down for an extended period. As water cools and forms ice, it expands, which may seriously damage the heat exchanger core unless the water is entirely removed.

For frosting or icing to occur, an airstream must be cooled to a dew point below 0°C. Enthalpy exchangers transfer moisture from the airstream with higher moisture content (usually the warmer airstream) to the less humid one. As a result, frosting or icing occurs at lower supply air temperatures in enthalpy exchangers than in sensible heat exchangers. Cross-flow heat exchangers are more frost tolerant than other plate exchangers because frost blockage only occurs over a fraction of the exchanger exhaust airflow passages.

For these reasons, some form of freeze control must be incorporated into heat exchangers that are expected to operate under freezing conditions. Frosting and icing can be prevented by preheating supply air or reducing heat exchanger effectiveness (e.g., reducing heat wheel speed, tilting heat pipes, bypassing some supply air around the heat exchanger). Alternatively, the heat exchanger may be periodically defrosted. If cyclic defrost methods are used, the defrost period should be long enough to completely remove the frost, ice, and water during each defrost period. Care should also be taken to ensure that minimum ventilation requirements are still satisfied when cyclic defrost is used. Manufacturers of commercially available packaged heat or energy ventilators routinely incorporate frosting control strategies or mechanisms appropriate to their equipment and its targeted application.

ASHRAE research project RP-543 discusses performance of several freeze control strategies (Phillips et al. 1989a, 1989b). ASHRAE research project RP-544 (Barringer and McGugan 1989a, 1989b) covers performance of enthalpy heat exchangers. Many effective defrost strategies have been developed for residential air-to-air heat exchangers, and may also be applied to commercial installations. Phillips et al. (1992) describe frost control strategies and their impact on energy performance in various climates. Rafatinasr (2016) investigated the frosting threshold of fixed-plate cross-flow energy exchanger and its comparison with sensible heat exchangers, and conducted an exhaustive literature review on past research and typical defrosting methodologies and their impact on the performance of the exchangers.

See the Bibliography for sources of more information on frost growth and control.

Frost Control Strategies for Air-to-Air Energy Recovery Systems

In all cases, the potential for frost is in the warm-return-air side of the heat exchanger, which cools during a winter condition. For energy recovery devices, the exact outdoor air temperatures at which frosting will start depends on the temperature and humidity of the exhaust air and the type and performance of the energy recovery device. This temperature is known as the frost threshold temperature. The frost threshold varies by specific technology, and

significantly by whether water vapor is transferred between airstreams:

- **Flat Plate Heat Exchangers.** In flat plate heat exchangers (Figures 2 and 4), warm return air cools as it passes through the heat exchanger. Moisture from the warm air condenses and creates water droplets on the media; as cool outdoor air enters the heat exchanger, the water droplets start to freeze, creating ice on the cold corner of the core. Figure 1 shows a typical temperature distribution of warm and humid; and cold and dry air streams. The circled area shows the potential problem area for frost formation. In general, frost buildup becomes a problem when outdoor air temperatures reach about –5°C for sensible devices, or approximately –20°C for total energy devices. Figure 3 shows frost threshold for energy (Afshin 2019) and heat recovery ventilators.
- **Energy Recovery Wheels.** In energy recovery wheels (Figure 6), warm return air cools as it passes through the rotating wheel. Moisture from the warm air condenses and creates water droplets on the surface of the wheel. The water molecules are then absorbed by the desiccant on the enthalpy wheel or adsorbed into the airstream, in the case of sensible wheels. As the wheel rotates through the cold supply air, the water can start to freeze and form ice before the water droplets can be cleared from the wheel surface. Ice typically forms on the internal surface of the wheel, near the outdoor air intake which can cause damage and reduce airflow and performance.
- **Heat Pipe, Thermosiphon Loop, and Runaround Glycol Heat Exchangers.** In these technologies, the return air is cooled by a fluid passing through a coil. (Figures 10 and 15) For frost to form, the coil fin surface must be freezing and below the return air dew point. For frost to build up, the return air must be cooled below freezing. Using the sensible effectiveness, the user can calculate the outdoor air temperature where frost would be expected. For example, with a sensible effectiveness of 50%, an outdoor air temperature of –21°C would cool 21°C return air to 0°C.

There are a variety of different approaches that can be used to determine the frost threshold temperature, including measuring temperature, humidity, or a variation in pressure drop. A frost control strategy is then determined to either eliminate the frost once it builds up on the exchanger (before it becomes too severe), or to prevent frost formation from ever starting at all. The choice between frost control and frost prevention will depend on the robustness of the air-to-air energy recovery device and the application.

An effective frost control strategy is one that meets the requirements of the application while being cost-effective and device appropriate. Figure 28 shows the possible control strategies (Afshin 2019) for controlling frost for plate heat exchangers used as ERVs. Figure 29 shows examples of frost threshold temperatures for energy and heat recovery exchangers (Afshin 2019; Rafatinasr 2016).

In all cases of frost prevention, the amount of energy recovery is reduced and there will need to be additional heat added into the system. Energy efficiencies for each solution vary somewhat, and the

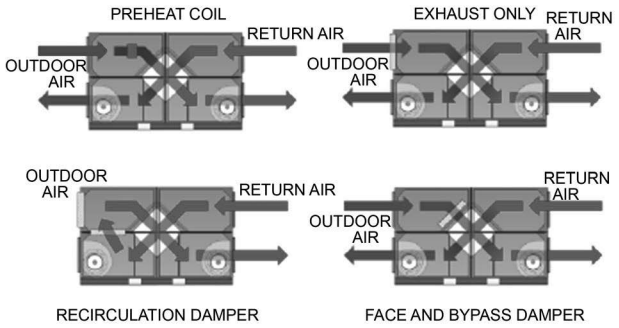

Fig. 28 Common Frost Control Strategies for Fixed-Plate Exchangers

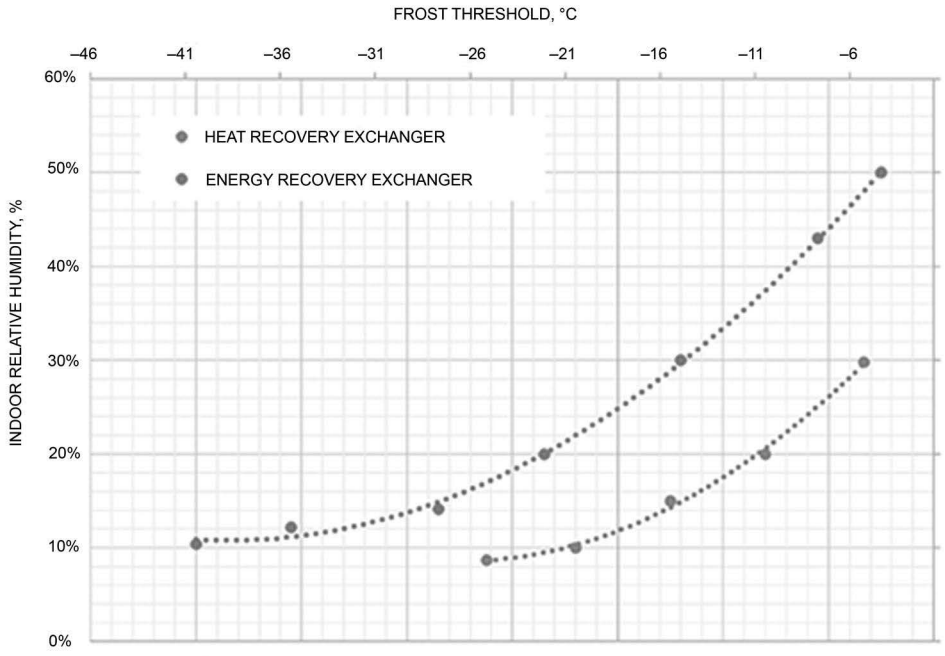

Fig. 29 Examples of Frost Threshold Temperatures for Energy and Heat Recovery Exchangers

(Afshin 2019)

best choice depends on application and the amount of upfront cost that can be tolerated.

Frost Prevention.

- *Preheat coil to heat up exhaust air*. Preheat frost control is a preventative strategy that can be used with any air-to-air energy recovery device. The objective is to prevent frost from occurring within the heat exchanger, while maintaining 100% or continuous ventilation. Energy recovery is reduced, because the difference in temperature between the preheated outside air and the return air has reduced. Heating coils (electric, steam, or hot water) are duct-mounted or integrated into the unit in the outdoor airstream so that the entering outdoor air temperature is preconditioned to a temperature above the frost threshold for the technology being used. While preheat typically has higher upfront costs than other strategies, it can result in significant operating savings in climates where frost control is required for a long period of time (more than a few hours). The preheater should be sized for the coldest outdoor air design temperature and to the appropriate outdoor air temperature where the exhaust air frost threshold is reached based on the design conditions and airflows for the type of heat exchanger selected. Figure 3 shows frost threshold characteristics for energy and heat recovery ventilators.
- *Face and bypass damper* (Figure 28). Face and bypass frost control is a preventative strategy that can be used for flat plates, heat pipes, and rotary wheel exchangers, with the objective of preventing frost formation while maintaining 100% ventilation. As the outdoor air becomes colder, face and bypass dampers upstream of the heat exchanger modulate to reduce the amount of outdoor air flowing through the heat exchanger. This reduces the amount of energy recovered and keeps the exhaust temperature above the frost threshold. The supply and exhaust fans, as well as the outdoor air and exhaust air dampers, continue to operate during the frost control cycle. With this strategy there is no interrupted ventilation which makes it ideal for harsher environments or source control applications like laboratories. Furthermore, as both fans run continuously there is no depressurization of the building, eliminating the potential for combustion appliance backdraft into the occupied space. The lower leaving supply air temperature would potentially require post-conditioning, or some type of terminal reheat within the space to ensure that occupants remain comfortable under extreme conditions. A further advantage would be that the face-and-bypass can also be used for free cooling (economizer) and/or supply air temperature control in different modes of operation if required.
- *Performance modulation*. The heat exchanger can be controlled to ensure that frost does not form in the return air, by reducing the effectiveness and, as a result, suppressing the frost threshold. For example, wheel rotational speed can be reduced, runaround pumps can be slowed, heat pipes can be equipped with control valves or tilted. Since the heat exchanger is recovering less energy, more heating is required in the process downstream.

Defrosting.

1. *Exhaust defrosting* (Figure 28). Exhaust-only defrost is one of the most cost-effective and simple strategies to implement. It periodically defrosts ice forming on the heat exchanger by shutting down the supply fan to remove the source of cold air, while using the warm exhaust air to heat up the exchanger. When the unit goes into a defrost cycle, the exhaust fan continues to operate, the supply fan is deenergized and the outdoor air damper closes. This method is most commonly used with flat plate or heat pipe heat exchangers and is ideal for source control applications where continuous exhaust is required. One drawback of this method is that ventilation is interrupted when the supply fan shuts down during the defrost cycle, which may not be acceptable as the equipment may not meet indoor air quality (IAQ) requirements as defined by ASHRAE *Standard* 62.1. This also creates negative indoor pressure, resulting in infiltration.
2. *Recirculation defrost* (Figure 28). Recirculation defrost is also cost-effective and simple, commonly used in light commercial stand-alone air-to-air ERVs that are not used as a primary ventilation system. Ice formation on the heat exchanger is periodically defrosted by shutting down the exhaust fan, by closing the outdoor and exhaust air dampers, and by opening a recirculation air damper to remove the source of cold air. When the unit goes into a defrost cycle, the supply fan remains on to recirculate building exhaust air back into the occupied space. The exhaust air goes through the heat exchanger and provides defrosting in the absence of cold outdoor air. A drawback of this method is that ventilation is interrupted when the exhaust fan shuts down during the defrost cycle. This may not be acceptable in all applications and may not meet indoor air quality (IAQ) requirements as set out in ASHRAE *Standard* 62.1. It may however be acceptable in more moderate climates where freezing conditions occur only during unoccupied hours for a few hours per year.

Direct and Indirect Evaporative Air Cooling

In indirect evaporative air cooling, exhaust air passing through a water spray absorbs water vapor until it becomes nearly saturated. As the water evaporates, it absorbs sensible energy from the air, lowering its temperature. The evaporatively cooled exhaust air can then be used to cool supply air through an air-to-air heat exchanger, which may be used either for year-round energy recovery or exclusively for its evaporative cooling benefits. This process follows a constant wet-bulb line on a psychrometric chart: the airstream enthalpy remains nearly constant, moisture content increases, and dry-bulb temperature decreases.

Indirect evaporative cooling has been used with heat pipe heat exchangers, runaround coil loop exchangers, and flat-plate heat exchangers for summer cooling (Dhital et al. 1995; Johnson et al. 1995; Mathur 1990a, 1990b, 1992, 1993; Scofield and Taylor 1986). Exhaust air or a scavenging airstream is cooled by passing it through a water spray, wet filter, or other wetted media, resulting in a greater overall temperature difference between the supply and exhaust or scavenging airstreams and thus more heat transfer. Energy recovery is further enhanced by improved heat transfer coefficients because of wetted exhaust-side heat transfer surfaces. No moisture is added to the supply airstream, and there are no auxiliary energy inputs other than fan and water pumping power. The coefficient of performance (COP) tends to be high, typically from 9 to 20, depending on available dry-bulb temperature depression. The dry-bulb temperature decrease in the exhaust airstream caused by evaporative cooling tends to be 85 to 95% of the maximum available difference between the exhaust air inlet dry-bulb and wet-bulb temperatures. Therefore, exhaust air evaporative cooling is usually most cost effective in hot, dry climates where the evaporator can be used frequently to obtain large exhaust air dry-bulb temperature depressions.

Without a bypass scheme for either the evaporator or air-to-air heat exchanger, the net annual energy costs include the extra annual fan power for these devices as well as the benefit of evaporative cooling.

Because less mechanical cooling is required with evaporative cooling, energy consumption and peak demand load are both reduced, yielding lower energy bills. Overall mechanical refrigeration system requirements are reduced, allowing use of smaller mechanical refrigeration systems. In some cases, the mechanical system may be eliminated. Chapter 41 of this volume and Chapter 53 of the 2023 *ASHRAE Handbook—HVAC Applications* have further information on evaporative cooling.

Example 3. Indirect Evaporative Cooling Recovery. Room air at 30°C and 17°C wb (ρ = 1.2 kg/m^3) with a flow rate of 15 m^3/s is used to pre-

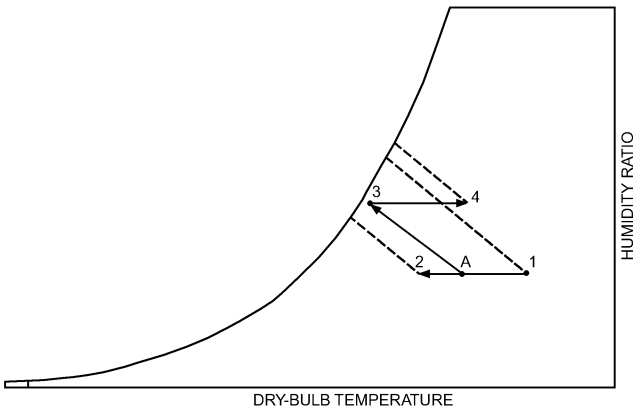

Fig. 30 Indirect Evaporative Cooling Recovery (Example 3)

cool 15 m^3/s of supply outdoor air at 39°C and 20°Cwb (ρ = 1.13 kg/m^3) using an aluminum fixed-plate heat exchanger and indirect evaporative cooling. The evaporative cooler increases the exhaust air to 90% rh before it enters the heat exchanger. The sensible effectiveness is given by the manufacturer as 78%. Assuming EATR = 0 and OACF ≈ 1, determine the leaving supply air conditions and energy recovered, and check the energy exchange balance.

Solution:

First, determine the exhaust air condition entering the exchanger (i.e., after it is adiabatically cooled). Air at 30°C db, 17°C wb cools to 18°C db, 17°C wb as shown by the process line from point A to point 3 in Figure 30. In this problem the volumetric flows are equal, but the mass flows are not.

1. Because data on pressure drop are missing, skip this step.

2. Calculate the theoretical maximum heat transfer.

Based on a preliminary assessment, the supply air is not expected to cool below its wet-bulb temperature of 20°C. Thus, use the denominator of sensible heat effectiveness Equation (2a) and, for simplification, assume the specific heat of 1.0 kJ/(kg·K).

$$q_{max}\ (\text{sensible}) = (1.13\ \text{kg/m}^3)(15\ \text{m}^3/\text{s})[1.0\ \text{kJ/(kg}\cdot\text{K)}](39 - 18) = 356\ \text{kW}$$

3. Establish the sensible effectiveness.

From manufacturer's exchanger selection data for indirect evaporative coolers, an effectiveness of 78% is found to be appropriate.

4. Calculate actual energy transfer at the design conditions.

$$q_{actual} = (0.78)(356\ \text{kW}) = 278\ \text{kW recovered}$$

5. Calculate leaving air conditions.

a. Leaving supply air temperature is

$$t_2 = 39°\text{C} + \frac{-278\ \text{kW}}{(1.13\ \text{kg/m}^3)(15\ \text{m}^3/\text{s})[1\ \text{kJ/(kg}\cdot\text{K)}]} = 22.6°\text{C}$$

b. Leaving exhaust air temperature is

$$t_4 = 18°\text{C} + \frac{278\ \text{kW}}{(1.2\ \text{kg/m}^3)(15\ \text{m}^3/\text{s})[1\ \text{kJ/(kg}\cdot°\text{C)}]} = 33.4°\text{C}$$

6. Check performance.

$q_s = (1.13\ \text{kg/m}^3)(15\ \text{m}^3/\text{s})[1\ \text{kJ/(kg}\cdot\text{K)}](39 - 22.6\text{K}) = 278\ \text{kW}$ recovered

$q_e = (1.2\ \text{kg/m}^3)(15\ \text{m}^3/\text{s})[1\ \text{kJ/(kg}\cdot\text{K)}](33.4 - 18\text{K})$
$= 278\ \text{kW}$ recovered

7. Plot conditions on psychrometric chart (Figure 30), and confirm that no latent exchange occurred.

Because EATR = 0 and OACF is 1, Steps 8 to 10 are not presented here.

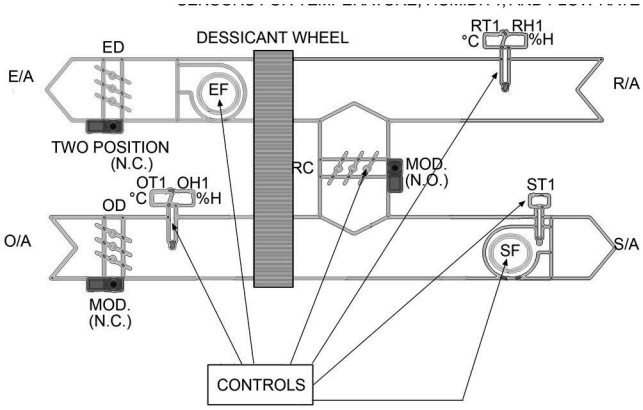

Fig. 31 Economizer with Dessicant Wheel

(Pieper 2015)

Use of Economizer

ASHRAE *Standard* 90.1 specifies the use of economizer whenever the conditions of the outdoor air, especially enthalpy, are lower than that of the return air. Typically, the use of economizer depends on factors such as the characteristics of the building envelope, number of occupants, internal loads, and the location of the building. An economizer may be required for buildings in U.S. climate zones other than 1a,1b, 2a, and 2b, provided the cooling capacity is higher than 11 tons in the moist region and 5 tons for the dry regions. Exceptions might exist for other regions for just a few hours of the year, which may not justify the use of economizer for economic considerations. A schematic of the economizer along with energy recovery wheel as shown in Figure 31.

If the outdoor temperature appears better than that of the return air (Pieper 2015), there would be a call for the economizer to engage, but if the enthalpy of the outdoor air could be worse than that of the return air, the economizer should not be in operation. Enthalpy comparison prevents excess moisture being brought into the space. It is also important to note that not all outdoor air passes through the energy recovery device, in order to prevent excessive fan power associated with recovery device and bypass dampers. Dampers shown in Figure 28 have a wide range of flow rates such that the system may provide 100% outdoor air or less flow rate in combination with the return air through return air damper. The controls may be programmed to supply the required supply air conditions such that the mass flow rate and the enthalpy of the supply air satisfy the following equation.

$$m_s(h_r - h_s) = q_t \tag{22}$$

where

m_s = mass flow rate of the supply air, kg/s
h_r = enthalpy of the room air, kJ/kg_{DA}
h_s = enthalpy of the supply air, kJ/kg_{DA}
q_t = total building load at the time, kW

Building loads vary each hour, as does the sensible heat ratio (SHR), however, for the peak load conditions, the supply air conditions are determined based on the supply air temperature (T_s) as shown in Figure 32. The letters X and Y in Figure 32 indicate the states of supply and room air, respectively, and that the SHR line AO on the protractor is parallel to the line XY.

In Figure 32, it is assumed that SHR = 0.7, however it changes by the hour. The challenge lies in the ability of the control system (shown in Figure 31) to modulate the flow rates of the outdoor air and the return air.

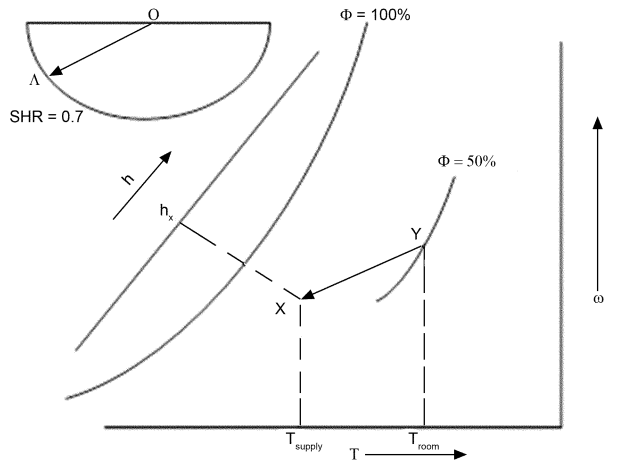

Fig. 32 Supply Conditions for Given Load q_t and Given SHR

6. COMPARISON OF AIR-TO-AIR HEAT OR HEAT AND MASS EXCHANGER CHARACTERISTICS

It is difficult to compare different types of air-to-air energy recovery systems based on overall performance. They can be compared based on certified ratings such as sensible, latent, and total effectiveness or on air leakage parameters. Comparing them on payback period or maximum energy cost savings requires accurate values of their capital cost, life, and maintenance cost, which vary from product to product for the same type of recovery system. Without such data, and considering the data available in the open literature such as that presented by Besant and Simonson (2003), use Table 3's comparative data for common types of air-to-air energy recovery devices.

7. USE OF AIR-TO-AIR HEAT OR HEAT AND MASS EXCHANGERS IN SYSTEMS

Characterizing System Efficiency of Heat or Energy Recovery Ventilators

A measure of energy recovery ventilator performance is the relative magnitude of actual energy recovered and power supplied to fans to circulate the airstreams. The cost of power supplied to the fans depends on the pressure drop of airstreams, volume flow rate, and combined efficiency of the fan motor systems. The quality of power supplied to the fans is high, and its cost per unit energy is much higher than the quality and cost of energy recovered in the ventilator. The magnitude and costs of these two forms of energy vary over the year. Besant and Simonson (2003) suggest that a parameter such as **recovery efficiency ratio (RER)** may be introduced to characterize the efficiency of the recovery ventilators:

$$\text{RER} = \frac{\int(\text{rate of energy recovered})\,dt}{\int(\text{rate of power supplied to fan motors})\,dt} \quad (23)$$

RER is similar to the energy efficiency ratio (EER) for chillers or unitary air-conditioning equipment. Besant and Simonson (2003) also suggest that the entire system performance, including the recovery ventilator, can be represented by the ratio of COP and RER.

RER is typically expressed in units of kJ/Wh; energy recovered can be sensible, latent, or total, in kilowatts, and energy expended is that spent for circulating exhaust and supply air through the energy recovery unit, expressed in watts. In AHRI *Guideline* V, RER_{Total}, $\text{RER}_{sensible}$, and RER_{latent} are defined as

$$\text{RER}_{Total} = \frac{\varepsilon_{net\ total}\,\dot{m}_{min}(h_1 - h_3)}{P_{blower} + P_{comp}} \quad (24a)$$

$$\text{RER}_{sensible} = \frac{\varepsilon_{net\ sensible}\,\dot{m}_{min}c_p(t_1 - t_3)}{P_{blower} + P_{comp}} \quad (24b)$$

$$\text{RER}_{latent} = \frac{\varepsilon_{net\ latent}\,\dot{m}_{min}h_{fg}(\omega_1 - \omega_3)}{P_{blower} + P_{comp}} \quad (24c)$$

where

$\dot{m}_{min}$ = minimum mass flow rate of supply and exhaust airstreams
h_1 = enthalpy at state 1
t_1 = temperature at state 1
ω_1 = humidity ratio at state 1
P_{comp} = direct power input of recovery component
P_{blower} = blower power required for energy recovery component

$$P_{blower} = \left[\frac{Q_{blower\ supply}\Delta P_{supply}}{\eta_{fan/motor\ supply}}\right] + \left[\frac{Q_{blower\ exhaust}\Delta P_{exhaust}}{\eta_{fan/motor\ exhaust}}\right] \quad (25)$$

where

ΔP = pressure loss of component for supply or exhaust airstreams, kPa
$Q_{blower\ supply}$ = supply fan airflow, L/s
$Q_{blower\ exhaust}$ = exhaust fan airflow, L/s
$\eta_{fan/motor}$ = combined fan and motor efficiency

Note that other alternatives (e.g., comparing operating points on a fan curve) that accurately characterize the additional fan power required by the component are acceptable means of obtaining blower power.

For a flow rate of 470 L/s and typical values of airstream pressure drop and motor and fan efficiencies, $\text{RER}_{sensible}$ can range from 26 to 32 kJ/Wh. The calculated value of RER suggest that the energy recovered is about 7.3 to 8.8 times that used to operate the energy recovery unit. The quality of thermal energy is about one-third that of electric power, so the actual energy recovered is about three times the cost of energy spent for energy recovery.

The **combined efficiency (CEF)** is the ratio of the net heating/cooling delivered to the total electric power consumed. CEF can also be related to the sensible, latent, or total recovered energy and is related to the RER; energy efficiency ratio (EER), which is typically provided by manufacturers of unitary equipment; and load ratio *Y*. It represents the percentage of the system load (heating, cooling, humidification and/or dehumidification) met by the energy recovery component. The higher load ratio allows use of smaller equipment, thereby affecting capital costs. $\text{CEF}_{cooling}$ can be estimated as

$$\text{CEF}_{cooling} = \frac{1}{Y_c/\text{RER} + (1 - Y_c)/\text{EER}} \quad (26)$$

where

$$Y_c = \frac{\text{Net cooling capacity of energy recovery unit}}{\text{System net cooling capacity}} \quad (27)$$

$$\text{EER} = \frac{\text{Net cooling capacity}}{\text{Total electric consumption}} \quad (28)$$

For a typical value of EER = 10 for a unitary system, and a load ratio of about 0.3, the $\text{CEF}_{cooling}$ can range from 15 to 19 kJ/Wh. Use of an energy recovery unit and its effects on system sizing and annual net savings for various climatic regions are discussed in AHRI *Guideline* V.

OACF = outdoor air correction factor

Selection of Heat or Energy Recovery Ventilators

Heat and energy recovery ventilators are available as heat exchangers only or as a complete system, including the heat exchangers and fan/motor systems, as indicated in Table 3. Energy recovery is also available integrated into unitary air-conditioning equipment or in both standard and custom air-handling systems. Selection of such units is primarily dictated by the quantity of ventilation air. Several manufacturers have developed software or tables to help select these units. The user may have to determine the required fan size (see Example 8), if only the heat exchanger is to be purchased.

However, the true overall system performance is the life-cycle cost, which takes into account the capital and maintenance costs. Because of lack of sufficient data on these factors, they are not presented in Table 3.

Systems with Multiple Energy Recovery Exchangers

Multiple exchangers are often used in air-handling systems that have a cooling coil, to enhance dehumidification capability. The first air-to-air exchanger in the outdoor airstream is used to recover exhaust energy and reduce the required coil capacity. The second exchanger's purpose is to increase the coil's latent removal. This second exchanger is either a sensible heat exchanger or a passive desiccant wheel. A sensible exchanger (e.g., coil loop, plate exchanger, heat pipe, wheel) reheats the air as it leaves the cooling coil. This simultaneously precools the return air. The cooled return air that is exhausted then precools the outdoor air by passing through the first exchanger. A passive dehumidification wheel works similarly: it removes water vapor from air leaving the coil and transfers the vapor, with some heat, to the return air. The second exchanger can be in parallel with the first exchanger, as shown in Figure 33 (Moffitt 2011). The corresponding processes are shown in Figure 34 (Moffitt 2011); use of a passive desiccant wheel is shown on the right side of the figure.

The second exchanger can also be placed in series with the cooling coil, as shown in Figure 35 (Moffitt 2011), where it has a similar effect. The first exchanger reduces the cooling capacity by recovery exhaust energy. The second exchanger improves latent cooling and reduces the sensible cooling delivered by the system. The corresponding processes are shown in Figure 36 (Moffitt 2011); use of a passive desiccant wheel is shown on the right side of the figure.

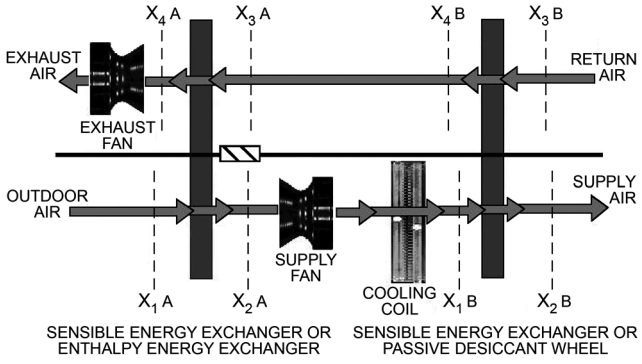

Fig. 33 Multiple Energy Recovery Exchangers in Parallel Mode

Using Air-to-Air Heat Exchangers to Modify the Latent Capacity Ratio of Cooling Coils

Air-to-air energy recovery can be used in a series application where heat is transferred from one location in an airstream (where the heat is detrimental) to another location in the same airstream (where the heat is beneficial). The most common example of this application is in series energy recovery around a cooling coil for summer dehumidification. During dehumidification the warm, humid outside air is cooled by a cooling coil so the dry bulb temperature reaches the desired dew point. This air is then reheated to reduce its relative humidity (for indoor air quality, IAQ), and to make it more comfortable before entering the building space. The in-series energy recovery device is placed in front of and after the cooling coil, where it provides precooling (reducing load on the cooling coil) and reheat (reducing load on the reheating equipment). Figure 37 provides an example and shows the driving force (left) and the enthalpy savings (right). In some cases, the outdoor air reaches saturation during precool, and humidity is removed before the air enters the cooling coil. The total energy consumption (kWh) and peak demand (kW) load are both reduced, yielding lower energy bills and healthier IAQ (Mathur 1997a, 1997b, 1997c, 1997d).

Since there must be energy balance between the precool side and reheat side, the changes in enthalpy will always be equal and opposite. Where there is no condensation during precool, the ΔT across the precool side will be equal and opposite to the reheat side. When condensation occurs during precool, the ΔT across the precool side will be smaller than the reheat side.

Even on direct-expansion (DX) systems where hot gas reheat is a resource created by the process, in-series energy recovery can be used to reduce compressor capacity and downsize equipment to reduce first costs, particularly where condensation takes place on more of the DX coil, which increases the cycle's coefficient of performance (COP).

Because both precooling and reheating are beneficial to the system, the RER in dehumidification applications is double that of an identical exchanger used in energy recovery. Also, the driving force is the dry-bulb temperature difference between the outdoor air and the cooling coil leaving temperature. For example, on a 32°C day and with 13°C air leaving the cooling coil, the driving force across the energy recovery device is 7°C. In contrast, a traditional air-to-air energy recovery device with outdoor air at 32°C and return air at 24°C is exposed to a driving temperature difference of only 8 K, a third of the in-series energy recovery device.

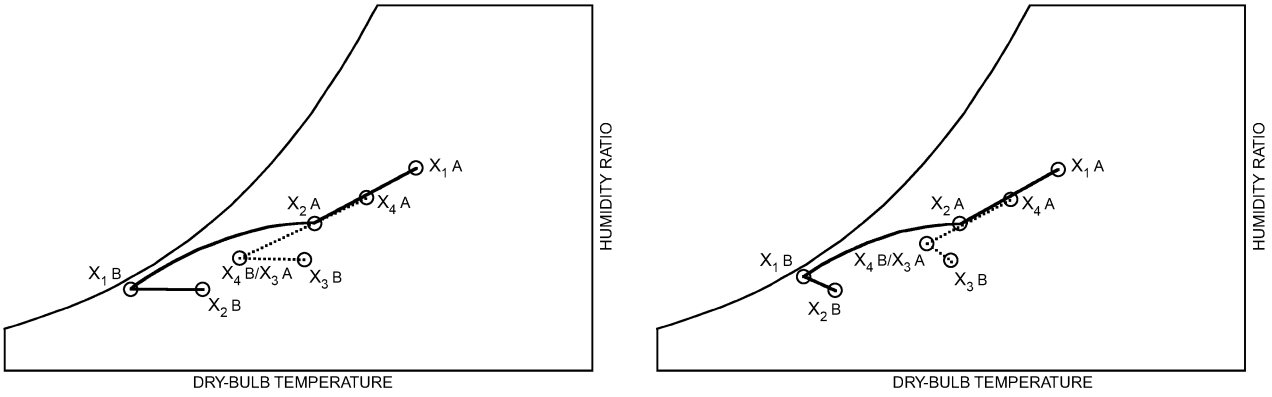

Fig. 34 Psychrometric Processes of Exchangers in Parallel Mode

(Moffitt 2011)

Furthermore, when the energy recovery device is in economizer mode (outdoor air temperatures of about 13 to 24°C) the in-series recovery device is still recovering energy.

The in-series energy recovery device should be sized for the highest dry-bulb temperature design condition, since this is when the device is exposed to the highest driving force and creates most reheat. This ensures the system will never provide too much reheat during the year. This approach is the simplest and is used when the primary goal is to downsize cooling equipment. The system designer must recognize that when the outdoor temperature is lower, that the driving force is also lower, and the device provides less reheat. If the design reheat is required during the whole cooling season, then supplemental reheat is still required after the in-series energy recovery device, albeit less than in a system without energy recovery.

An alternative design strategy is to optimize energy recovery. In this strategy, the system designer selects a device with a higher effectiveness than in the previous strategy, and provides a means of modulating its performance. By modulating the performance during the warmest outdoor air conditions, excessive reheat is avoided. During cooler conditions the device operates at full performance to recover more energy. The device is usually sized with a mind to pressure drop, recognizing that the airstream passes through the device twice, and initial purchase cost and is optimized against annual energy savings.

Examples of devices are wraparound heat pipes and thermosiphons (Figures 38 and 41), flat heat exchangers like wheels and heat pipes (Figure 39), and plate heat exchangers (Figure 40). Footprint and condensation management should be considered when designing the layout. Where a controllable device is required, options include: wraparound heat pipes and thermosiphons that use valves to control refrigerant flow; bypass around

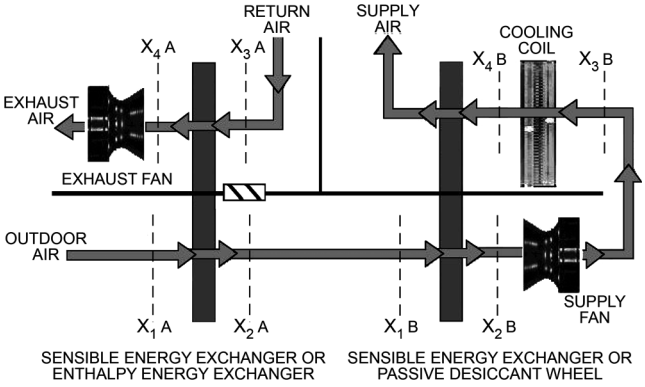

Fig. 35 Multiple Energy Recovery Exchangers in Parallel Mode

(Moffitt 2011)

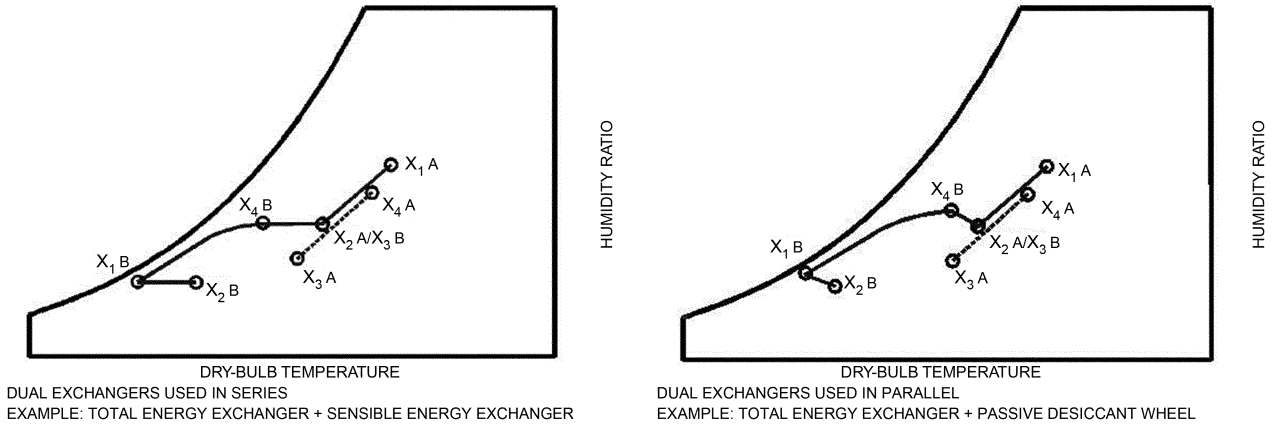

Fig. 36 Psychrometric Processes of Exchangers in Series Mode

(Moffitt 2011)

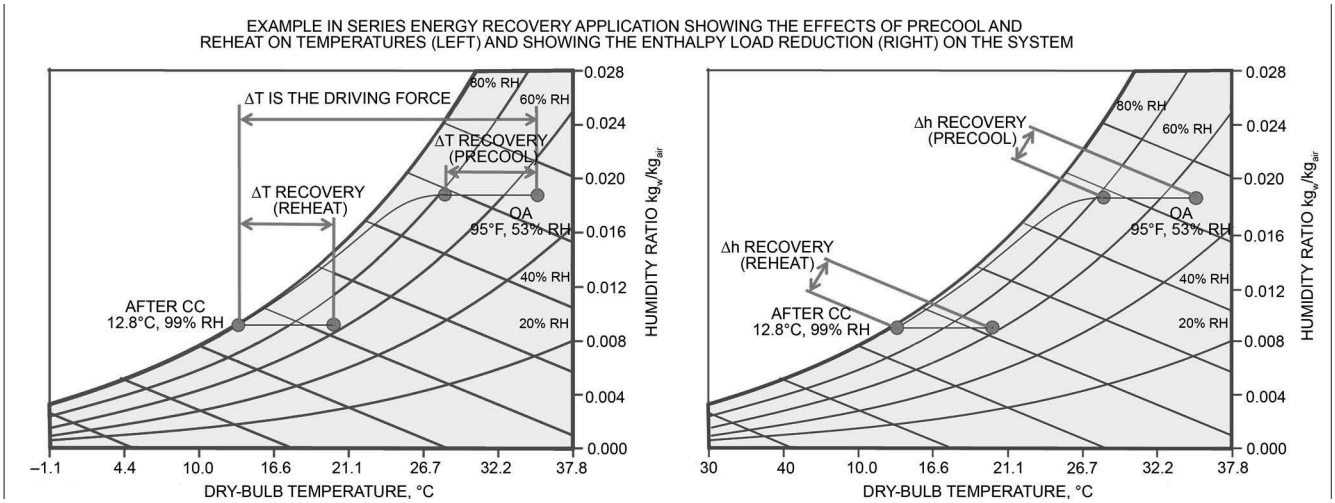

Fig. 37 Psychrometric Chart: In-Series Energy Recovery

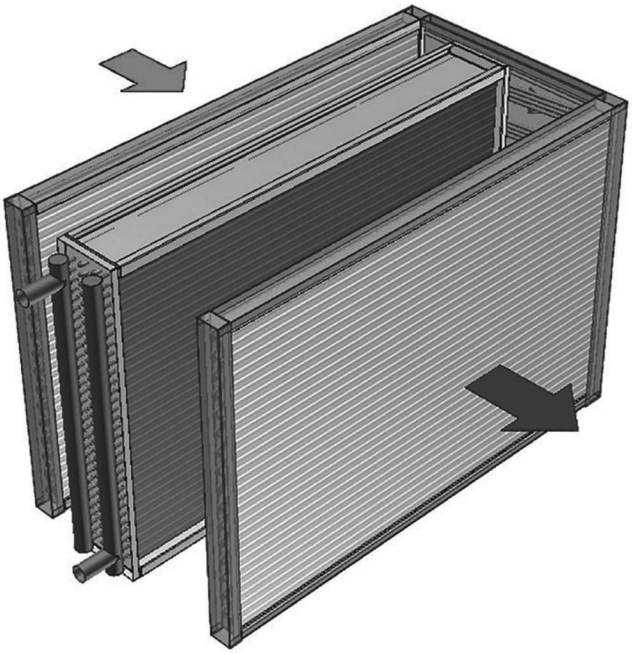

Fig. 38 Wraparound (In-Series) Heat Pipe

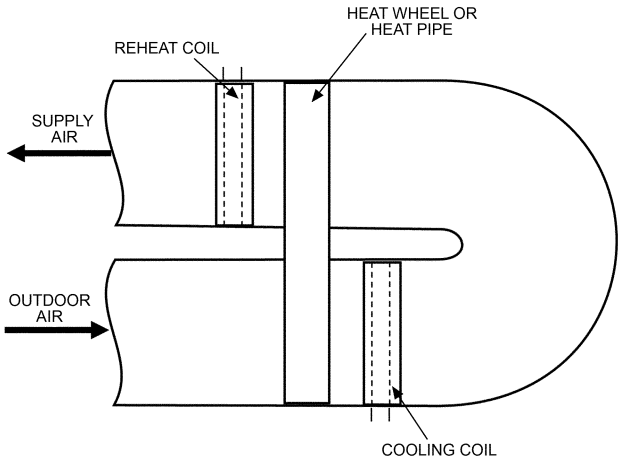

Fig. 39 Flat Heat Recovery Device in Wraparound (In-Series) Configuration

the device (but not through the cooling coil); or, for wheels, modulating wheel speed.

Example 4. Precooling Air Reheater Dehumidifier. In this application, 1.6m^3/s of outdoor supply air at 35 and 27°Cwb (ρ = 1.11 kg/m^3) is used to reheat 1.6 m^3/s of the same air leaving a cooling coil (exhaust) at 11.2 and 11.0°C wb using a sensible heat exchanger as a precooling air reheater. The reheated air is to be between 24 and 26°C. In this application, the warm airstream is outdoor air and the cold airstream is the same air after it leaves the cooling coil. The unit's manufacturer lists its effectiveness as 58.4%. For EATR = 0 and OACF ≈1, determine the leaving precooled and reheated air conditions and energy recovered, and check the energy exchange balance.

Solution:

Step 1. Because data on pressure drop are missing, skip this step.

Step 2. Calculate the theoretical maximum energy transfer.

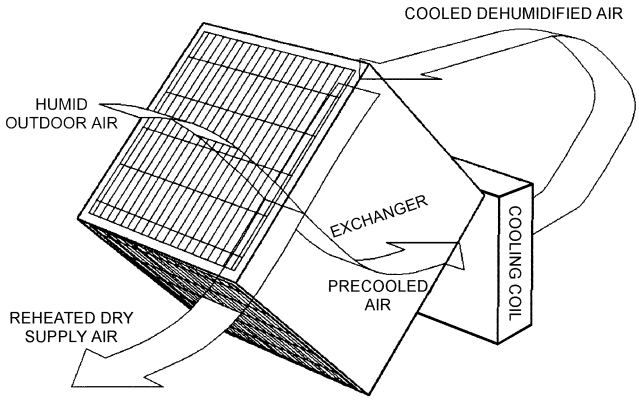

Fig. 40 Flat Plate Heat Exchanger in Wraparound (In-Series) Configuration

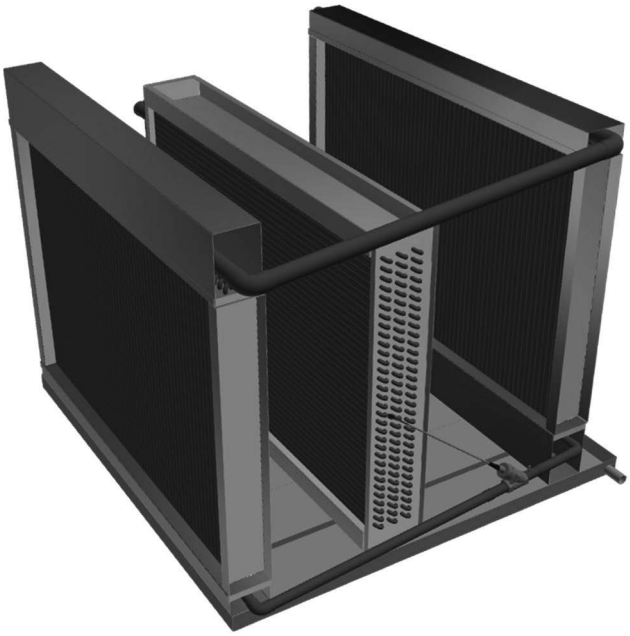

Fig. 41 Wraparound (In-Series) Thermosiphon with a Valve for Modulation

The air being reheated will have less mass than the outdoor air entering the precooler because moisture will condense from it as it passes through the precooler and cooling coil. Reheat is sensible heat only, so the denominator of Equation (2a) is used to determine the theoretical maximum energy transfer. To simplify the calculation, it is assumed that specific heat of dry air is constant at 1 kJ/(kg·K.

$$q_s = 1.11(1.6)(1)(35 - 11.2) = 42.3 \text{ kW saved}$$

Step 3. Establish the sensible effectiveness. The manufacturer gives the effectiveness as 58.4% at the designated operating conditions.

Step 4. Calculate actual energy transfer at design conditions.

$$q_{actual} = 0.584(42.3) = 24.7 \text{ kW}$$

Step 5. Calculate leaving air conditions. Because condensation occurs as the outdoor airstream passes through the precooling side of the heat exchanger, use Equation (4e) to determine its leaving enthalpy, which is the inlet condition for the cooling coil. Sensible heat transfer Equation (5a) is used to determine the temperature of air leaving the preheat side of the heat exchanger.

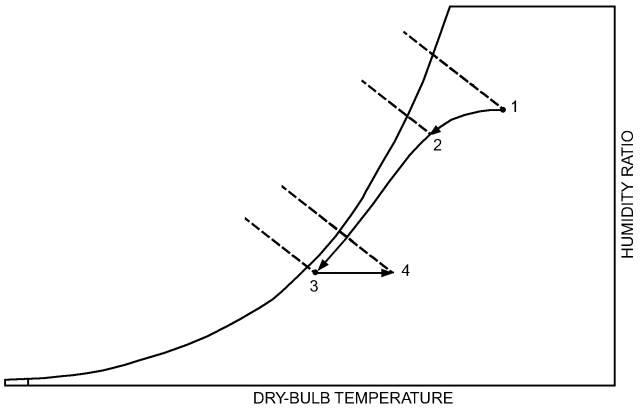

Fig. 42 Precooling Air Reheater Dehumidifier (Example 4)

a. Precooler leaving air conditions

Entering enthalpy, determined from the psychrometric chart for 35°C db and 27°C wb, is 85.2 kJ/kg.

$$h_2 = 85.2 + \frac{-24.7}{1.11(1.6)} = 71.3 \text{ kJ/kg}$$

The wet-bulb temperature for saturated air with this enthalpy is 23.5°C. This is point 2 on the psychrometric chart (Figure 42), which is near saturation. Note that this precooled air is further dehumidified by a cooling coil.

b. Reheater leaving air conditions

$$t_4 = 11.2 + \frac{24.7}{1.11(1.6)(1)} = 25.1°\text{C}$$

Entering enthalpy, determined from the psychrometric chart for 11.2°C db and 11.0°C wb, is 32.0 kJ/kg.

$$h_4 = 32 + \frac{24.7}{1.11(1.6)} = 45.9 \text{ kJ/kg}$$

The wet-bulb temperature for air with this temperature and enthalpy is 16.3°C.

Step 6. Check performance.

$$q_s = 1.11(1.6)(85.2 - 71.3) = 24.7 \text{ kW precooling}$$

$$q_e = 1.11(1.6)(1)(25.1 - 11.2) = 24.7 \text{ kW reheat}$$

Step 7. Plot conditions on psychrometric chart (Figure 42). Because EATR = 0 and OACF ≈ 1, Steps 8 to 10 are not presented here.

Dessicant and Heat Wheel Systems

The Center for Climate and Energy Solutions' 2015 international conference on climate change emphasized reducing greenhouse gas emissions and requiring more efficient equipment, including HVAC systems (which consume significant electrical power) (C2ES 2015). Sensible and desiccant wheels can be used in combination with a heat pump direct evaporative cooler (DEC) to achieve this goal, as shown in the following cases.

The heat dissipated in the condenser of a heat pump can be used to regenerate the desiccant wheel (Sheng et al. 2015) and has a potential of significant energy cost savings. At design conditions for Atlanta, Georgia, for a 100% replacement air system as shown in Figure 43, this approach can reduce cooling capacity requirements by 52% and net electrical shaft power requirements by more than 24% compared to the conventional vapor-compression system (Dhamshala 2016).

Figure 44 shows an advanced desiccant system for 100% outdoor supply air (OSA) mode with heat and desiccant wheels and

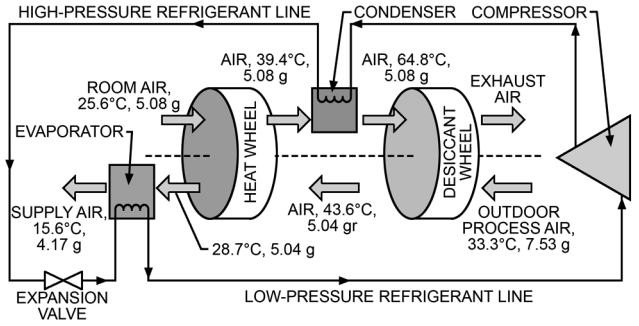

Fig. 43 Heat Pump Augmented by Heat and Dessicant Wheels

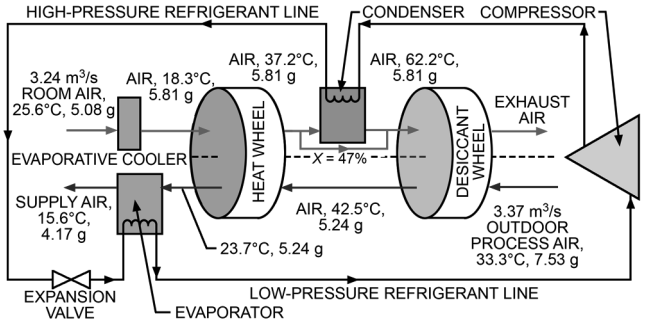

Fig. 44 Heat Pump Augmented by Evaporative Cooler and Heat and Dessicant Wheels

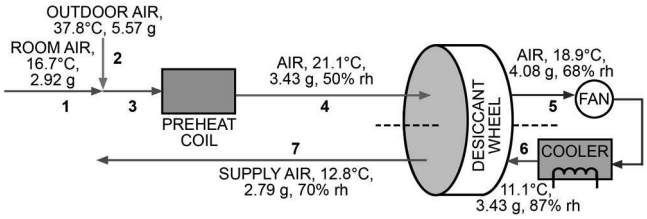

Fig. 45 System for Surgery Room

(based on concepts presented in Murphy 2006)

direct evaporative cooler (DEC) in combination with a heat pump. This system could reduce cooling capacity requirements by 59% and net electrical shaft power requirements by close to 30% at the same design conditions as for Figure 43 (Dhamshala 2016).

A simplified system suitable for surgery rooms (able to provide optimum temperature and humidity control) consists of a preheater, desiccant wheel with type 3 desiccant, and a cooling coil, as shown in Figure 45. The type 3 desiccant in the desiccant wheel has a large affinity to adsorb water vapor when the relative humidity of the air is high (as it is in states 6 and 7), whereas it gives off moisture at states 4 and 5 (which have lower humidity). The simplicity of this system not only reduces maintenance costs but can also save significant energy costs.

A desiccant system consisting of two evaporative coolers and heat and desiccant wheels for a 100% replacement air application, as shown in Figure 46, could provide all the space summer cooling needs without the use of an air conditioner. Such a system can reduce net electrical power requirements by more than 90% at design conditions for the city of Phoenix, Arizona (Dhamshala 2016). The only electrical power required is for the fan power and rotation of the wheels. The magnitude of estimated electrical power savings should be of similar range for the entire dry (B) region of the ASHRAE climatic zones, with small differences.

Note that the minuscule heat energy required (6.15 kW) in the heater can easily be obtained from an air-to-air heat exchanger using

outdoor air (which, at 39.4°C, exceeds the minimum temperature) before it enters the desiccant wheel. The cost of water supplied to the evaporative coolers is estimated to be negligible.

Accurate estimates of energy cost savings over a year can be obtained through detailed computer simulations of systems for a specific building with given building loads using the hourly weather data. Highly specialized desiccant systems using a DOAS can be designed to serve the buildings with specific loads or needs (Moffitt 2015). Sultan et al. (2015) provide an overview of various widely used solid-desiccant air systems.

In the case that outdoor air requirements are less than 100%, use of direct evaporative coolers adds more humidity into the supply air. An alternative to replace the direct evaporative cooler is the indirect evaporative cooler (M-cycle), as shown in Figure 47 for the cooling season, which has a potential to save 32% of cooling capacity, while the system shown in Figure 48 (suitable for winter heating) has a potential to save 22% of heating costs.

These systems are particularly suitable for sustainable systems, where the emphasis is placed on the use of renewable energy resources such as solar, wind, and bioenergy. A PV/T panel system in combination with water-to-water heat pump, absorption chiller, and thermal storage can provide the energy requirements for cooling and heating seasons.

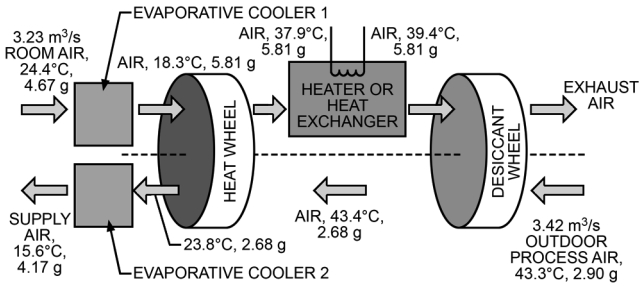

Fig. 46 Dessicant System of Evaporative Coolers and Heat and Dessicant Wheels

However, these systems are also suitable if renewable energy resources are not available at the site. The heat energy required by the heater placed between the heat and desiccant wheels to regenerate the air can be obtained from the condenser of the air-conditioner, similar to the system shown in Figure 14.

Sustainability. Recently, due to climate change, greater emphasis has been on reducing the greenhouse gas emissions (UN Climate Change Report; UNFCCC 2018), and on the rapid adoption of renewable energy resources. In light of the urgent need, the systems shown in Figures 47 and 48pave the way to accommodate the use of renewable energy resources to meet the future goals of the HVAC systems to be compatible with smart grid applications. The desiccant and heat wheels shown in Figures 47 and 48 and not only perform the energy recovery from the outgoing exhaust air but also meet the peak loads of the building through proper selection of flow rates, mixing of outdoor air with exhaust air, and regenerating temperature. Several other options of these variations may be possible to suit the level of regenerating temperatures.

Ge et al. (2015), Tu et al. (2015), and Zeng et al. (2014) find that two-stage desiccant systems can be designed to use low-grade heat energy resources, such as waste energy at the site or solar collectors, which can yield greater energy cost savings.

To best use existing energy resources available at a specific temperature or grade, perform a series of second-law analyses on a variety of desiccant systems (including a two-stage unit) to find the maximum energy cost savings and to identify the components of the system that have largest exergy destruction (Enteria et al. 2013; Liu et al. 2016; Tu et al. 2015a, 2015b).

An emerging technology combining liquid-desiccant solutions (e.g., lithium chloride) with an evaporative cooler has the potential to save significant energy costs (Gao et al. 2015). A simplified schematic suitable for use in various climates is shown in Figure 49.

Note that the minuscule heat energy required (6.15 kW) in the heater can easily be obtained from an air-to-air heat exchanger using outdoor air (which, at 39.4°C, exceeds the minimum temperature) before it enters the desiccant wheel. The cost of water supplied to the evaporative coolers is estimated to be negligible.

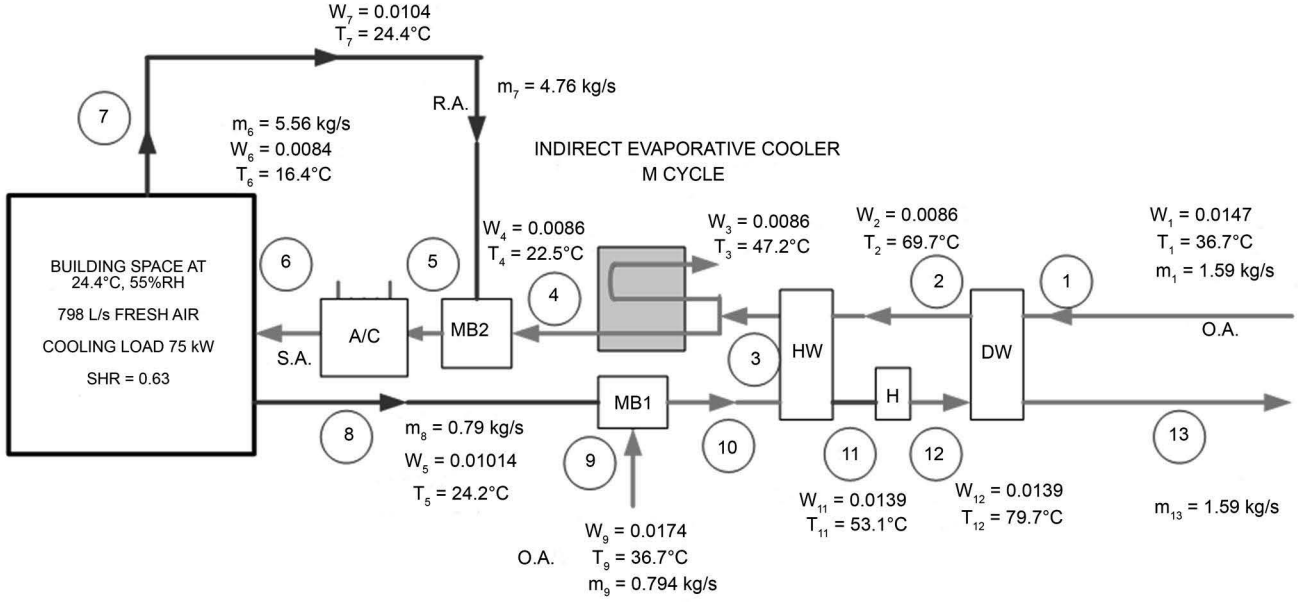

Fig. 47 Dessicant and Heat Wheels with Indirect Evaporative Cooler (M-Cyle)

Dhamshala et al. (2019)

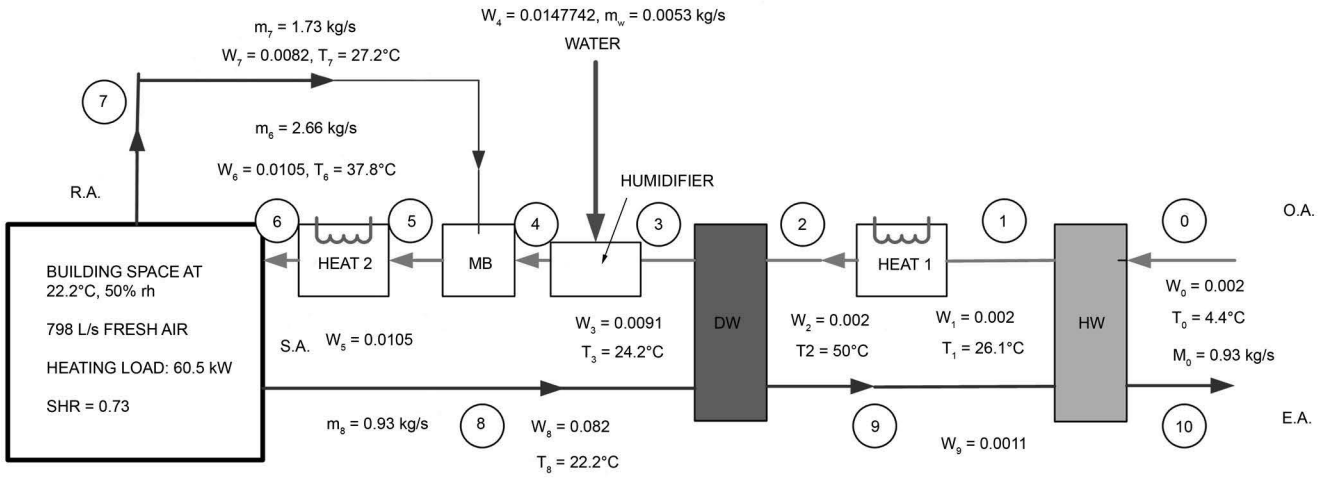

Fig. 48 Dessicant and Heat Wheels with Humidifier for Winter Heating

Dhamshala et al. (2019)

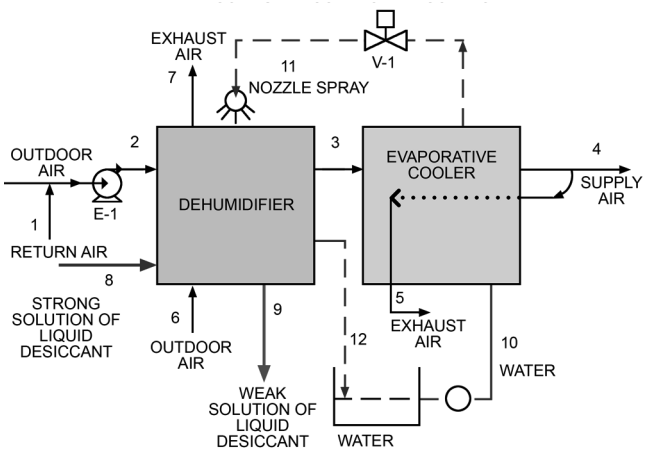

Fig. 49 Schematic of Liquid Dessicant System and Evaporative Cooler

NREL

Heat energy is required to regenerate the liquid desiccant solution; it can use waste heat energy, if available at the site, or use solar collectors. A combination of heat and desiccant wheels with this liquid-desiccant system might provide an economical system that is environmentally friendly.

8. ECONOMIC CONSIDERATIONS

Air-to-air energy recovery systems are used in both new and retrofit applications. These systems should be designed for the maximum cost benefit or least life-cycle cost (LCC) expressed either over the service life or annually and with an acceptable payback period.

The annualized system owning, operating, and maintenance costs are discussed in Chapter 38 of the 2023 *ASHRAE Handbook—HVAC Applications*. Although the capital cost and interest term in this method imply a simple value, it is in fact a complex function of the future value of money as well as all the design variables in the energy/heat exchanger. These variables include the mass of each material used, cost of forming these materials into a highly effective energy/heat exchanger, cost of auxiliary equipment and controls, and cost of installation.

The **operating energy cost** for energy recovery systems involves functions integrated over time, including variables such as flow rate, pressure drop, fan efficiency, energy cost, and energy recovery rate. The calculations are complex because air-heating and/or cooling loads are, for a range of supply temperatures, time dependent in most buildings. Time-of-use schedules for buildings can impose different ventilation rates for each hour of the day. Electrical utility charges often vary with time of day, amount of energy used, and peak power load. For building ventilation air-heating applications, the peak heat recovery rate usually occurs at the outdoor supply temperature at which frosting control throttling must be imposed. In addition to designing for the winter design temperature, heat recovery systems should be optimized for peak heat recovery rate, taking frost control into account.

Overall exchanger effectiveness ε should be high (see Table 3 for typical values); however, a high ε implies a high capital cost, even when the exchanger is designed to minimize the amount of materials used. Energy costs for fans and pumps are usually very important and accumulate operating cost even when the energy recovery system must be throttled back. For building ventilation, throttling may be required much of the time. Thus, the overall LCC minimization problem for optimal design may involve 10 or more independent design variables as well as several specified constraints and operating conditions (see, e.g., Besant and Johnson [1995]).

In addition, comfort-to-comfort energy recovery systems often operate with much smaller temperature differences than most auxiliary air-heating and cooling heat exchangers. These small temperature differences need more accurate energy transfer models to reach the maximum cost benefit or lowest LCC. Most importantly, recovered energy at design may be used to reduce the required capacity of heating and cooling equipment, which can be significant in both system performance/efficiency and economics.

The **payback period (PP)** is best computed after the annualized costs have been evaluated. It is usually defined as

$$\begin{aligned} \text{PP} &= \frac{\text{Capital cost and interest}}{\text{Annual operating enery cost saved}} \\ &= \frac{C_{s,init} - \text{ITC}}{C_e(1 - T_{inc})}\text{CRF}(i'', n) \end{aligned} \tag{29}$$

where

$C_{s,\,init}$ = initial system cost

ITC = investment tax credit for energy-efficient improvements
C_e = cost of energy to operate the system for one period
T_{inc} = net income tax rate where rates are based on last dollar earned (i.e., marginal rates) = (local + state + federal rate) – (federal rate) (local + state rate)
CRF = capital recovery factor
i'' = effective discount rate adjusted for energy inflation
n = total number of periods under analysis

The inverse of this term is usually called the **return on investment (ROI).** Well-designed energy recovery systems normally have a PP of less than 5 years, and often less than 3 years. Paybacks of less than 1 year are not uncommon in comfort-to-comfort applications in hot, humid climates, primarily because of the reduced size of cooling equipment required.

Other economic factors include the following.

System Installed Cost. Initial installed HVAC system cost is often lower for air-to-air energy recovery devices because mechanical refrigeration and fuel-fired heating equipment can be reduced in size. Thus, a more efficient HVAC system may also have a lower installed total HVAC cost. The installed cost of heat recovery systems becomes lower per unit of flow as the amount of outdoor air used for ventilation increases.

Life-Cycle Cost. Air-to-air energy recovery cost benefits are best evaluated considering all capital, installation, operating, and energy-saving costs over the equipment life under normal operating conditions in terms of the life-cycle cost. As a rule, neither the most efficient nor the least expensive energy recovery device will be most economical. Optimizing the life-cycle cost for maximum net savings may involve many design variables, requiring careful cost estimates and use of an accurate recovery system model with all its design variables (see, e.g., Besant and Simonson [2000]).

Energy Costs. The absolute cost of energy and relative costs of various energy forms are major economic factors. High energy costs favor high levels of energy recovery. In regions where electrical costs are high relative to fuel prices, heat recovery devices with low pressure drops are preferable.

Amount of Recoverable Energy. Economies of scale favor large installations. Equipment is commercially available for air-to-air energy recovery applications using 25 L/s and above.

Grade of Exhaust Energy. High-grade (i.e., high-temperature) exhaust energy is generally more economical to recover than low-grade energy. Energy recovery is most economical for large temperature differences between the waste energy source and destination.

Coincidence and Duration of Waste Heat Supply and Demand. Energy recovery is most economical when supply coincides with demand and both are relatively constant throughout the year. Thermal storage may be used to store energy if supply and demand are not coincident, but this adds cost and complexity to the system.

Proximity of Supply to Demand. Applications with a large central energy source and a nearby waste energy use are more favorable than applications with several scattered waste energy sources and uses.

Operating Environment. High operating temperatures or the presence of corrosives, condensable gases, and particulates in either airstream results in higher equipment and maintenance costs. Increased equipment costs result from the use of corrosion- or temperature-resistant materials, and maintenance costs are incurred by an increase in the frequency of equipment repair and wash down and additional air filtration requirements.

Effect on Pollution Control Systems. Removing process heat may reduce the cost of pollution control systems by (1) allowing less expensive filter bags to be used, (2) improving the efficiency of electronic precipitators, or (3) condensing out contaminant vapors, thus reducing the load on downstream pollution control systems. In some applications, recovered condensable gases may be returned to the process for reuse.

Effect on Heating and Cooling Equipment. Heat recovery equipment may reduce the size requirements for primary utility equipment such as boilers, chillers, and burners, as well as the size of piping and electrical services to them. Larger fans and fan motors (and hence fan energy) are generally required to overcome increased static pressure loss caused by the energy recovery devices. Auxiliary heaters may be required for frost control.

Effect on Humidifying or Dehumidifying Equipment. Selecting total energy recovery equipment results in the transfer of moisture from the airstream with the greater humidity ratio to the airstream with the lesser humidity ratio. This is desirable in many situations because humidification costs are reduced in cold weather and dehumidification loads are reduced in warm weather.

9. ENERGY AND/OR MASS RECOVERY CALCULATION PROCEDURE

The rate of energy transfer to or from an airstream depends on the rate and direction of heat transfer and water vapor (moisture) transfer. Under customary design conditions, heat and water vapor transfer will be in the same direction, but the rate of heat transfer often will not be the same as the rate of energy transfer by the cross-stream flow of water vapor. This is because the driving potentials for heat and mass transfer are different, as are the respective wall resistances for the two types of transport. Both transfer rates depend on exchanger construction characteristics.

The following general procedure may be used to determine the performance and energy recovered in air-to-air energy recovery applications at each operating condition.

Step 1. Determine supply and exhaust air pressure drops Δp_s and Δp_e across exchanger.

Request air pressure drops Δp_s and Δp_e across the heat or energy exchanger from the manufacturer, who may have certified AHRI *Standard* 1061 test condition data obtained using ASHRAE *Standard* 84 as a test procedure and analysis guide. These data may be extrapolated to non-AHRI conditions by the manufacturer using correlations such as Equations (12) or (13), if their restrictions are satisfied. For other flow conditions, somewhat different correlations may be more accurate to determine the pressure drop.

Step 2. Calculate theoretical maximum moisture and energy transfer rates m_{max} and q_{max}.

The airstream with the lower mass flow m_{min} limits heat and moisture transfer. Some designers specify and prefer working with airflows stated at standard temperature and pressure conditions. To correctly calculate moisture or energy transfer rates, the designer must determine mass flow rates. For this reason, the designer must know whether airflow rates are quoted for the entry conditions specified or at standard temperature and pressure conditions. If necessary, convert flow rates to mass flow rates (e.g., L/s or m^3/s at standard temperature and pressure to kg/s) and then determine which airstream has the minimum mass.

The theoretical maximum sensible heat, latent heat and total energy rates are given by the denominators of Equations (2a), (2b), and (2c), respectively.

The split between latent and sensible energy can be determined by plotting airstream conditions on a psychrometric chart as shown in Figure 50. Maximum sensible heat transfer is represented by a horizontal line drawn between the two dry-bulb temperatures, and maximum latent energy transfer is represented by the vertical line.

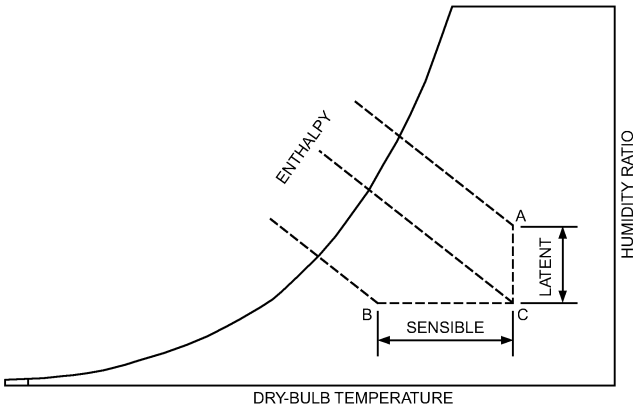

Fig. 50 Maximum Sensible and Latent Heat from Process A-B

Step 3. Establish moisture, sensible, and total effectiveness ε_s, ε_L, and ε_t.

Each of these ratios is obtained from manufacturers' product data using input conditions and airflows for both airstreams. The effectiveness for airflows depends on (1) exchanger construction, including configuration, heat transfer material, moisture transfer properties, transfer surface area, airflow path, distance between heat transfer surfaces, and overall size; and (2) inlet conditions for both airstreams, including pressures, velocities, temperatures, and humidities. In applications with unequal airflow rates, the enthalpy change will be higher for the airstream with the lesser mass flow.

Step 4. Calculate actual moisture (latent) and energy (sensible, latent or total) transfer rates.

The actual moisture, sensible heat, latent heat, and total energy rates are given by Equations (5a), (5b), (5c), and (5d or 5e), respectively.

Step 5. Calculate leaving air properties for each airstream using Equations (4a), (4b), (4c), (4d), (4e), and (4f).

With an enthalpy or moisture-permeable heat exchanger, moisture (and its inherent latent energy) is transferred between airstreams. With a sensible-only heat exchanger, if the warmer airstream is cooled below its dew point, the resulting condensed moisture transfers additional energy. When condensation occurs, latent heat is released, maintaining that airstream at a higher temperature than if condensation had not occurred. This higher air temperature (potential flux) increases the heat transfer to the other airstream. The sensible and total effectiveness are widely used because the energy flow in the condensate is relatively small in most applications. (Freezing and frosting are unsteady conditions that should be avoided unless a defrost cycle is included.) Equations (4c) and (4d) must be used to calculate the leaving air humidity conditions, and Equations (4e) and (4f) to calculate the enthalpy values for airstreams in which inherent latent energy transfer occurs. Equations (4a) and (4b) may be used for airstreams if only sensible energy transfer is involved.

Step 6. Check energy transfer balance between airstreams.

Equation (5a) can be used to estimate the sensible energy transfer rate into the supply airstream, and can be adapted to estimate the energy transfer rate out of the exhaust airstream by substituting T_3 for T_1, and substituting T_4 for T_2. Equation (5d) or (5e) can estimate the total energy for the two airstreams, using similar substitutions. Total energy transferred from one airstream should equal total heat transferred to the other. Calculate and compare the energy transferred to or from each airstream. Differences between these energy flows are usually because of measurement errors.

Step 7. Plot entering and leaving conditions on psychrometric chart.

Examine the plotted information for each airstream to verify that performance is reasonable and accurate.

(*Steps 8 to 10 apply only when EATR ≠ 0 and OACF ≠ 1.*)

Step 8. Obtain data on exhaust air transfer ratio (EATR > 0 and typically 0.05 > EATR > 0 for regenerative wheels).

Request the EATR data from the manufacturer, who may have certified AHRI *Standard* 1061 test condition data obtained using ASHRAE *Standard* 84 as a test procedure and analysis guide. These data may be extrapolated to non-AHRI test conditions using correlations relating EATR to air pressure differences between the supply and exhaust and, for rotary regenerative wheels, carryover caused by wheel rotation. Shang et al. (2001a) show that, for regenerative wheels, a correlation may be developed between EATR and carryover ratio, R_c, and OACF, but for other air-to-air exchangers EATR will be very small or negligible.

Step 9. Obtain data on outdoor air correction factor (OACF ≈ 1 and typically 0.9 < OACF < 1.1 for regenerative wheels).

Request the OACF data from the manufacturer, who may have certified AHRI *Standard* 1061 test condition data obtained using ASHRAE *Standard* 84 as a test procedure and analysis guide. These data may be extrapolated to non-AHRI test conditions using correlations relating OACF to pressure differences (Shang et al. 2001b), for regenerative wheels; for other exchangers, OACF will be very nearly 1.0.

Step 10. Correct the supply air ventilation rate, moisture transfer rate, and energy transfer rates for EATR ≠ 0 and OACF ≠ 1.0.

Values of EATR significantly larger than zero and OACF significantly different than 1.0 imply the air-to-air exchanger is transferring air between the exhaust and supply airstreams. This transfer may be important, especially for some devices such as regenerative wheels. Shang et al. (2001b) show a method to correct the energy rates when EATR ≠ 0 and OACF ≠ 1. The procedure to correct the supply air ventilation rate is shown in Example 8.

Example 5. Sensible Heat Recovery in Winter. Exhaust air at 23°C and 10% rh with a flow rate of 6 kg/s preheats an equal mass flow rate of outdoor air at –18°C and 60% rh (ρ = 1.39 kg/m^3) using an air-to-air heat exchanger with a measured effectiveness of 60%. Airflows are specified as mass flow rates at standard temperature and pressure (i.e., 15°C and 101.325 kPa). Assuming EATR = 0 and OACF ≈ 1, determine the leaving supply air temperatures and energy recovered, and check the heat exchange balance. To simplify the calculation, assume that specific heat of dry air is constant at 1 kJ/kg·K

Solution:

Note: the numbers correspond to the steps in the calculation procedure.

1. Because data on pressure drop are missing, skip this step.

2. Calculate the theoretical maximum heat transfer.

The two inlet conditions plotted on a psychrometric chart (Figure 51) indicate that, because the exhaust air has low relative humidity, latent energy transfer does not occur. Using the denominator of Equation (2a), the theoretical maximum sensible heat transfer rate q_s is

$$q_{max} = (6\ \text{kg/s})[1\ \text{kJ/(kg·K)}][23 - (-18)] = 246\ \text{kW}$$

3. Establish the sensible effectiveness.

From manufacturer's literature and certified performance test data, effectiveness is determined to be 60% at the design conditions.

4. Calculate actual heat transfer at given conditions.

Using Equation (5a),

$$q_s = (0.6)(246)\ \text{kW} = 148\ \text{kW}$$

5. Calculate leaving air conditions.

Because no moisture or latent energy transfer will occur,

a. Leaving supply air temperature t_2 is given as

$$t_2 = -18°\text{C} + \frac{148\ \text{kW}}{(6\ \text{kg/s})[1\ \text{kJ/(kg·K)}]} = 6.7°\text{C}$$

b. Leaving exhaust air temperature t_4 is given as

$$t_4 = 23°\text{C} - \frac{148\ \text{kW}}{(6\ \text{kg/s})[1\ \text{kJ/(kg·K)}]} = -1.7°\text{C}$$

6. Using Equation (5a), check performance.

$$q_s = (6\ \text{kg/s})[1\ \text{kJ/(kg·K)}][6.7 - (-18)] = 148\ \text{kW saved}$$

7. Plot conditions on psychrometric chart to confirm that no moisture exchange occurred (Figure 52).

Because EATR = 0 and OACF ≈ 1, Steps 8 to 10 of the calculation procedure are not presented here.

Example 6. Sensible Heat Recovery in Winter with Water Vapor Condensation. Exhaust air at 23°C and 28% rh (ρ = 1.2 kg/m^3) and flow rate of 5 m^3/s is used to preheat 4.5 m^3/s of outdoor air at –10°C and 50% rh (ρ = 1.34 kg/m^3) using a heat exchanger with a sensible effectiveness of 70%. Assuming EATR = 0 and OACF ≈ 1, determine the leaving supply air conditions and energy recovered, and check the energy exchange balance.

Solution:

The supply airstream has a lower airflow rate than the exhaust airstream, so it may appear that the supply airstream limits heat transfer. However, determination of mass flow rates for the given entry conditions shows that the mass flow rate of the supply airstream (6.03 kg/s) is slightly greater than that of the exhaust airstream (6.0 kg/s), so exhaust is the limiting airstream. Nevertheless, because the mass difference is negligible, it is convenient to use supply air volume as the limiting airstream. Also, to simplify the calculation, assume that specific heat of dry air is constant at 1 kj/kg·K.

1. Because data on pressure drop are missing, skip this step.

2. Calculate the theoretical maximum sensible heat transfer.

The limiting airstream, the supply airstream, will be preheated in the heat exchanger, so it is not subject to condensation. Therefore, the denominator of Equation (2a) is used:

$$q_{max} = (4.5\ \text{m}^3\text{/s})(1.34\ \text{kg/m}^3)[1\ \text{kJ/(kg·K)}][23 - (-10)]°\text{C} = 199\ \text{kW}$$

3. Select sensible effectiveness.

From manufacturer's literature and performance test data, the sensible effectiveness is determined to be 70% at the design conditions.

4. Calculate actual heat transfer at design conditions using Equation (5a):

$$q_s = (0.7)(199\ \text{kW}) = 139\ \text{kW}$$

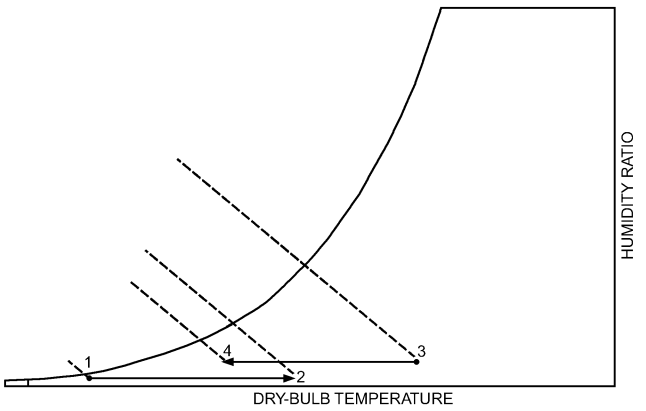

Fig. 51 Sensible Heat Recovery in Winter (Example 5)

5. Calculate leaving air conditions.

a. Leaving supply air temperature is calculated by

$$t_2 = -10°\text{C} + \left\{\frac{139\ \text{kW}}{(1.34\ \text{kg/m}^3)(4.5\ \text{m}^3\text{/s})[1\ \text{kJ/(kg·K)}]}\right\} = 13.1°\text{C}$$

b. Because the dew point of exhaust air at inlet is 3.54°C, condensation occurs on the exhaust side, so the leaving exhaust air temperature cannot be determined using Equation (4b). The entering exhaust air enthalpy and humidity ratio are determined for the dry-bulb temperature of 23°C and 28% rh using a psychrometric chart and found to be h_3 = 36 kJ/kg and w_3 = 0.0052 kg/kg. However, the leaving exhaust air enthalpy can be determined by

$$h_4 = 36\ \text{kJ/kg} - \left[\frac{139\ \text{kW}}{(1.2\ \text{kg/m}^3)(5\ \text{m}^3\text{/s})}\right] = 12.83\ \text{kJ/kg}$$

Because the air will be saturated at the outlet of exhaust air, the dry-bulb or wet-bulb temperature and humidity ratio corresponding to an enthalpy of 12.83 kJ/kg is found to be t_4 = 1.4°C and w_4 = 0.0044 kg/kg. The rate of moisture condensed m_w is

$$m_w = m_e\,(w_3 - w_4) = (6\ \text{kg/s})(0.0049 - 0.0042) = 0.0042\ \text{kg/s}$$

6. Check performance.

$$q_s = (134\ \text{kg/m}^3)(4.5\ \text{m}^3\text{/s})[0.24\ \text{kJ/(kg·°C)}][13.1 - (-10)]$$
$$= 139.3\ \text{kW saved}$$

Neglect the enthalpy of the condensed water by adding the energy lost through condensation of vapor to the sensible heat lost of the exhausting air.

$$q_e = (1.2\ \text{kg/m}^3)(5\ \text{m}^3\text{/s})[1\ \text{kJ/(kg·K)}][23 - 1.4)]$$
$$+ (0.0042\ \text{kg/s})(2560\ \text{kJ/kg})$$
$$= 140.35\ \text{kW saved, which is very close to } 139.3\ \text{kW}$$

7. Plot conditions on psychrometric chart (Figure 53). Note that moisture condenses in the exhaust side of the heat exchanger.

Because EATR = 0 and OACF ≈ 1, Steps 8 to 10 of the calculation procedure are not presented here.

Example 7. Total Heat Recovery in Summer. Exhaust air at 23°C and 17°C wb (ρ = 1.2 kg/m^3) with a flow rate of 5 m^3/s is used to precool 4 m^3/s of supply outdoor air at 35°C and 27°C wb (ρ = 1.15 kg/m^3) using a hygroscopic total energy exchanger. The sensible and total effectiveness for this heat exchanger are 70 and 56.7%, respectively. Assuming EATR = 0 and OACF ≈ 1, determine the leaving supply air conditions and energy recovered, and check the energy exchange balance. To simplify the calculation, assume that specific heat of dry air is constant at 1 kJ/kg·K.

Solution:

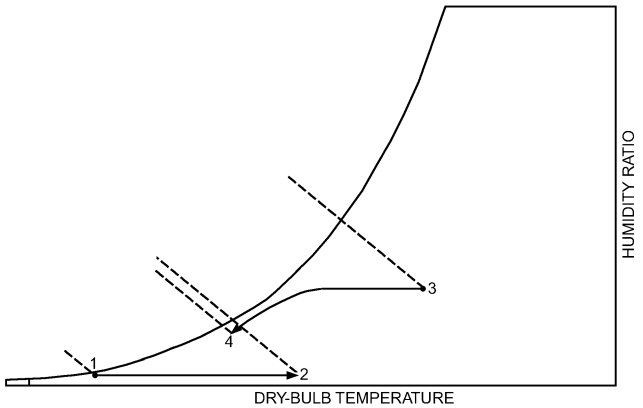

Fig. 52 Sensible Heat Recovery in Winter with Condensate (Example 5)

1. Because data on pressure drop are missing, skip this step.
2. Calculate the theoretical maximum heat transfer.

The supply airstream is a lesser or limiting airstream for energy and moisture transfer. Determine entering airstream enthalpies and humidity ratio from psychrometric chart.

Supply inlet (35°C db, 27°C wb) $h_1 = 85.2$ kJ/kg $w_1 = 0.0194$ kg/kg

Exhaust inlet (23°C db, 17°C wb) $h_3 = 47.8$ kJ/kg $w_3 = 0.0093$ kg/kg

The theoretical maximum sensible and total heat transfer rates can be obtained as follows:

$$q_{max}\,(\text{sensible}) = (1.15\ \text{kg/m}^3)(4\ \text{m}^3/\text{s})[1\ \text{kJ/(kg·K)}](35 - 23) = 55.2\ \text{kW}$$

$$q_{max}\,(\text{total energy}) = (1.15\ \text{kg/m}^3)(4\ \text{m}^3/\text{s})(85.2 - 47.8) = 172\ \text{kW}$$

3. Determine supply sensible and total effectiveness.

The manufacturer's selection data for the design conditions provide the following effectiveness ratios:

$$\varepsilon_s = 70\% \qquad \varepsilon_t = 56.7\%$$

4. Calculate energy transfer at design conditions.

$$q_t = (0.567)(172\ \text{kW}) = 97.52\ \text{kW total recovered}$$
$$q_s = -(0.7)(55.2\ \text{kW}) = -38.64\ \text{kW sensible recovered}$$
$$q_{tat} = 58.8\ \text{kW latent recovered}$$

5. Calculate leaving air conditions.

a. Supply air conditions

$$t_2 = 35°\text{C} + \frac{-38.64\ \text{kW}}{(1.15\ \text{kg/m}^3)(4\ \text{m}^3/\text{s})[1\ \text{kJ/(kg·K)}]} = 26.6°\text{C}$$

$$h_2 = 85.2\ \text{kJ/kg} + \frac{-97.52\ \text{kW}}{(1.15\ \text{kg/m}^3)(4\ \text{m}^3/\text{s})} = 64\ \text{kJ/kg}$$

From the psychrometric chart, the supply air humidity ratio and wet-bulb temperature are found to be $w_2 = 0.0145$ and $t_{w2} = 21.8°\text{C}$.

b. Exhaust air conditions

$$t_4 = 23°\text{C} + \frac{38.64\ \text{kW}}{(1.2\ \text{kg/m}^3)(5\ \text{m}^3/\text{s})[1\ \text{kJ/(kg·K)}]} = 29.4°\text{C}$$

$$h_4 = 47.8\ \text{kJ/kg} + \frac{97.52\ \text{kW}}{(1.2\ \text{kg/m}^3)(5\ \text{m}^3/\text{s})} = 64.1\ \text{kJ/kg} = 64.1\ \text{kJ/kg}$$

From the psychrometric chart, the exhaust humidity ratio and wet-bulb temperature are found to be $w_4 = 0.0134$ and $t_{w4} = 21.8°\text{C}$.

6. Check total performance (Equation 5d).

$$q_t = (1.15\ \text{kg/m}^3)(4\ \text{m}^3/\text{s})(85.2 - 64) = 97.52\ \text{kW saved}$$

$$q_t = (1.2\ \text{kg/m}^3)(5\ \text{m}^3/\text{s})\{[1\ \text{kJ/(kg · K)}](29.4 - 23) + (0.013 - 0.0093)(2560\ \text{kJ/kg})\} = 95.23\ \text{kW, which is close to 94.1 kW}$$

7. Plot conditions on psychrometric chart (Figure 54).

Because EATR = 0 and OACF ≈ 1, Steps 8 to 10 are not presented here.

Example 8. Total Energy Recovery with EATR ≠ 0 and OACF ≠ 1.0. An ERV manufacturer claims a product has performance characteristics as shown here at 400 L/s:

Pressure drop $\Delta p = 225$ Pa
$\varepsilon_{sensible} = 0.73$
$\varepsilon_{latent} = 0.68$
$\varepsilon_{total} = 0.715$

A building has a ventilation requirement of 400 L/s and exhaust air at 23°C and 17°C wb ($\rho = 1.2$ kg/m^3) is used to precool supply outdoor air at 35°C and 27°C wb ($\rho = 1.15$ kg/m^3).

(a) Assuming EATR = 0 and OACF ≈ 1, determine the leaving supply air conditions and energy recovered, and check the energy exchange balance.

(b) Assuming EATR = 5% and OACF = 1.05, determine the actual airflow rates.

In both cases, to simplify the calculation, assume that specific heat of dry air is constant at 1 kj/kg·K.

Solution:

1. From the manufacturer's claims, at a flow rate of 400 L/s, the pressure drop $\Delta p = 225$ Pa. Assuming the effective efficiency of the fan motor combination is about 0.6, the power P_s required to circulate the supply air can be obtained from Equation (8) as

$$P_s = (400\ \text{L/s})(1\ \text{m}^3/1000\ \text{L})(225\ \text{Pa})/(0.6) = 150\ \text{W or } 0.15\ \text{kW}$$

Assuming the balanced flow the power required to circulate the exhaust air would be same, therefore the total power P required to circulate the airstreams would be twice this amount.

$$P = 300\ \text{W or } 0.3\ \text{kW}$$

2. Calculate the theoretical maximum heat transfer.

Determine entering airstream enthalpies and humidity ratio from the psychrometric chart.

Supply inlet (35°C db, 27°C wb) $h_1 = 85.2$ kJ/kg $w_1 = 0.0194$ kg/kg

Exhaust inlet (23°C db, 17°C wb) $h_3 = 47.8$ kJ/kg $w_3 = 0.0093$ kg/kg

The theoretical maximum heat transfer rates can be obtained as follows:

$$q_{max}(\text{sensible}) = (1.15\ \text{kg/m}^3)(400\ \text{L/s})(1\ \text{m}^3/1000\ \text{L}) \times [1\ \text{kJ/(kg · K)}](35 - 23) = 5.52\ \text{kW}$$

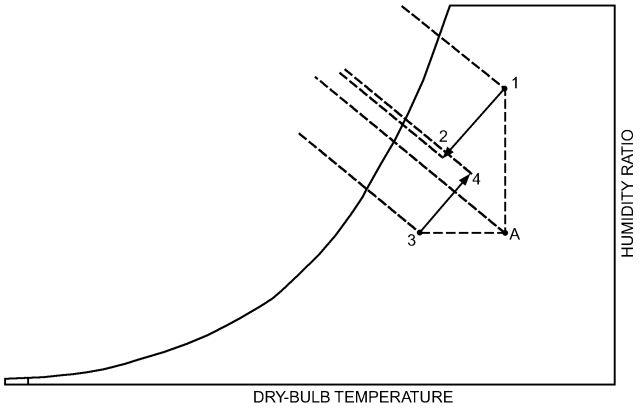

Fig. 53 Total Heat Recovery in Summer (Example 6)

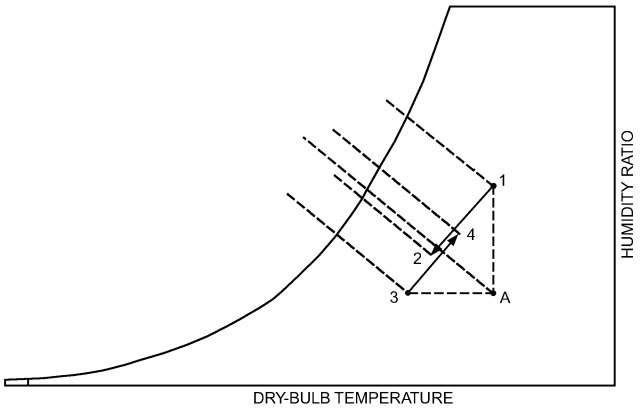

Fig. 54 Total Energy Recovery with EATR ≠ 0 and OACF ≠ 1 (Example 7)

$$q_{max}(\text{latent}) = (1.15\ \text{kg/m}^3)(400\ \text{L/s})(1\ \text{m}^3/1000\ \text{L}) \times (2560\ \text{kJ/kg})(0.0194 - 0.0093) = 11.89\ \text{kW}$$

$$q_{max}(\text{total}) = (1.15\ \text{kg/m}^3)(400\ \text{L/s})(1\ \text{m}^3/1000\ \text{L}) \times (85.2 - 47.8) = 17.2\ \text{kW}$$

Note that sum of sensible and latent energy should equal the total energy.

3. Determine supply sensible and total effectiveness.

From the manufacturer's claims, at a flow rate of 400 L/s, $\varepsilon_s = 0.73$, $\varepsilon_L = 0.68$, and $\varepsilon_t = 0.715$.

4. Calculate energy transfer at design conditions.

$$q_s = (0.73)(5.52\ \text{kW}) = 4.03\ \text{kW sensible recovered}$$

$$q_L = (0.68)(11.89\ \text{kW}) = 8.09\ \text{kW latent recovered}$$

$$q_t = (0.715)(17.2\ \text{kW}) = 12.3\ \text{kW total recovered}$$

5. Calculate leaving air conditions.

a. Supply air conditions

$$t_2 = 35°\text{C} + \frac{-4.03\ \text{kW}}{(1.15\ \text{kg/m}^3)(0.4\ \text{m}^3/\text{s})[1\ \text{kJ/(kg·K)}]} = 26.2°\text{C}$$

$$h_2 = 85.2\ \text{kJ/kg} + \frac{-12.3\ \text{kW}}{(1.15\ \text{kg/m}^3)(0.4\ \text{m}^3/\text{s})} = 58.5\ \text{kJ/kg}$$

From the psychrometric chart, the supply air humidity ratio and wet-bulb temperature are $w_2 = 0.0129$ and $t_{w2} = 20.2°\text{C}$.

b. Exhaust air conditions

$$t_4 = 23°\text{C} + \frac{4.03\ \text{kW}}{(1.2\ \text{kg/m}^3)(0.4\ \text{m}^3/\text{s})[1\ \text{kJ/(kg·K)}]} = 31.4°\text{C}$$

$$h_4 = 47.8\ \text{kJ/kg} + \frac{12.3\ \text{kW}}{(1.2\ \text{kg/m}^3)(0.4\ \text{m}^3/\text{s})} = 73.43\ \text{kJ/kg}$$

From the psychrometric chart, the exhaust humidity ratio and wet-bulb temperature are found to be $w_4 = 0.0164$, $t_{w4} = 24.2°\text{C}$.

6. Check total performance.

$$q_t = (1.15\ \text{kg/m}^3)(0.4\ \text{m}^3/\text{s})(85.2 - 58.5) = 12.28\ \text{kW saved}$$

$$q_t = (1.2\ \text{kg/m}^3)\ (0.4\ \text{m}^3/\text{s})\{[1\ \text{kJ/(kg·K)}](31.4 - 23) + (0.0164 - 0.0093)(2560\ \text{kJ/kg})\} = 12.7\ \text{kW},$$
which is close to 12.28 kW

7. Plot conditions on psychrometric chart (Figure 54).

8. Obtain data on EATR. (Given: EATR = 5% or 0.05.)

9. Obtain data on OACF. (Given: OACF = 1.05.)

10. Correct the supply air ventilation rate, the moisture transfer rate, and energy transfer rates EATR ≠ 0 and OACF ≠ 1.0.

The net ventilation rate is 400 L/s and the EATR = 0.05; therefore, the actual flow rate Q_2 to the space can be obtained from Equation (19) as

$$Q_3 = Q_2 = \frac{Q_v}{1 - (\text{EATR}/100)} = \frac{400\ \text{L/s}}{1 - 5/100} = 421\ \text{L/s}$$

Because OACF = 1.05, the actual flow rate Q_1 of fresh air from outdoor can be calculated from Equation (21) as

$$Q_1 = Q_2(\text{OACF})\frac{Q_v(\text{OACF})}{1 - (\text{EATR}/100)} = \frac{(400\ \text{L/s})(1.05)}{1 - 5/100} = 442\ \text{L/s}$$

To balance the flow rates into the ERV, the actual air flow rates at states 3 and 4 are as shown in Figure 55.

Supply and exhaust fan capacity should match the flows required at their locations. Example 8's results are for balanced flow. Assuming flow rates in the ERV are same as the outdoor air ventilation requirements, then the effectiveness would be same as that for no air leakage. If air leaks at the inlet and outlet of the energy recovery ventilator, then the exit conditions of air temperature and humidity at states 3 and 4 can be calculated as those of the airstream mixture. For instance, the properties at state 2 would be those of an airstream mixture at state 2 for no air leakage and air quantity (Q_{32}) at state 3. The error for these calculations should be less than 5%.

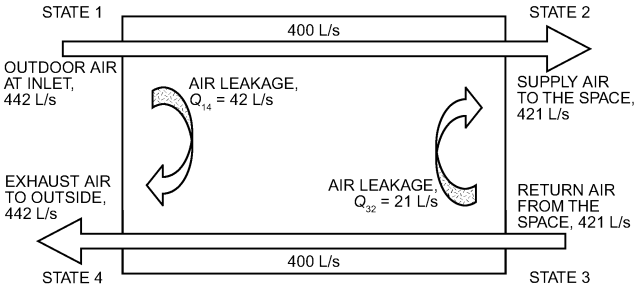

Fig. 55 Actual Airflow Rates at Various State Points (Example 8)

Shang et al. (2001a) show a method to accurately estimate the energy rates when EATR ≠ 0 and OACF ≠ 1.

10. SYMBOLS

A = area of recovery exchanger, m^2
c_p = specific heat of moist air, kJ/(kg·K)
C = capital cost
C_e = cost of energy
C_p = specific heat of air kJ/(kg·K)
C_r = ratio of C_{min}/C_{max}
$C_{s,int}$ = initial system capital cost
CRF = capital recovery factor
h = enthalpy, kJ/kg
h_{fg} = enthalpy of vaporization, kJ/kg
i = arbitrary state, or discount rate
ITC = income tax credit
m_s = mass flow rate of supply moist air from outdoors, kg/s
m_e = mass flow rate of exhaust moist air, kg/s
m_{min} = minimum mass flow rate of supply and exhaust airstreams, kg/s
n = number of years in economic consideration, years
NTU = number of transfer units = UA/C_{min}
p = pressure, Pa
pp = payback period, years
P = pumping power, W or kW
q = heat transfer rate, W or kW
Q = volume flow rate, m^3/s
S = reference temperature, K
t = moist air temperature at state i, °C
t_{w3} = wet-bulb temperature of moist air at state 3, °C
T = absolute temperature, K, or tax
U = overall heat transfer coefficient, $\text{W/(m}^2\text{·K)}$
V = mean velocity, m/s
w = humidity ratio

Greek Letters

ε_s = sensible effectiveness of heat or energy wheel
ε_L = latent effectiveness of energy wheel
ε_t = total effectiveness of ERV
η = efficiency
ρ = density, kg/m^3
σ = volume fraction
ϕ = relative humidity
ω = rotational speed of the wheel, rpm

Subscripts

a = air
e = exhaust side of heat/energy exchanger, exit or energy
f = fan or fan motor combination
if = threshold temperature of the outdoor air for freezing to occur
in = indoor conditions of building space
inc = increment
h = hydraulic

L = latent
max = maximum value
min = minimum value
n = station number indicating supply and exhaust inlets and outlets (see Figure 1)
o = reference state or outlet
p = constant pressure
s = supply side or suction side
t = total

CHAPTER 27

AIR-HEATING COILS

Coil Construction and Design 27.1
Coil Selection 27.3
Installation Guidelines 27.4
Coil Maintenance 27.5

AIR-HEATING coils are used to heat air under forced convection. The total coil surface may consist of a single coil section or several coil sections assembled into a bank. The coils described in this chapter apply primarily to comfort heating and air conditioning using steam, hot water, refrigerant vapor heat reclaim (including heat pumps), and electricity. The choice between the various methods of heating depends greatly on the cost of the various available energy sources. For instance, in areas where electric power is cheaply available and heating requirements are limited, heat pumps are a very viable option. With available power and higher heat requirements, electric heat is used. If electric power is considerably expensive, steam or hot water generated using gas-fired sources is used in larger buildings and district cooling. In smaller buildings, heat is supplied using gas furnaces, which are covered in Chapters 33 and 34. Water and steam heating are also widely used where process waste heat is available.

1. COIL CONSTRUCTION AND DESIGN

Extended-surface coils consist of a primary and a secondary heat-transfer surface. The primary surface is the external surface of the tubes, generally consisting of rows of round tubes or pipes that may be staggered or parallel (in-line) with respect to the airflow. Flattened tubes or tubes with other nonround internal passageways are sometimes used. The inside of the tube is usually smooth and plain, but some coil designs feature various forms of internal fins or turbulence promoters (either fabricated and then inserted, or extruded) to enhance fluid coil performance. The secondary surface is the fins' external surface, which consists of thin metal plates or a spiral ribbon uniformly spaced or wound along the length of the primary surface. The intimate contact with the primary surface provides good heat transfer. Air-heating fluid and steam coils are generally available with different circuit arrangements and combinations that offer varying numbers of parallel water flow passes in the tube core.

Copper and aluminum are the materials most commonly used for extended-surface coils. Tubing made of steel or various copper alloys is used where corrosive forces might attack the coils from inside or outside. The most common combination for low-pressure applications is aluminum fins on copper tubes. Low-pressure steam coils are usually designed to operate up to 350 kPa (gage). Higher-strength tube materials such as red brass, admiralty brass, or cupronickel assembled by brazed construction are usable up to 186°C water or 1 MPa (gage) saturated steam. Higher operating conditions call for electric welded stainless steel construction, designed to meet Section II and Section VIII requirements of the ASME *Boiler and Pressure Vessel Code*.

Customarily, the coil casing consists of a top and bottom channel (also known as baffles or side sheets), two end supports (also known as end plates or tube sheets), and, on longer coils, intermediate supports (also known as center supports or tube sheets). Designs vary, but most are mounted on ducts or built-up systems. Most often, casing material is spangled zinc-coated (galvanized) steel with a minimum coating designation of G90-U. Some corrosive air conditions may require stainless steel casings or corrosive-resistant coating, such as a baked phenolic applied by the manufacturer to the entire coil surface. Steam coil casings should be designed to accommodate thermal expansion of the tube core during operation (a **floating core** arrangement).

Common core tube diameters vary from 8 up to 25 mm outside diameter (OD) and fin spacings from 1.4 to 6.4 mm. Fluid heating coils have a tube spacing from 20 to 45 mm and tube diameters from 8 to 16 mm OD. Steam coils have tube spacing from 30 to 75 mm and tube diameters from 13 to 25 mm OD. The most common arrangements are one- or two-row steam coils and two- to four-row hot-water coils. Fins should be spaced according to the application requirements, with particular attention given to any severe duty conditions, such as inlet temperatures and contaminants in the airstream.

Tube wall thickness and the required use of alloys other than (standard) copper are determined primarily by the coil's specified maximum allowable working pressure (MAWP) requirements. A secondary consideration is expected coil service life. Fin type, header, and connection construction also play a large part in this determination. All applicable local job site codes and national safety standards should be followed in the design and application of heating coils.

Flow direction can strongly affect heat transfer surface performance. In air-heating coils with only one row of tubes, the air flows at right angles to the heating medium. Such a cross-flow arrangement is common in steam heating coils. The steam temperature in the tubes remains uniform, and the mean temperature difference is the same regardless of the direction of flow relative to the air. The steam supply connection is located either in the center or at the top of the inlet header. The steam condensate outlet (return connection) is always at the lowest point in the return header.

When coils have two or more tube rows in the direction of airflow, such as hot-water coils, the heating medium in the tubes may be circuited in various parallel-flow and counterflow arrangements. Counterflow is the arrangement most preferred to obtain the highest possible mean temperature difference, which determines the heat transfer of the coil. The greater this temperature difference, the greater the coil's heat transfer capacity. In multirow coils circuited for counterflow, water enters the tube row on the leaving air side of the coil.

Steam Coils

Steam coils are generally classified, similarly to boilers, by operating pressure: low (≤100 kPa) or high (>100 kPa). However, various organizations use other pressure classification schemes with differing divisions [e.g., low (≤100 kPa), medium (100 to 690 kPa), or high (>690 kPa). Steam coils can also be categorized by operating limits of the tube materials:

Standard steam	≤1030 kPa	185°C	copper tube
High-pressure steam	≤1625 kPa	204°C	special material [e.g., cupronickel (CuNi)]

Although these operating conditions are allowed by code, long exposures to them will shorten coil tube life. Leaks are less likely when the coil tube core has thicker walls of higher-strength materials.

The preparation of this chapter is assigned to TC 8.4, Air-to-Refrigerant Heat Transfer Equipment.

Table 1 Preferred Operating Limits for Continuous-Duty Steam Coil Materials in Commercial and Institutional Applications

Pressure, kPa	Material	Tube Wall Thickness, mm
≤35	Copper	0.51
35 to 100		0.64
100 to 200		0.89
200 to 345		1.25
345 to 515	Red brass	0.64
515 to 690		0.89
690 to 1035	90/10 CuNi	0.89
1035 to 1380		1.25

Note: Red brass and CuNi may be interchanged, depending on coil manufacturer's specifications.

Operational experience suggests preferred limits for continuous-duty steam coils (tube OD ranging from 16 to 25 mm) in commercial and institutional applications, as shown in Table 1.

Steam coils also can be categorized by type as basic steam, steam-distributing, or face-and-bypass.

Basic steam coils generally have smooth tubes with fins on the air side. The steam supply connection is at one end and the tubes are pitched toward the condensate return, which is usually at the opposite end. For horizontal airflow, the tubes can be either vertical or horizontal. Horizontal tubes should be pitched within the casing toward the condensate return to facilitate condensate removal. Uniform steam distribution to all tubes is accomplished by careful selection of header size, its connection locations, and positioning of inlet connection distributor plates. Orifices also may be used at the core tube entrances in the supply header.

Steam-distributing coils most often incorporate perforated inner tubes that distribute steam evenly along the entire coil. The perforations perform like small steam ejector jets that, when angled in the inner tube, help remove condensate from the outer tube. An alternative design for short coils is an inner tube with no distribution holes, but with an open end. On all coils, supply and return connections can be at the same end or at opposite ends of the coil. For long, low-pressure coils, supply is usually at both ends and the condensate return on one end only.

Face-and-bypass steam coils have short sections of steam coils separated by air bypass openings. Airflow through the coil or bypass section is controlled by coil face-and-bypass dampers linked together. As a freeze protection measure, large installations use face-and-bypass steam coils with vertical tubes.

For proper performance of all types of steam heating coils, air or other noncondensables in the steam supply must be eliminated. Equally important, condensate from the steam must easily drain from inside the coil. Air vents are located at a high point of the piping and at the coil's inlet steam header. Whether airflow is horizontal or vertical, the coil's finned section is pitched toward the condensate return connection end of the coil. Installers must give particular care in the selection and installation of piping, controls, and insulation necessary to protect the coil from freeze-up caused by incomplete condensate drainage.

When entering air is at or below 0°C, the steam supply to the coil should not be modulated, but controlled as full on or full off. Coils located in series in the airstream, with each coil sized and controlled to be full on or completely off (in a specific sequence, depending on the entering air temperature), are not as likely to freeze. Temperature control with face-and-bypass dampers is also common. During part-load conditions, air is bypassed around the steam coil with full steam flow to the coil. In a face-and-bypass arrangement, high-velocity streams of freezing air must not impinge on the coil when the face dampers are partially closed. The section on Overall Requirements in this chapter and the section on Heating Coils in Chapter 48 of the 2023 *ASHRAE Handbook—HVAC Applications* have more details.

Water/Aqueous Glycol Heating Coils

Normal-temperature hot-water heating coils can be categorized as booster coils or standard heating coils. Booster (duct-mounted or reheat) coils are commonly found in variable-air-volume systems. They are one or two rows deep, have minimal water flow, and provide a small air temperature rise. Casings can be either flanged or slip-and-drive construction. Standard heating coils are used in run-around systems, makeup air units, and heating and ventilating systems. All use standard construction materials of copper tube and aluminum fins.

High-temperature water coils may operate with up to 200°C water, with pressures comparable or somewhat higher than the saturated vapor temperature of the water supply. The temperature drop across the coil may be as high as 85 K. To safely accommodate these fluid temperatures and thermal stresses, the coil requires industrial-grade construction that conforms to applicable boiler and safety codes. These requirements should be listed in detail by the specifying engineer, along with the inspection and certification requirements and a compliance check before coil installation and operation.

Proper water coil performance depends on eliminating air and on good water distribution in the coil and its interconnecting piping. Unless properly vented, air may accumulate in the coil circuits, which reduces heat transfer and possibly causes noise and vibration in the pipes. For this reason, water coils should be constructed with self-venting, drainable circuits. The self-venting design is maintained by field-connecting the water supply connection to the bottom and the water return connection to the top of the coil. Ideally, water is supplied at the bottom, flows upward through the coil, and forces any air out the return connection. Complete fluid draining at the supply connection indicates that coils are self draining and without air or water traps. Such a design ensures that the coil is always filled with water, and it should completely drain when it is required to be empty. Most manufacturers provide vent and drain fittings on the supply and return headers of each water coil.

When water does get trapped in the coil core, it is usually caused by a sag in the coil core or by a nondraining circuit design. During freezing periods, even a small amount of water in the coil core can rupture a tube. Also, such a static accumulation of either water or glycol can corrode the tube over an extended period. Large multirow, multicircuited coils may not drain rapidly, even with self-draining circuitry; if they are not installed level, complete self draining will not take place. This problem can be prevented by including intermediate drain headers and installing the coil so that it is pitched toward the connections.

To produce desired ratings without excessive water pressure drop, manufacturers use various circuit arrangements. A single-feed serpentine circuit is commonly used on booster coils with low water flows. With this arrangement, a single feed carrying the entire water flow makes a number of passes across the airstream. The more common circuit arrangement is called a **full row feed** or **standard circuit**. With this design, all the core tubes of a row are fed with an equal amount of water from the supply header. Others, such as quarter, half, and double-row feed circuit arrangements, may be available, depending on the total number of tubes and rows of the coil. Uniform flow in each water circuit is obtained by designing each circuit's length as equal to the other as possible.

Generally, higher velocity provides greater capacity and more even discharge air temperature across the coil face, but with diminishing returns. To prevent erosion, do not exceed 1.8 m/s for copper coils. At higher velocities, only modest gains in capacity can be achieved at increasingly higher pumping power penalties. Above 2.4 m/s, any gain is negligible.

Velocities with fluid flow Reynolds numbers (Re) between 2000 and 10 000 fall into a transition range where heat transfer capacity predictions are less likely to be accurately computed. Below Re = 2000, flow is laminar, where heat transfer prediction is again reliable, but coil capacity is greatly diminished and tube fouling can become a problem. For further insight on the transition flow effect on capacity, refer to Figure 16 of Air-Conditioning, Heating, and Refrigeration Institute (AHRI) *Standard* 410. Methods of controlling water coils to produce a uniform exit air temperature are discussed in Chapter 47 of the 2023 *ASHRAE Handbook—HVAC Applications*.

In some cases, the hot water circulated may contain a considerable amount of sand and other foreign matter such as minerals. This matter should be filtered from the water circuit. Additionally, some coil manufacturers offer removable water header boxes (some are plates), or a removable plug at the return bends of each tube, allowing the tubes to be rodded clean. In an area where build-up of scale or other deposits is expected, include a fouling factor when computing heating coil performance. Hot-water coil ratings (AHRI *Standard* 410) include a 44 $(mm^2 \cdot K)/W$ fouling factor. Cupronickel, red brass, admiralty, stainless steel, and other tube alloys can protect against corrosion and erosion, which can be common in hot-water/glycol systems.

Volatile Refrigerant Heat Reclaim Coils

A heat reclaim coil with a volatile refrigerant can function as a condenser either in series or parallel with the primary condenser of a refrigeration system. Heat from condensing or desuperheating vapor warms the airstream. It can be used as a primary source of heat or to assist some other form of heating, such as reheat for humidity control. In the broad sense, a heat reclaim coil functions at half the heat-dissipating capacity of its close-coupled refrigerant system's condenser. Thus, a heat reclaim coil should be (1) piped to be upstream from the condenser and (2) designed with the assumption that some condensate must be removed from the coil. For these reasons, locate the coil outlet at the lowest point of the coil and trap it if this location is lower than the condenser inlet.

Heat reclaim coils are normally circuited for counter-flow of air and refrigerant. However, most supermarket heat reclaim coils are two rows deep and use a cross-flow design. The section on Air-Cooled Condensers in Chapter 39 has additional information on this topic. Because refrigerant heat reclaim involves specialized heating coil design, a refrigerant equipment manufacturer is the best source for information on the topic.

Electric Heating Coils

An electric heating coil consists of a length of resistance wire (commonly nickel/chromium) to which a voltage is applied. The resistance wire may be bare or sheathed in an electrically insulating layer, such as magnesium oxide, and compacted inside a finned steel tube. Sheathed coils are more expensive, have a higher air-side pressure drop, and require more space. A useful comparison for sizing is a heat transfer capacity of 130 kW/m^2 of face area compared to 320 kW/m^2 for bare resistance wire coils. However, the outer surface temperature of sheathed coils is lower, the coils are mechanically stronger, and contact with personnel or housing is not as dangerous. Coils with sheathed heating elements having an extended finned surface are generally preferred (1) for dust-laden atmospheres, (2) where there is a high probability of maintenance personnel contact, or (3) downstream from a dehumidifying coil that might have moisture carryover. Manufacturers can provide further information, including selection recommendations, applications, and maintenance instructions.

2. COIL SELECTION

The following factors should be considered in coil selection:

- Required duty or capacity considering other components
- Temperature of air entering the coil and air temperature rise
- Available heating media's operating and maximum pressure(s) and temperature(s)
- Space and dimensional limitations
- Air volume, speed, distribution, and limitations
- Heating media volume, flow speed, distribution, and limitations
- Permissible flow resistances for both the air and heating media
- Characteristics of individual designs and circuit possibilities
- Individual installation requirements, such as type of control and material compatibility
- Specified and applicable codes and standards regulating the design and installation.

Load requirements are discussed in Chapters 17 and 18 of the 2021 *ASHRAE Handbook—Fundamentals*. Much is based on the choice of heating medium, as well as operating temperatures and core tube diameter. Also, proper selection depends on whether the installation is new, being modified, or a replacement. Dimensional fit is usually the primary concern of modified and replacement coils; heating capacity is often unknown.

Air quantity is regulated by factors such as design parameters, codes, space, and size of the components. Resistance through the air circuit influences fan power and speed. This resistance may be limited to allow use of a given size fan motor or to keep operating expenses low, or because of sound level requirements. All of these factors affect coil selection. The air friction loss across the heating coil (summed with other series air pressure drops for system component such as air filters, cooling coils, grilles, and ductwork) determines the static pressure requirements of the complete air system. See Chapter 21 for selecting the fan component.

Permissible resistance through the water or glycol coil circuitry may be dictated by the available pressure from a given size pump and motor. This is usually controlled within limits by careful selection of coil header size and the number of tube circuits. Additionally, the adverse effect of high fluid velocity in contributing to erosion/corrosion of the tube wall is a major factor in selecting tube diameter and the circuit. Heating coil performance depends on the correct choice of original equipment and proper application and installation. For steam coils, proper performance relies first on selecting the correct type of steam coil, and then the proper size and type of steam trap. Properly sized connecting refrigerant lines, risers, and traps are critical to heat reclaim coils.

Heating coil thermal performance is relatively simple to derive. It only involves a dry-bulb temperature and sensible heat, without the complications of latent load and wet-bulb temperature for dehumidifying cooling performance. Even simpler, consult coil manufacturers' catalogs for ratings and selection. Most manufacturers provide computerized coil selection and rating programs on request; some are certified accurate within 5% of an application parameter, representative of a normal application range. Many manufacturers participate in the AHRI Coil Certification Program, which approves application ratings that conform to all AHRI *Standard* 410 requirements, based on qualifying testing to ASHRAE *Standard* 33.

Coil Ratings

Coil ratings are based on uniform face velocity. Nonuniform airflow may be caused by the system, such as air entering at odd angles, or by inadvertent blocking of part of the coil face. To obtain rated performance, the airflow quantity in the field must correspond to the design requirements and the velocity vary no greater than 20% at any point across the coil face.

The industry-accepted method of coil rating is outlined in AHRI *Standard* 410. Test requirements for determining standard coil ratings are specified in ASHRAE *Standard* 33. AHRI application ratings are derived by extending the ASHRAE standard rating test results for other operating conditions, coil sizes, row depths, and

fin count for a particular coil design and arrangement. Steam, water, and glycol heating coils are rated within the following limits (Table 1 of AHRI *Standard* 410), which may be exceeded for special applications.

Air face velocity. 1 to 8 m/s, based on air density of 1.2 kg/m^3

Entering air temperature. Steam coils: –29 to 38°C
Water coils: –18 to 38°C

Steam pressure. 14 to 1723 kPa (gage) at coil steam supply connection (pressure drop through steam control valve must be considered)

Fluid temperatures. Water: 49 to 121°C
Ethylene glycol and propylene glycol: –18 to 93°C

Fluid velocities. Water: 0.1 to 2.4 m/s
Ethylene glycol and propylene glycol: 0.1 to 1.8 m/s

Overall Requirements

Individual installations vary widely, but the following values can be used as a guide. The air face velocity is usually between 2.5 and 5 m/s. Delivered air temperature varies from about 22°C for ventilation only to about 65°C for complete heating. Steam pressure typically varies from 15 to 100 kPa (gage), with 35 kPa (gage) being the most common. A minimum steam pressure of 35 kPa (gage) is recommended for systems with entering air temperatures below freezing. Hot-water (or glycol) temperature for comfort heating is commonly between 80 and 95°C, with water velocities between 1.2 and 1.8 m/s. For high-temperature water, water temperatures can be over 200°C with operating pressures of 100 to 170 kPa over saturated water temperature.

Water quantity is usually based on about 11 K temperature drop through the coil. Air resistance is usually limited to 100 to 150 Pa for commercial buildings and to about 250 Pa for industrial buildings. High-temperature water systems commonly have a water temperature between 150 and 200°C, with up to 80 K drop through the coil.

Steam coils are selected with dry steam velocities not exceeding 30 m/s and with acceptable condensate loading per coil core tube depending on the type of steam coil. Table 2 shows some typical maximum condensate loads.

Steam coil performance is maximized when the supply is dry, saturated steam, and condensate is adequately removed from the coil and continually returned to the boiler.

Although steam quality may not significantly affect the coil's heat transfer, the back-up effect of too rapid a condensate rate, augmented by a wet supply stream, can cause a slug of condensate to travel through the coil and condensate return. This situation can result in noise and possible damage.

Complete mixing of return and outdoor air is essential to proper coil operation. The design of the air mixing damper or ductwork connection section is critical to the proper operation of a system and its air temperature delivery. Systems in which the air passes through a fan before flowing through a coil do not ensure proper air mixing. Dampers at the inlet air face of a steam coil should be the opposed-blade type, which are better than in-line blades for controlling air volume and reducing individual blade-directed cold airstreams when modulating in low-heat mode.

Heat Transfer and Pressure Drops. For air-side heat transfer and pressure drop, the information in Chapter 23 for sensible cooling coils is applicable. For water (or glycol) coils, Chapter 23's information on water-side heat transfer and pressure drop also applies here. For steam coils, the heat transfer coefficient of condensing steam must be calculated (see Chapter 4 of the 2021 *ASHRAE Handbook—Fundamentals*). For estimating the pressure drop of condensing steam, see Chapter 5 of the 2021 *ASHRAE Handbook—Fundamentals*.

Table 2 Typical Maximum Condensate Loads

Tube Outside Diameter	Maximum Allowable Condensate Load, g/s	
	Basic Coil	Steam Distributing Coil
16 mm	8.6	5.0
25 mm	21.2	12.0

Parametric Effects. The heat transfer performance of a given coil can be changed by varying the airflow rate and/or the temperature of the heating medium, both of which are relatively linear. Understanding the interaction of these parameters is necessary for designing satisfactory coil capacity and control. A review of manufacturers' catalogs and selection programs, many of which are listed in AHRI's *Directory of Certified Product Performance* and *Forced-Circulation Air-Cooling and Air-Heating Coils*, shows the effects of varying these parameters.

3. INSTALLATION GUIDELINES

Steam systems designed to operate at outdoor air temperatures below 0°C should be different from those designed to operate above it. Below 0°C, the steam air-heating system should be designed as a preheat and reheat pair of coils. The preheat coil functions as a nonmodulating basic steam coil, which requires full steam pressure whenever the outdoor temperature is below freezing. The reheat coil, typically a modulated steam-distributing coil, provides the heating required to reach the design air temperature. Above 0°C, the heating coil can be either a basic or steam-distributing type as needed for the duty.

When the leaving air temperature is controlled by modulating steam supply to the coil, steam-distributing tube coils provide the most uniform exit air temperature (see the section on Steam Coils). Correctly designed steam-distributing tube coils can limit the exit air temperature stratification to a maximum of 3 K over the entire length of the coil, even when steam supply is modulated to a fraction of full-load capacity.

Low-pressure steam systems and coils controlled by modulating steam supply should have a vacuum breaker or be drained through a vacuum-return system to ensure proper condensate drainage. It is good practice to install a closed vacuum breaker (where required) connected to the condensate return line through a check valve. This unit breaks the vacuum by equalizing the pressure, yet minimizes the possibility of air bleeding into the system. Steam traps should be located at least 300 mm below the condensate outlet to allow the coil to drain properly. Also, coils supplied with low-pressure steam or controlled by modulating steam supply should not be trapped directly to an overhead return line. Condensate can be lifted to overhead returns only when enough pressure is available to overcome the condensate head and any return line pressure. If overhead returns are necessary, the condensate must be pumped to the higher elevation (see Chapter 11).

Water coils for air heating generally have horizontal tubes to avoid air pockets. Where water or glycol coils may be exposed to a freezing condition, drainability must be considered. If a coil is to be drained and then exposed to below-freezing temperatures, it should first be flushed with a nonfreeze solution.

To minimize the danger of freezing in both steam and water-heating coils, the outdoor air inlet dampers usually close automatically when the fan is stopped (system shutdown). In steam systems with very cold outdoor air conditions (e.g., –30°C or below), it is desirable to fully open the steam valve when the system is shut down. If outdoor air is used for proportioning building makeup air, the outdoor air damper should be an opposed-blade design.

Heating coils are designed to allow for expansion and contraction resulting from the temperature ranges in which they operate. Be careful not to impose strains from the piping to the coil connections,

particularly on high-temperature hot-water applications. Expansion loops, expansion or three-elbow swing joints, or flexible connections usually provide the needed protection (see Chapter 11).

Good practice supports banked coils individually in an angle-iron frame or a similar supporting structure. With this arrangement, the lowest coil is not required to support the mass of the coils stacked above. This design also facilitates removing individual coils in a multiple-coil bank for repair or replacement.

Heat reclaim coils depend on a closely located, readily available source of high-side refrigerant vapor. For example, supermarket rack compressors and the air handler's coil section should be installed close to the store's motor room. Most commonly, the heat reclaim coil section is piped in series with the rack's condenser and sized for 50% heat extraction. Heat reclaim in supermarkets is discussed in Chapter 2 of the 2023 *ASHRAE Handbook—HVAC Applications*; also see Chapter 15 of the 2022 *ASHRAE Handbook—Refrigeration*.

In heat pump applications, the heating coil is usually the indoor coil that is used for cooling in the summer. The heat pump system is normally optimized for cooling load and efficiency. Heating performance is a by-product of cooling performance, and any unsatisfied heating requirement is met using electric heating coils. The refrigerant circuiting is also specialized and involves driving the refrigerant in the reverse direction from the cooling mode. Heat pump coils also have an additional check valve bypass to the expansion device for operating in heat pump mode. For additional details about heat pump coil design and operation, see Chapters 9 and 49.

4. COIL MAINTENANCE

Both internal and external surfaces must be clean for coils to deliver their full rated capacity. The tubes generally stay clean in glycol systems and in adequately maintained water systems. Should scale be detected in the piping where untreated water is used, chemical or mechanical cleaning of the internal tube surfaces is required. The need for periodic descaling can be minimized by proper boiler water treatment and deaeration.

Internal coil maintenance consists primarily of preventing scale and corrosion in the coil core tubes and piping of potable-water-heating (including steam) systems. In its simplest form, this involves removing dissolved oxygen, maintaining deionized water, and controlling boiler water pH. Boiler water can be deaerated mechanically. Vacuum deaerating simultaneously removes oxygen and carbon dioxide. The last traces of oxygen can be removed chemically by adding sodium sulfide. For steam coils, 100% dry steam contains 0% air. Good boiler water results in the absence of oxygen and a pH maintained at 10.5. If this is not practicable, a pH of 7 to 9 with a corrosion inhibitor is recommended. Because calcium carbonate is less soluble in water at higher pH, the inhibitor most often used for this purpose is sodium nitrate. Usually, the requirements for chemical treatment increase as the temperature of the coil's return flow drops. With few exceptions, boiler water chemical treatment programs use only proportional feeding, which is the recommended way of maintaining a constant concentration at all times. Periodic batch or slug feeding of water treatment chemicals is not an accurate way to treat boiler water, particularly if the system has a high water makeup rate. Only use chemicals known to be compatible with the coil's tube and connection metal(s). Chemical treatment of boiler water is complicated and has environmental effects. For this reason, it is important to consult a water treatment specialist to establish a proper boiler water treatment program. For further information on boilers, see Chapter 32.

The finned surface of heating coils can sometimes be brushed and cleaned with a vacuum cleaner. Coils are commonly surface-cleaned annually using pressurized hot water containing a mild detergent. Reheat coils that contain their refrigerant charge should never be cleaned with a spray above 65°C. In extreme cases of neglect, especially in restaurants where grease and dirt have accumulated, coil(s) may need to be removed to completely clean off the accumulation with steam, compressed air and water, or hot water containing a suitable detergent. Pressurized cleaning is more thorough if first done from the coil's air leaving side, before cleaning from the coil's air entry side. Often, outdoor makeup air coils have no upstream air filters, so they should be visually checked on a frequent schedule. Overall, coils should be inspected and serviced regularly. Visual observation should not be relied on to judge cleaning requirements for coils greater than three rows deep because airborne dirt tends to pack midway through the depth of the coil.

CHAPTER 28

UNIT VENTILATORS, UNIT HEATERS, AND MAKEUP AIR UNITS

Unit Ventilators 1
Unit Heaters 4
Makeup Air Units 8

1. UNIT VENTILATORS

A **HEATING unit ventilator** is an assembly whose principal functions are to heat, ventilate, and cool a space by introducing outdoor air in quantities up to 100% of its rated capacity. The heating medium may be steam, hot water, gas, or electricity. The essential components of a heating unit ventilator are the fan, motor, heating element, damper, filter, automatic controls, and outlet grille, all of which are encased in a housing.

An **air-conditioning unit ventilator** is similar to a heating unit ventilator; however, in addition to the normal winter function of heating, ventilating, and cooling with outdoor air, it is also equipped to cool and dehumidify during the summer. It is usually arranged and controlled to introduce a fixed quantity of outdoor air for ventilation during cooling in mild weather. The air-conditioning unit ventilator may be provided with a various of combinations of heating and air-conditioning elements. Some of the more common arrangements include

- Combination hot- and chilled-water coil (two-pipe)
- Separate hot- and chilled-water coils (four-pipe)
- Hot-water or steam coil and direct-expansion coil
- Electric heating coil and chilled-water or direct-expansion coil
- Gas-fired furnace with direct-expansion coil

The typical unit ventilator has controls that allow heating, ventilating, and cooling to be varied while the fans operate continuously. In normal operation, the discharge air temperature from a unit is varied in accordance with the room requirements. The heating unit ventilator can provide **ventilation cooling** by bringing in outdoor air whenever the room temperature is above the room set point and outside air is below its set point. Air-conditioning unit ventilators can provide refrigerated cooling when the outdoor air temperature is too high to be used effectively for ventilation cooling.

Unit ventilators are available for floor mounting, ceiling mounting, and recessed applications. They are available with various airflow and capacity ratings, and the fan can be arranged so that air is either blown through or drawn through the unit. With direct-expansion refrigerant cooling, the condensing unit can either be furnished as an integral part of the unit ventilator assembly or be remotely located.

Figure 1A shows a typical heating unit ventilator. The heating coil can be hot water, steam, or electric. Hot-water coils can be provided with face-and-bypass dampers for capacity control, if desired. Valve control of capacity is also available.

Figure 1B shows a typical air-conditioning unit ventilator with a combination hot- and chilled-water coil for use in a two-pipe system. This type of unit is usually provided with face-and-bypass dampers for capacity control.

Figure 1C illustrates a typical air-conditioning unit ventilator with two separate coils, one for heating and the other for cooling with a four-pipe system. The heating coil may be hot water, steam, or electric. The cooling coil can be either a chilled-water coil or a direct-expansion refrigerant coil. Heating and cooling coils are sometimes combined in a single coil by providing separate tube circuits for each function. In such cases, the effect is the same as having two separate coils.

Figure 1D illustrates a typical air-conditioning unit ventilator with a fan section, a gas-fired heating furnace section, and a direct-expansion refrigerant coil section.

Application

Unit ventilators are used primarily in schools, meeting rooms, offices, and other areas where the density of occupancy requires controlled ventilation to meet local codes.

Floor-model unit ventilators are normally installed on an outer wall near the centerline of the room. Ceiling models are mounted against either the outer wall or one of the inside walls. Ceiling models discharge air horizontally. Best results are obtained if the unit can be placed so that the airflow is not interrupted by ceiling beams or surface-mounted lighting fixtures.

Downdraft can be a problem in classrooms with large window areas in cold climates. Air in contact with the cold glass is cooled and flows down into the occupied space. Floor-standing units often include one of the following provisions to prevent downdraft along the windows (Figure 2):

- **Window sill heating** uses finned radiators of moderate capacity installed along the wall under the window area. Heated air rises upward by convection and counteracts the downdraft by tempering it and diverting it upward.
- **Window sill recirculation** is achieved by installing the return air intake along the window sill. Room or return air to the unit includes the window's cold downdrafts, thereby removing them from the occupied area.
- **Window sill discharge** directs a portion of the unit ventilator discharge air into a delivery duct along the sill of the window. The discharge air, delivered vertically at the window sill, is distributed throughout the room, and the upwardly directed air combats downdraft.

Selection

Items to be considered in the application of unit ventilators are

- Unit air capacity
- Percent minimum outdoor air
- Heating and cooling capacity
- Cycle of control
- Location of unit

Mild-weather cooling capacity and number of occupants in the space are the primary considerations in selecting the unit's air capacity. Other factors include state and local requirements, volume of the room, density of occupancy, and use of the room. The number of air changes required for a specific application also depends on window area, orientation, and maximum outdoor temperature at which the unit is expected to prevent overheating.

The preparation of the sections on Unit Ventilators and Unit Heaters is assigned to TC 6.1, Hydronic and Steam Equipment and Systems.

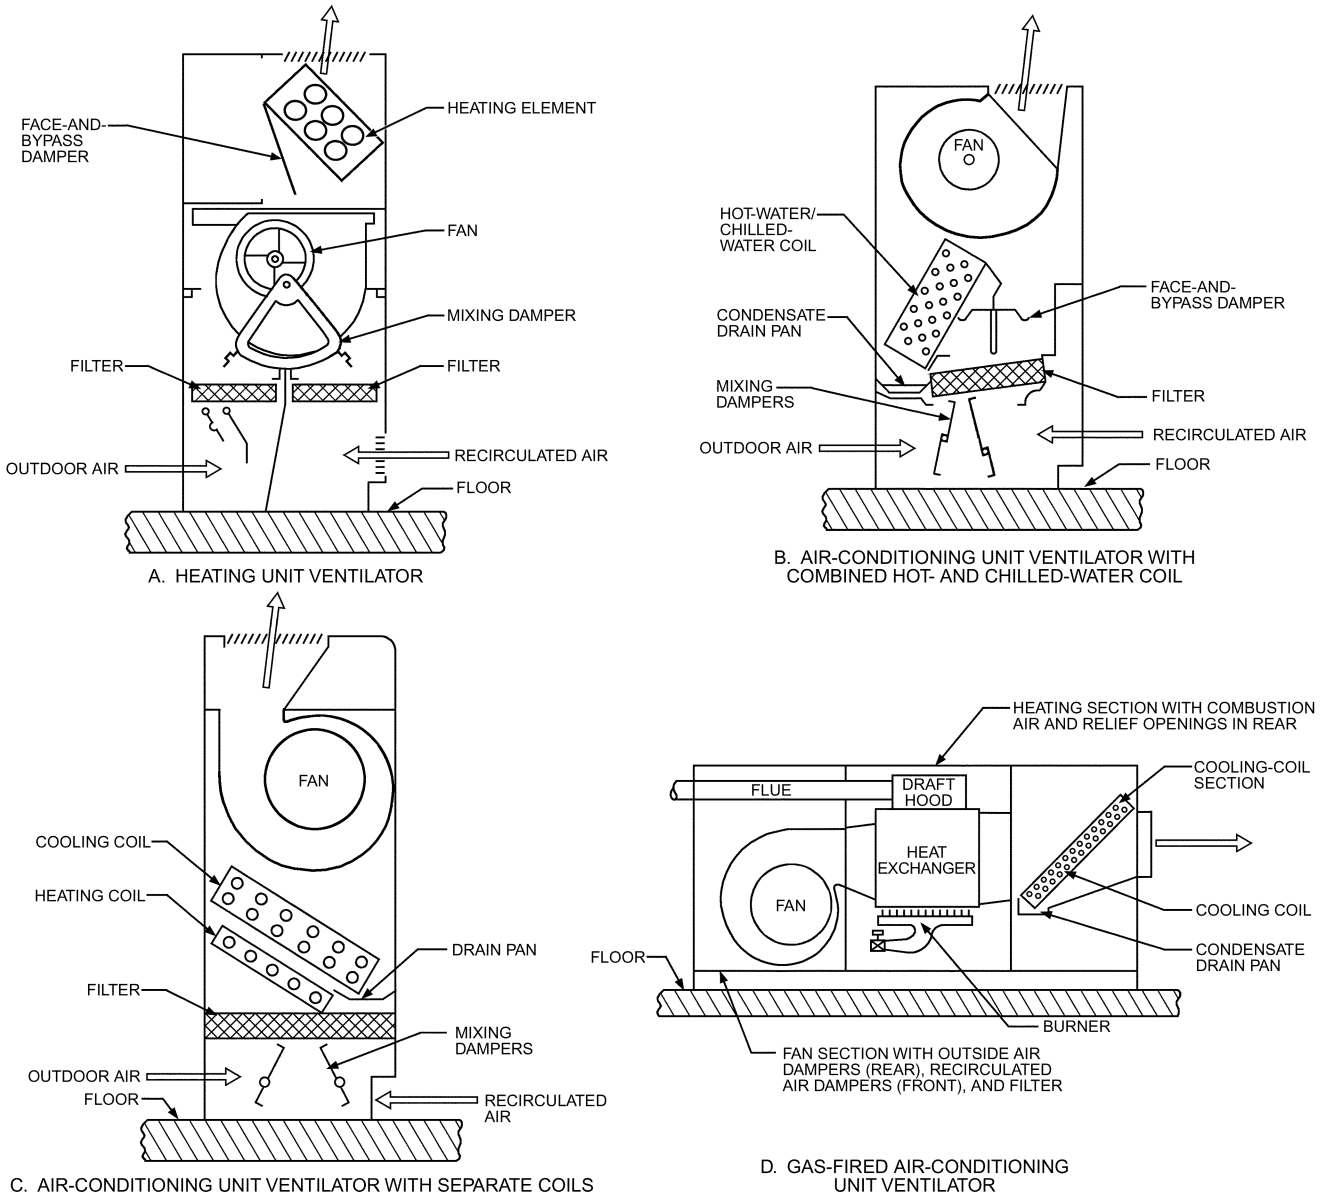

Fig. 1 Typical Unit Ventilators

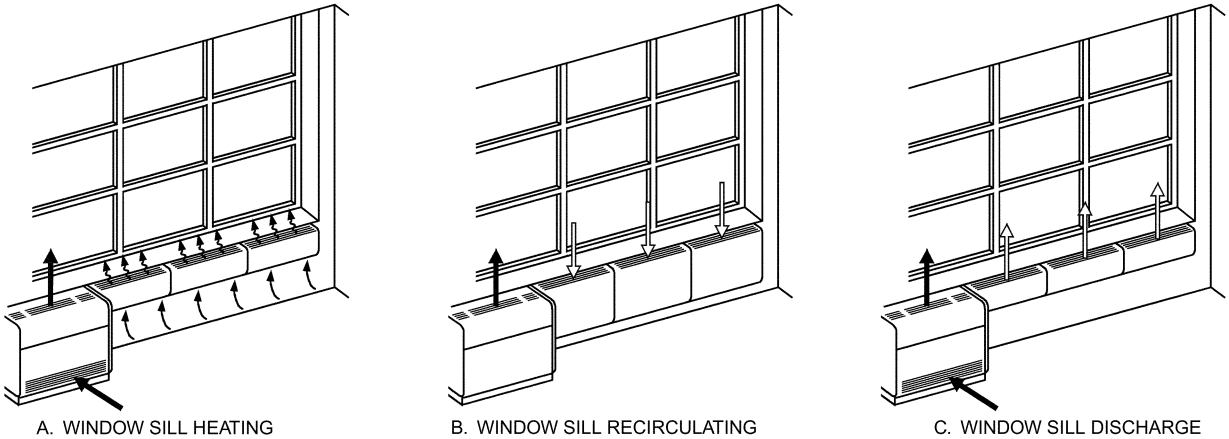

Fig. 2 Methods of Preventing Downdraft along Windows

Rooms oriented to the north (in the northern hemisphere) with small window areas require about 6 air changes per hour (ach). About 9 ach are required in rooms oriented to the south that have large window areas. As many as 12 ach may be required for very large window areas and southern exposures. These airflows are based on preventing overheating at outdoor temperatures up to about 13°C. For satisfactory cooling at outdoor air temperatures up to 15°C, airflow should be increased accordingly.

These airflows apply principally to classrooms. Factories and kitchens may require 30 to 60 ach (or more). Office areas may need 10 to 15 ach.

The minimum amount of outdoor air for ventilation is determined after the total air capacity has been established. It may be governed by local building codes, or it may be calculated to meet the ventilating needs of the particular application. For example, ASHRAE *Standard* 62.1 requires 3.8 to 5 L/s of outdoor air per occupant [0.3 to 0.9 L/(s · m^2)] in lecture halls or classrooms, laboratories, and cafeterias, and 2.5 L/s per occupant in conference rooms.

The heating and cooling capacity of a unit to meet the heating requirement can be determined from the manufacturer's data. Heating capacity should always be determined after selecting the unit air capacity for mild-weather cooling.

Capacity. Manufacturers publish the heating and cooling capacities of unit ventilators. Table 1 lists typical nominal capacities.

Heating Capacity Requirements. Because a unit ventilator has a dual function of introducing outdoor air for ventilation and maintaining a specified room condition, the required heating capacity is the sum of the heat required to bring outdoor ventilation air to room temperature and the heat required to offset room losses. The ventilation cooling capacity of a unit ventilator is determined by the air volume delivered by the unit and the temperature difference between the unit discharge and the room temperature.

Example. A room has a heat loss of 7.0 kW at a winter outdoor design condition of –18°C and an indoor design of 21°C, with 20% outdoor air. Minimum air discharge temperature from the unit is 15°C. To obtain the specified number of air changes, a 600 L/s unit ventilator is required. Determine the ventilation heat requirement, the total heating requirement, and the ventilation cooling capacity of this unit with outdoor air temperature below 15°C.

Solution:

Ventilation heat requirement:

$$q_v = \rho c_p Q(t_i - t_o)$$

where

q_v = heat required to heat ventilating air, W
ρ = density of air at standard conditions = 1.2 kg/m^3
c_p = air specific heat = 1.0 kJ/(kg · K)
Q = ventilating airflow, L/s
t_i = required room air temperature, °C
t_o = outdoor air temperature, °C

$$q_v = 1.2 \times 1.0 \times 600 \times (20/100)[21 - (-18)] = 5600 \text{ W}$$

Total heating requirement:

$$q_t = q_v + q_s$$

where

q_t = total heat requirement, W
q_s = heat required to make up heat losses, W

$$q_t = 5.6 + 7.0 = 12.6 \text{ W}$$

Ventilation cooling capacity:

$$q_c = \rho c_p Q(t_i - t_f)$$

where

q_c = ventilation cooling capacity of unit, W
t_f = unit discharge air temperature, °C

Table 1 Typical Unit Ventilator Capacities

Airflow, L/s	Heating Unit Ventilator Total Heating Capacity, kW	A/C Unit Ventilator Total Cooling Capacity, kW
240	10.7	5.6
360	15.6	8.4
480	20.4	11.2
600	25.3	14.0
720	30.2	16.8

$$q_c = 1.2 \times 1.0 \times 600(21 - 15) = 4320 \text{ W}$$

Control

Many cycles of control are available. The main difference in the various cycles is the amount of outdoor air delivered to the room. Usually, a room thermostat simultaneously controls both a valve and either damper or step controller, to regulate the heat supply, and an outdoor and return air damper. A thermostat in the airstream prevents discharge of air below the desired minimum temperature. Unit ventilator controls provide the proper sequence for the following stages:

- **Warm-up.** All control cycles allow rapid warm-up by having the units generate full heat with the outdoor damper closed. Thus 100% of the room air is recirculated and heated until the room temperature approaches the desired level.
- **Heating and ventilating.** As the room temperature rises into the thermostat's operating range, the outdoor air damper partially or completely opens to provide ventilation, depending on the cycle used. Auxiliary heating equipment is shut off. As the room temperature continues to rise, the unit ventilator heat supply is throttled.
- **Cooling and ventilating.** When the room temperature rises above the desired level, the room thermostat throttles the heat supply so that cool air flows into the room. The thermostat gradually shuts off the heat and then opens the outdoor air damper. The airstream thermostat frequently takes control during this stage to keep the discharge temperature from falling below a set level.

There are three cycles of control commonly used for unit ventilators:

- **Cycle I.** 100% outdoor air is admitted at all times, except during warm-up.
- **Cycle II.** A minimum amount of outdoor air (normally 20 to 50%) is admitted during the heating and ventilating stage. This percentage is gradually increased to 100%, if needed, during the ventilation cooling stage.
- **Cycle III.** Except during warm-up, a variable amount of outdoor air is admitted, as needed, to maintain a fixed temperature of air entering the heating element. The amount of air admitted is controlled by the airstream thermostat set low enough (often at 13 °C) to provide cooling when needed.

Air-conditioning unit ventilators can include any of the three cycles in addition to the mechanical cooling stage, where a fixed amount of outdoor air is introduced. The cooling capacity is controlled by the room thermostat.

For maximum heating economy, the building temperature is reduced at night and during weekends and vacations. Several arrangements are used to accomplish this. One arrangement takes advantage of the natural convective capacity of the unit when the fans are off. This capacity is supplemented by cycling the fan with the outdoor damper closed as required to maintain the desired room temperature.

2. UNIT HEATERS

A unit heater is an assembly of elements with the main function of heating a space. The essential elements are a fan and motor, a heating element, and an enclosure. Filters, dampers, directional outlets, duct collars, combustion chambers, and flues may also be included. Some types of unit heaters are shown in Figure 3.

Unit heaters can usually be classified in one or more of the following categories:

- **Heating medium.** Media include (1) steam, (2) hot water, (3) gas indirect-fired, (4) oil indirect-fired, and (5) electric heating.
- **Type of fan.** Three types of fans can be considered: (1) propeller, (2) centrifugal, and (3) remote air mover. Propeller fan units may be arranged to blow air horizontally (horizontal blow) or vertically (downblow). Units with centrifugal fans may be small cabinet units or large industrial units. Units with remote air movers are known as duct unit heaters.
- **Arrangement of elements.** Two types of units can be considered: (1) draw-through, in which the fan draws air through the unit; and (2) blow-through, in which the fan blows air through the heating element. Indirect-fired unit heaters are always blow-through units.

Application

Unit heaters have the following principal characteristics:

- Relatively large heating capacities in compact casings
- Ability to project heated air in a controlled manner over a considerable distance
- Relatively low installed cost per unit of heat output
- Application where an elevated sound level is permissible

They are, therefore, usually placed in applications where the heating capacity requirements, physical volume of the heated space, or both, are too large to be handled adequately or economically by other means. By eliminating extensive duct installations, the space is freed for other use.

Unit heaters are mostly used for heating commercial and industrial structures such as garages, factories, warehouses, showrooms, stores, and laboratories, as well as corridors, lobbies, vestibules, and similar auxiliary spaces in all types of buildings. Unit heaters may often be used to advantage in specialized applications requiring spot or intermittent heating, such as at outer doors in industrial plants or in corridors and vestibules. Cabinet unit heaters may be used where heated air must be filtered.

Unit heaters may be applied to a number of industrial processes (e.g., drying and curing) that use heated air in rapid circulation with uniform distribution. They may be used for moisture absorption applications, such as removing fog in dye houses, or to prevent condensation on ceilings or other cold surfaces of buildings where process moisture is released. When such conditions are severe, unit ventilators or makeup air units may be required.

Selection

The following factors should be considered when selecting a unit heater:

- Heating medium to be used
- Type of unit
- Location of unit for proper heat distribution
- Permissible sound level
- Rating of the unit
- Need for filtration

Heating Medium. The proper heating medium is usually determined by economics and requires examining initial cost, operating cost, and conditions of use.

Steam or **hot-water unit heaters** are relatively inexpensive but require a boiler and piping system. The unit cost of such a system generally decreases as the number of units increases. Therefore, steam or hot-water heating is most frequently used (1) in new installations involving a relatively large number of units, and (2) in existing systems that have sufficient capacity to handle the additional load. High-pressure steam or high-temperature hot-water units are normally used only in very large installations or when a high-temperature medium is required for process work. Low-pressure steam and conventional hot-water units are usually selected for smaller installations and for those concerned primarily with comfort heating.

Gas and **oil indirect-fired unit heaters** are frequently preferred in small installations where the number of units does not justify the expense and space requirements of a new boiler system or where individual metering of the fuel supply is required, as in a shopping center. Gas indirect-fired units usually have either horizontal propeller fans or industrial centrifugal fans. Oil indirect-fired units largely have industrial centrifugal fans. Some codes limit the use of indirect-fired unit heaters in some applications. Indirect-fired oil and gas units are of blow-through design to mitigate the possibility of combustion products entering the occupied space.

Electric unit heaters are used when the cost of available electric power is lower than that of alternative fuel sources and for isolated locations, intermittent use, supplementary heating, or temporary service. Typical applications are ticket booths, security offices, factory offices, locker rooms, and other isolated rooms scattered over large areas. Electric units are particularly useful in isolated and untended pumping stations or pits, where they may be thermostatically controlled to prevent freezing.

Type of Unit. Propeller fan units are generally used in nonducted applications where the heating capacity and distribution requirements can best be met by units of moderate output and where heated air does not need to be filtered. Horizontal-blow units are usually installed in buildings with low to moderate ceiling heights. Downblow units are used in spaces with high ceilings and where floor and wall space limitations dictate that heating equipment be kept out of the way. Downblow units may have an adjustable diffuser to vary the discharge pattern from a high-velocity vertical jet (to achieve the maximum distance of downward throw) to a horizontal discharge of lower velocity (to prevent excessive air motion in the zone of occupancy). Revolving diffusers are also available.

Cabinet unit heaters are used when a more attractive appearance is desired. They are suitable for free-air delivery or low static pressure duct applications. They may be equipped with filters, and they can be arranged to discharge either horizontally or vertically up or down.

Industrial centrifugal fan units are applied where heating capacities and space volumes are large or where filtration of the heated air or operation against static resistance is required. Downblow or horizontal-blow units may be used, depending on the requirements.

Duct unit heaters are used where the air handler is remote from the heater. These heaters sometimes provide an economical means of adding heating to existing cooling or ventilating systems with ductwork. They require flow and temperature limit controls.

Location for Proper Heat Distribution. Units must be selected, located, and arranged to provide complete heat coverage while maintaining acceptable air motion and temperature at an acceptable sound level in the working or occupied zone. Proper application depends on size, number, and type of units; direction of airflow and type of directional outlet used; mounting height; outlet velocity and temperature; and air volumetric flow. Many of these factors are interrelated.

The mounting height may be governed by space limitations or by the presence of equipment such as display cases or machinery. The higher a downblow heater is mounted, the lower the temperature of air leaving the heater must be to force the heated air into the occupied zone. Also, the distance that air leaving the heater travels

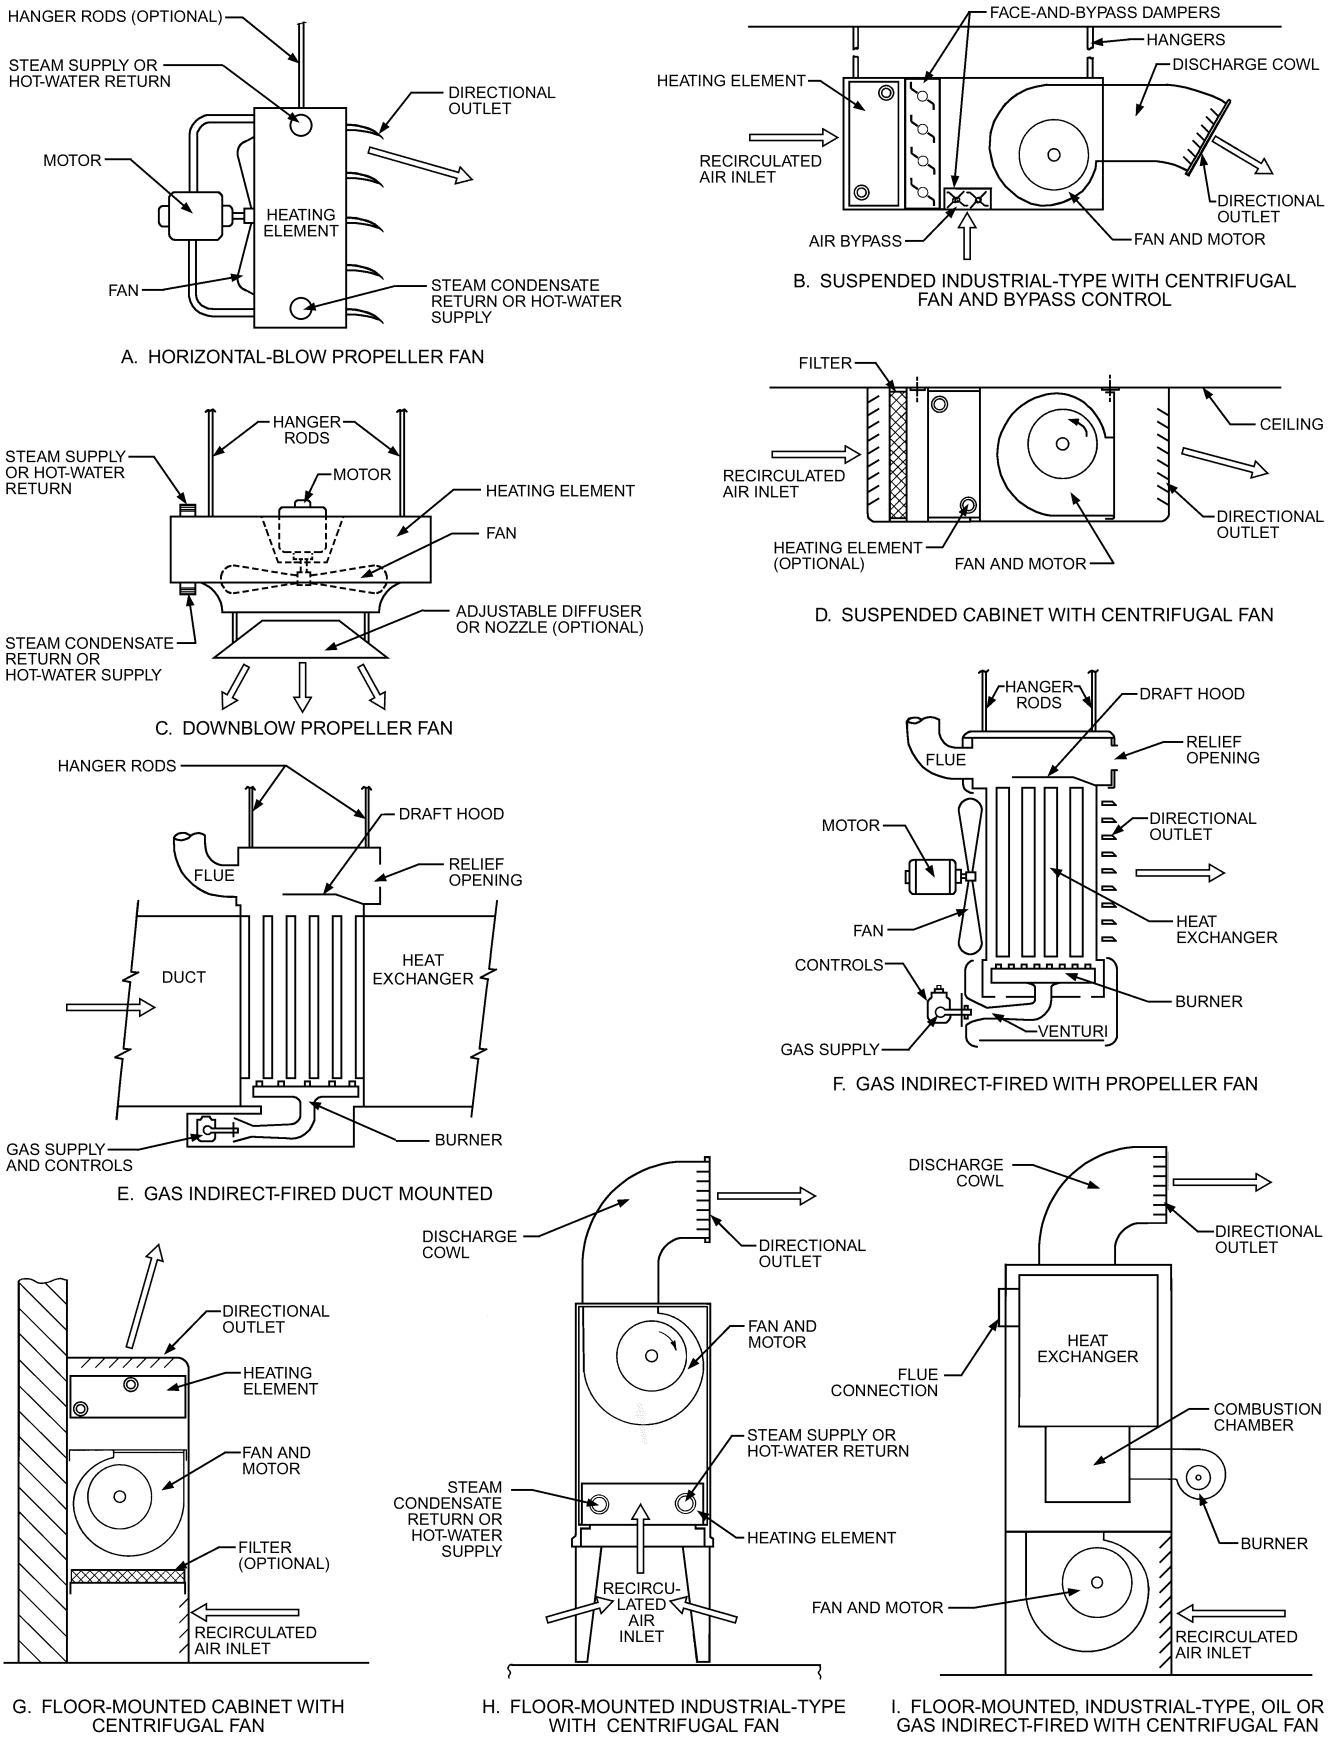

Fig. 3 Typical Unit Heaters

depends largely on the air temperature and initial velocity. A high discharge temperature reduces the area of effective heat coverage because of its buoyancy. High-temperature air is less dense than the cooler air of the space being heated.

Unit heaters for high-pressure steam or high-temperature hot water should be designed to produce approximately the same leaving air temperature as would be obtained from a lower temperature heating medium.

To obtain the desired air distribution and heat diffusion, unit heaters are commonly equipped with directional outlets, adjustable louvers, or fixed or revolving diffusers. For a given unit with a given discharge temperature and outlet velocity, the mounting height and heat coverage can vary widely with the type of directional outlet, adjustable louver, or diffuser. High-volume, low-speed fans in high-ceilinged areas are often used to augment air distribution and reduce temperature stratification.

Other factors that may substantially reduce heat coverage include obstructions (such as columns, beams, or partitions) or machinery in either the discharge airstream or approach area to the unit. Strong drafts or other air currents also reduce coverage. Exposures such as large glass areas or outer doors, especially on the windward side of the building, require special attention; arrange units so that they blanket the exposures with a curtain of heated air and intercept the cold drafts.

For area heating, place horizontal-blow unit heaters in exterior zones such that they blow either along the exposure or toward it at a slight angle. When possible, arrange multiple units so that the discharge airstreams support each other and create a general circulatory motion in the space. Interior zones under exposed roofs or skylights should be completely blanketed. Arrange downblow units so that the heated areas from adjacent units overlap slightly to provide complete coverage.

For spot heating of individual spaces in larger unheated areas, single unit heaters may be used, but allowance must be made for the inflow of unheated air from adjacent spaces and the consequent reduction in heat coverage. Such spaces should be isolated by partitions or enclosures, if possible.

Horizontal unit heaters should have discharge outlets located well above head level. Both horizontal and vertical units should be placed so that the heated airstream is delivered to the occupied zone at acceptable temperature and velocity. Outlet air temperature of free-air delivery unit heaters used for comfort heating should be 27 to 33 K higher than the design room temperature. When possible, locate units so that they discharge into open spaces, such as aisles, and not directly on the occupants. For further information on air distribution, see Chapter 20 of the 2021 *ASHRAE Handbook—Fundamentals*.

Manufacturers' catalogs usually include suggestions for the best arrangements of various unit heaters, recommended mounting heights, heat coverage for various outlet velocities, final temperatures, directional outlets, and sound level ratings.

Sound Level in Occupied Spaces. Sound pressure levels in workplaces should be limited to values listed in Table 1 in Chapter 49 of the 2023 *ASHRAE Handbook—HVAC Applications*. Although the noise level is generated by all equipment within hearing distance, unit heaters may contribute a significant portion of noise level. Both noise and air velocity in the occupied zone generally increase with increased outlet velocities. An analysis of both the diverse sound sources and the locations of personnel stations establishes the limit to which the unit heaters must be held.

Ratings of Unit Heaters.

Steam or Hot Water. Heating capacity must be determined at a standard condition. Variations in entering steam or water temperature, entering air temperature, and steam or water flow affect capacity. Typical standard conditions for rating steam unit heaters are dry saturated steam at 14 kPa (gage) pressure at the heater coil, air at 15.6°C (101.3 kPa barometric pressure) entering the heater, and the heater operating free of external resistance to airflow. Standard conditions for rating hot-water unit heaters are entering water at 93.3°C, water temperature drop of 11.1 K, entering air at 15.6°C and 101.3 kPa barometric pressure, and the heater operating free of external resistance to airflow.

Gas-Fired. Gas-fired unit heaters are rated in terms of both input and output, in accordance with the approval requirements of the American Gas Association.

Oil-Fired. Ratings of oil-fired unit heaters are based on heat delivered at the heater outlet.

Electric. Electric unit heaters are rated based on the energy input to the heating element.

Effect of Airflow Resistance on Capacity. Unit heaters are customarily rated at free-air delivery. Airflow and heating capacity decrease if outdoor air intakes, air filters, or ducts on the inlet or discharge are used. The capacity reduction caused by this added resistance depends on the characteristics of the heater and on the type, design, and speed of the fans. As a result, no specific capacity reduction can be assigned for all heaters at a given added resistance. The manufacturer should have information on the heat output to be expected at other than free-air delivery.

Effect of Inlet Temperature. Changes in entering air temperature influence the total heating capacity in most unit heaters and the final temperature in all units. Because many unit heaters are located some distance from the occupied zone, possible differences between the temperature of the air actually entering the unit and that of air being maintained in the heated area should be considered, particularly with downblow unit heaters.

Higher-velocity units and units with lower vertical discharge air temperature maintain lower temperature gradients than units with higher discharge temperatures. Valve- or bypass-controlled units with continuous fan operation maintain lower temperature gradients than units with intermittent fan operation. Directional control of the discharged air from a unit heater can also be important in distributing heat satisfactorily and in reducing floor-to-ceiling temperature gradients.

Filters. Air from propeller unit heaters cannot be filtered because the heaters are designed to operate with heater friction loss only. If dust in the building must be filtered, centrifugal fan units or cabinet units should be used. Chapter 29 has further information on air cleaners for particulate contaminants.

Control

The controls for a steam or hot water unit heater can provide either (1) on/off operation of the unit fan, or (2) continuous fan operation with modulation of heat output. For on/off operation, a room thermostat is used to start and stop the fan motor or group of fan motors. A limit thermostat, often strapped to the supply or return pipe, prevents fan operation in the event that heat is not being supplied to the unit. An auxiliary switch that energizes the fan only when power is applied to open the motorized supply valve may also be used to prevent undesirable cool air from being discharged by the unit.

Continuous fan operation eliminates both the intermittent blasts of hot air resulting from on/off operation and the stratification of temperature from floor to ceiling that often occurs during off periods. In this arrangement, a proportional room thermostat controls a valve modulating the heat supply to the coil or a bypass around the heating element. A limit thermostat or auxiliary switch stops the fan when heat is no longer available.

One type of control used with downblow unit heaters is designed to automatically return the warm air, which would normally stratify at the higher level, down to the zone of occupancy. Two thermostats

and an auxiliary switch are required. The lower thermostat is placed in the zone of occupancy and is used to control a two-position supply valve to the heater. An auxiliary switch is used to stop the fan when the supply valve is closed. The higher thermostat is placed near the unit heater at the ceiling or roof level where the warm air tends to stratify. The lower thermostat automatically closes the steam valve when its setting is satisfied, but the higher thermostat overrides the auxiliary switch so that the fan continues to run until the temperature at the higher level falls below a point sufficiently high to produce a heating effect.

Indirect-fired and electric units are usually controlled by intermittent operation of the heat source under control of the room thermostat, with a separate fan switch to run the fan when heat is being supplied. For more information on automatic control, refer to Chapter 48 of the 2023 *ASHRAE Handbook—HVAC Applications*.

Unit heaters can be used to circulate air in summer. In such cases, the heat is shut off and the thermostat has a bypass switch, which allows the fan to run independently of the controls.

Piping Connections

Piping connections for steam unit heaters are similar to those for other types of fan blast heaters. Unit heater piping must conform strictly to the system requirements, while allowing the heaters to function as intended. Basic piping principles for steam systems are discussed in Chapter 11.

Steam unit heaters condense steam rapidly, especially during warm-up periods. The return piping must be planned to keep the heating coil free of condensate during periods of maximum heat output, and the steam piping must be able to carry a full supply of steam to the unit to take the place of condensed steam. Adequate pipe size is especially important when a unit heater fan is operated under on/off control because the condensate rate fluctuates rapidly.

Recommended piping connections for unit heaters are shown in Figure 4. In steam systems, the branch from the supply main to the heater must pitch toward the main and be connected to its top to prevent condensate in the main from draining through the heater, where it might reduce capacity and cause noise.

The return piping from steam unit heaters should provide a minimum drop of 250 mm below the heater, so that the water pressure required to overcome resistances of check valves, traps, and strainers does not cause condensate to remain in the heater.

Dirt pockets at the outlet of unit heaters and strainers with 1.6 mm perforations to prevent rapid plugging are essential to trap dirt and scale that might affect the operation of check valves and traps. Always install strainers in the steam supply line if the heater has steam-distributing coils or is valve controlled.

An adequate air vent is required for low-pressure closed gravity systems. The vertical pipe connection to the air vent should be at least 20 mm DN to allow water to separate from the air passing to the vent. If thermostatic instead of float-and-thermostatic traps are used in vacuum systems, a cooling leg must be installed ahead of the trap.

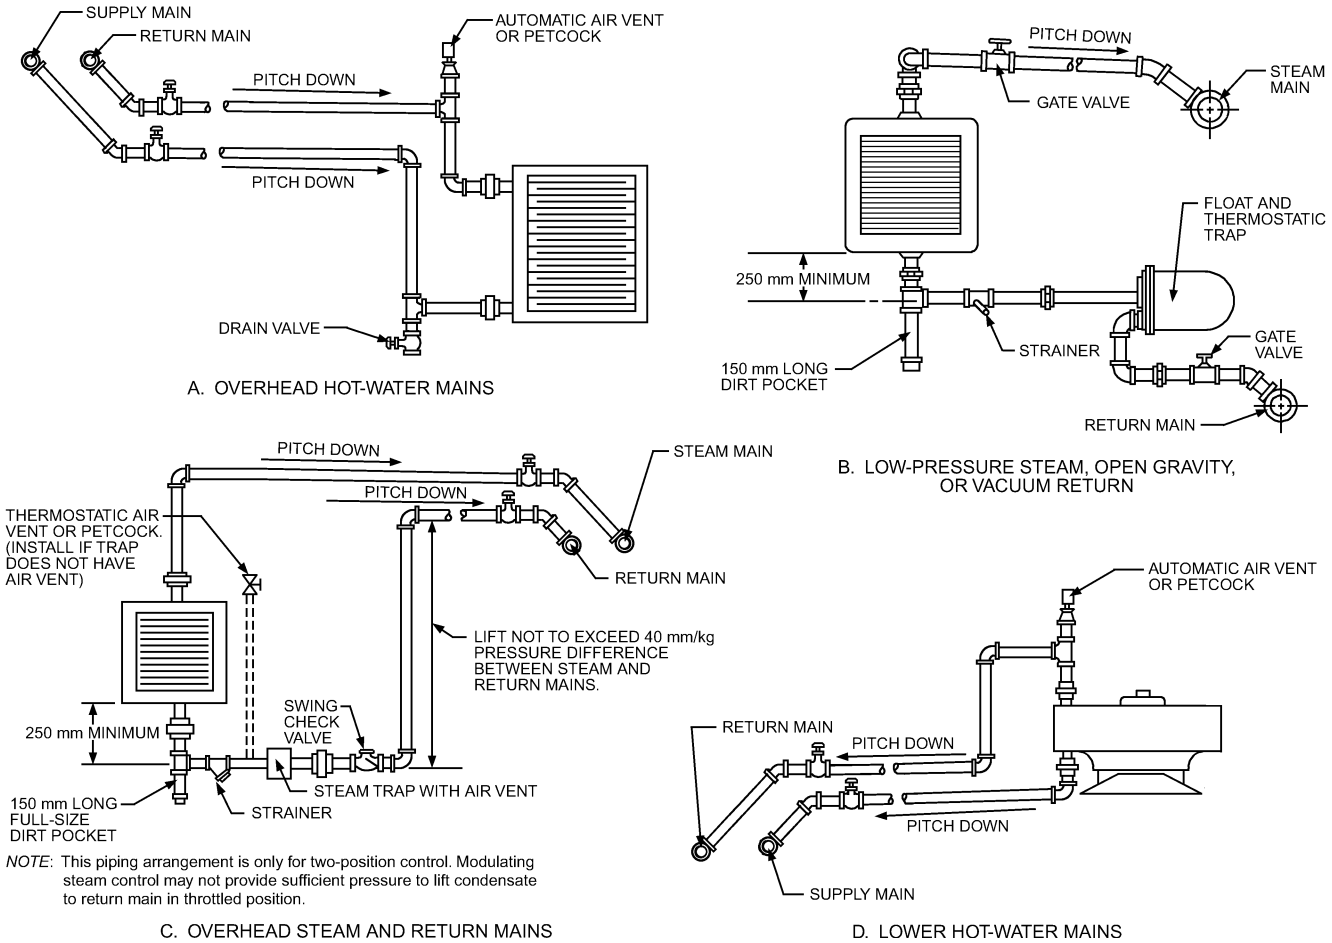

Fig. 4 Hot Water and Steam Connections for Unit Heaters

In high-pressure systems, it is customary to continuously vent the air through a petcock (as shown in Figure 4C), unless the steam trap has a provision for venting air. Most high-pressure return mains terminate in flash tanks that are vented to the atmosphere. When possible, use pressure-reducing valves to allow heater operation at low pressure. Traps must be suitable for the operating pressure encountered.

When piping is connected to hot-water unit heaters, it must be pitched to allow air to vent to the atmosphere at the high point in the piping. An air vent at the heater is used to facilitate air removal or to vent the top of the heater. The system must be designed for complete drainage, including placing nipple and cap drains on drain cocks when units are located below mains.

Maintenance

Regular inspection, based on a schedule determined by the amount of dirt in the atmosphere, assures maximum operating economy and heating capacity. During design, ensure sufficient space for maintenance access to each component. Clean heating elements when necessary, by brushing or blowing with high-pressure air or by using a steam spray. A portable sheet metal enclosure may be used to partially enclose smaller heaters for cleaning in place with air or steam jets. In some installations, however, it may be necessary to remove the heating element and wash it with a mild alkaline solution, followed by a thorough rinsing with water. Propeller units do not have filters and are, therefore, more susceptible to dust build-up on the coils.

Dirt on fan blades reduces capacity and may unbalance the blades, which causes noise and bearing damage. Fan blades should be inspected and cleaned when necessary. Vibration and noise may also be caused by improper fan position or loose set screws. Place a fan guard on downblow unit heaters that have no diffuser or other device to catch the fan blade if it comes loose and falls from the unit.

The amount of attention required by the various motors used with unit heaters varies greatly. Instructions for lubrication, in particular, must be followed carefully for trouble-free operation: excess lubrication, for example, may damage the motor, and an improper lubricant may cause the bearings to fail. Get instructions for care of the motor on any unit heater from the manufacturer and keep them at the unit.

Fan bearings and drives must be lubricated and maintained according to the instructions specified by the manufacturer. If the unit is direct connected, inspect the couplings periodically for wear and alignment. V-belt drives should have all belts replaced with a matched set if one belt shows wear.

Periodic inspections of traps, inspections of check and air valves, and the replacement of worn fans are other important maintenance functions. Strainers should be cleaned regularly. Filters, if included, must be cleaned or replaced when dirty.

3. MAKEUP AIR UNITS

Description and Applications

Makeup air units are designed to condition ventilation air introduced into a space or to replace air exhausted from a building, in compliance with ASHRAE *Standard* 62.1 as applicable. The air exhausted may be from a process or general area exhaust, through either powered exhaust fans or gravity ventilators. The units may be used to prevent negative pressure within buildings or to reduce airborne contaminants in a space.

If temperature and/or humidity in the structure are controlled, the makeup air system must have the capacity to condition the replacement air. In most cases, makeup air units must be used to supply this conditioned makeup air. The units may heat, cool, humidify, dehumidify, and/or filter incoming air. They may be used to replace air in the conditioned space or to supplement or accomplish all or part of the airflow needed to satisfy the heating, ventilating, or cooling airflow requirements.

Makeup air can enter at a fixed flow rate or as a variable volume of outdoor air. It can be used to accomplish building pressurization or contamination reduction, and may be controlled in a manner that responds directly to exhaust flow. When compatible with the characteristics and class of the air being exhausted, makeup air units should also be connected to process exhaust with air-to-air heat recovery units, thermal wheels, heat pipes, or runaround coils (recovery loop exchangers) tested (when applicable) under ANSI/ASHRAE *Standard* 84.

Buildings under negative pressure because of inadequate makeup air may have the following symptoms:

- Gravity stacks from unit heaters and processes back-vent.
- Exhaust systems do not perform at rated volume.
- The perimeter of the building is cold in winter because of high infiltration.
- Severe drafts occur at exterior doors.
- Exterior doors are hard to open or close completely.
- Heating systems cannot maintain comfortable conditions throughout the building because the central core area becomes overheated.
- Excessive condensation occurs.

Other Applications.

Spot Cooling. High-velocity air jets in the unit may be directed to working positions. During cold weather, supply air must be tempered or reduced in velocity to avoid overcooling workers.

Door Heating. Localized air supply at swinging doors or overhead doors, such as for loading docks, can be provided by makeup air units. Heaters may blanket door openings with tempered air. The temperature may be reset from the outdoor temperature or with dual-temperature air (low when the door is closed and high when the door is open during cold weather). Heating may be arranged to serve a single door or multiple doors by an air distribution system. Door heating systems may also be arranged to minimize entry of insects during warm weather. Air curtain units for door openings should be tested and comply with ANSI/AMCA *Standard* 220-21, section C408.2.3.

Selection

Makeup air systems used for ventilation may be (1) sized to balance air exhaust volumes or (2) sized in excess of the exhaust volume to dilute contaminants. In applications where contaminant levels vary, variable-flow units should be considered so that the supply air varies for contaminant control and the exhaust volume varies to track supply volume. In critical spaces, the exhaust volume may be based on requirements to control pressure in the space.

Location. Makeup air units are defined by their location or the use of a key component. Examples are rooftop makeup air units, truss- or floor-mounted units, and sidewall units. Some manufacturers differentiate their units by heating mode, such as steam or direct gas-fired makeup air units.

Rooftop units are commonly used for large single-story industrial buildings to simplify air distribution. Access (via roof walks) is more convenient than access to equipment mounted in the truss; truss units are only accessible by installing a catwalk adjacent to the air units. Disadvantages of rooftop units are (1) they increase foot traffic on the roof, thus reducing its life and increasing the likelihood of leaks; (2) inclement weather reduces equipment accessibility; and (3) units are exposed to weather.

Makeup air units can also be placed around the perimeter of a building with air ducted through the sidewall. This approach limits future building expansion, and the effectiveness of ventilating internal spaces decreases as the building gets larger. However, access to

the units is good, and minimum support is required because the units are mounted on the ground.

Use caution in selecting the location of the makeup air unit and/or its associated combustion air source, to avoid introducing combustible vapors into the unit. Consult state and local fire codes for specific guidance.

Heating and Cooling Media.

Heating. Makeup air units are often identified by the heating or cooling medium they use. Heaters in makeup air systems may be direct gas-fired burners, electric resistance heating coils, indirect gas-fired heaters, steam coils, or hot-water heating coils. (Chapter 27 covers the design and application of heating coils.) Air distribution systems are often required to direct heat to spaces requiring it.

Natural gas can be used to supply an indirect-fired burner, as for a large furnace. (Chapter 33 has more information, including detailed heater descriptions.) In a **non-recirculating** direct-fired heater, levels of combustion products generated by the heater are very low (CO < 5.0 mg/kg, NO_2 < 0.5 mg/kg, and CO_2 < 4000 mg/kg) and are released directly into the airstream being heated. All air to a non-recirculating makeup air heater must be ducted directly from outdoor source. Non-recirculating direct gas-fired industrial air heaters are typically certified to comply with ANSI *Standard* Z83.4b/CSA3.7b-2017. In a **recirculating** makeup air heater, ventilation air to the heater must be ducted directly from an outdoor source to limit the concentration of combustion products in the conditioned space to a level below 25 mg/kg for CO, 3 mg/kg for NO_2, and 5000 mg/kg for CO_2. Recirculating direct gas-fired industrial air heaters are typically certified to comply with ANSI *Standard* Z83.18-2017. Installing carbon monoxide detectors to protect building occupants in the event of a heater malfunction is good engineering practice, and may be required by local codes.

Hydronic heating sections in spaces requiring a fully isolated source (100%) of outdoor air must be protected from freezing in cold climates. Low-temperature protection includes two-position control of steam coils; careful selection of the water coil heating surface and control valves; careful control of water supply temperature; and use of an antifreeze additive.

Cooling. Mechanical refrigeration with direct-expansion or chilled-water cooling coils, direct or indirect evaporative cooling sections, or well water coils may be used. Air distribution systems are often required to direct cooling to specific spaces that experience or create heat gain.

Because industrial facilities often have high sensible heat loads, evaporative cooling can be particularly effective. An evaporative cooler helps clean the air, as well. A portion of the spray water must be bled off to keep the water acceptably clean and to maintain a low solids concentration. Chapter 41 of this volume and Chapter 53 of the 2023 *ASHRAE Handbook—HVAC Applications* cover evaporative cooling in more detail.

Chapter 23 provides information on air-cooling coils. If direct-expansion coils are used in conjunction with direct-fired gas coils, the cooling coils' headers must be isolated from the airstream and directly vented outdoors.

Filters. High-efficiency filters (approximately MERV 16 for near-HEPA performance) are not normally used in a makeup air unit because of their relatively high cost. HVAC prefilters are generally in the MERV 6 to 13 range, depending on particulate removal needs. Designers should ensure that all filters are easy to change or clean. Appropriate washing equipment should be located near all washable filters. Throwaway filters should be sized for easy removal and disposal. Chapters 29 and 30 have more information on air filters and cleaners.

Fans. Follow AMCA *Standard* 205-19 for fan selection. This standard addresses fans with a minimum impeller diameter of 125 mm, operating with a shaft power of at least 750 W, and with a total efficiency calculated according to one of the following fan test standards:

- ANSI/AMCA *Standard* 210 (ANSI/ASHRAE *Standard* 51)
- ANSI/AMCA *Standard* 230
- AMCA *Standard* 260
- ISO *Standard* 5801

ASHRAE *Standard* 90.1-2020 requires a fan and fan array efficiency index (FEI) of 1.00 or higher and fans and fan arrays of variable volume to have and FEI of 0.95 or higher, and that the fan should be sized and selected within 15% of its peak total efficiency (FEI 71 calculated under AMCA *Standard* 205 Annex C and ICC [2021]).

Fans should have variable-speed drives for possible energy savings or for use in variable-airflow systems.

Control

Controls for a makeup air unit fall into the following categories: (1) local temperature controls, (2) airflow controls, (3) plant-wide controls for proper equipment operation and efficient performance, (4) safety controls for burner gas, and (5) building smoke control systems. For control system information, refer to Chapters 42, 43, and 48 of the 2023 *ASHRAE Handbook—HVAC Applications*.

Safety controls for gas-fired units include components to properly light the burner and to provide a safeguard against flame failure. The heater and all attached inlet ducting must be purged with at least four air changes before initiating an ignition sequence and before reignition after a malfunction. A flame monitor and control system must be used to automatically shut off gas to the burner upon burner ignition or flame failure. Critical malfunctions include flame failure, supply fan failure, combustion air depletion, power failure, control signal failure, excessive or inadequate inlet gas supply pressure, excess air temperature, and gas leaks in motorized valves or inlet gas supply piping.

Makeup air units should be interlocked with exhaust units to avoid overpressurization, and should include shutoff dampers with limit switches for when not in use. Damper leakage rates should be within limits set in ASHRAE *Standard* 90.1. These units should also be interlocked to the building's fire alarm system to shut down in the case of a fire, where required by applicable codes.

Consider using automatic safety shutoff valves on interconnecting piping systems where there are risks of overtemperature, overpressure, or gas leaks.

Applicable Codes and Standards

A gas-fired makeup air unit must be designed and built in accordance with NFPA *Standard* 54 and the requirements of the owner's insurance underwriter. Local codes must also be observed when using direct-fired gas makeup air units because some jurisdictions prohibit or restrict their use and may also require exhaust fans to be used while the unit is in operation.

The following standard and codes and the sources in the References may also apply, depending on the application.

Commissioning

Commissioning of makeup air systems is similar to that of other air-handling systems, requiring attention to

- Equipment identification
- Piping system identification
- Belt drive adjustment
- Control system checkout in accordance with ASHRAE *Guideline* 11-2009
- Documentation of system installation
- Lubrication
- Electrical system checkout for overload heater size and function
- Cleaning and degreasing of hydronic piping systems
- Pretreatment of hydronic fluids
- Setup of chemical treatment program for hydronic systems and evaporative apparatus
- Start-up of major equipment items by factory-trained technician
- Testing and balancing
- Planning of preventive maintenance program
- Instruction of owner's operating and maintenance personnel in accordance with proposed ASHRAE *Guideline* GPC 1.3P, Building Operation and Maintenance Training for the HVAC&R Commissioning Process

Maintenance

Basic operating and maintenance data required for makeup air systems may be obtained from the ASHRAE Handbook chapters covering the components. Specific operating instructions are required for makeup air heaters that require changeover from winter to summer conditions, including manual fan speed changes, air distribution pattern adjustment, or heating cycle lockout. Operating and maintenance documentation should comply with ASHRAE *Guideline* 4-2008 (RA13).

Operations handling 100% outdoor air may require more frequent maintenance, such as changing filters, lubricating bearings, and checking the water supply to evaporative coolers/humidifiers. Filters on systems in locations with dirty air require more frequent changing, so a review may determine whether upgrading filter media would be cost-effective. More frequent cleaning of fans' blades and heat transfer surfaces may be required in such locations to maintain airflow and heat transfer performance.

AIR CLEANERS FOR PARTICULATE CONTAMINANTS

Terminology 29.1
Atmospheric Aerosols 29.2
Aerosol Characteristics 29.2
Air-Cleaning Applications 29.3
Mechanisms of Particle Collection 29.3
Types of Air Cleaners and Performance 29.4
Air Cleaner Test Methods 29.7
Selection and Maintenance 29.10
Air Cleaner Installation 29.13
Safety Considerations 29.14

THIS chapter discusses removal of contaminants from both ventilation and recirculated air used for conditioning building interiors. The filters mentioned in this chapter are primarily used for HVAC systems and for the protection of equipment. Complete air cleaning may require removing of airborne particles, microorganisms, and gaseous contaminants, but this chapter only covers removal of airborne particles and briefly discusses bioaerosols. Chapter 47 of the 2023 *ASHRAE Handbook—HVAC Applications* covers the removal of gaseous contaminants. Chapter 62 of the 2023 *ASHRAE Handbook—HVAC Applications* covers bioaerosols and UV air cleaners in more depth.

The total suspended particulate concentration in applications discussed in this chapter seldom exceeds 2 mg/m^3 and is usually less than 0.2 mg/m^3 of air (Chapter 11 of the 2022 *ASHRAE Handbook—Fundamentals*). This is in contrast to flue gas or exhaust gas from processes, where dust concentrations typically range from 200 to 40 000 mg/m^3. Chapter 46 of the 2023 *ASHRAE Handbook—HVAC Applications* discusses exhaust gas control.

Most air cleaners discussed in this chapter are not used in exhaust gas streams because of the extreme dust concentration, large particle size, high temperature, high humidity, and high airflow rate requirements that may be encountered in process exhaust. However, the air cleaners discussed here are used extensively in supplying makeup air with low particulate concentration to industrial processes.

1. TERMINOLOGY

Definitions

Aerodynamic diameter. The diameter of a spherical particle with a density of 1000 kg/m^3 and the same settling velocity as the irregular particle of interest.

Aerosol. Solid and/or liquid particles suspended in air.

Air cleaner. Device or system for removing contaminants from air in a ventilation system, building or other enclosed space.

Air filter. A device containing filter media, typically mounted in a frame, that is designed to remove particles from an air stream onto the fibers in the *air filter media.*

Air filter media. Portion of a filtration system (such as close-woven textiles, metal screens, papers, nonwoven fabrics, granular beds, or porous media) that effects separation of particles from air.

Air purifier. See *Air cleaner*

Arrestance. Measure of the ability of a filter to remove a standard test from the air passing through it, under given operating conditions. Arrestance is expressed as a percentage by weight of the test dust (ISO 29464).

Bioaerosol. Particles of biological origin suspended in air (ISO 29464).

Dust-holding capacity. Total mass of synthetic loading dust captured by an air-cleaning device added up over all of the incremental dust loading steps.

Duct air cleaner. See *In-duct air cleaner*

Duct-mounted air cleaner. See *In-duct air cleaner*

Electret air filter. An air filter in which the fibers in the filter media contain a one-time initial electrical charge designed to boost particle capture efficiency, particularly early in the life of the filter.

Electrically enhanced air purifier. See *Electrically enhanced air cleaner*

Electrically enhanced air cleaner. A type of electronic air cleaner that includes filter media positioned within an electric field and/or actively ionically charged to increase the particle collection efficiency of the filter media. Additionally, particles may be ionically precharged prior to their arrival at the filter media.

Electronic air cleaner (EAC). An air cleaner that uses electrical power for at least part of the mechanism by which particles are removed from an airstream. Types include electrostatic precipitators (ESPs) and electrically enhanced air purifiers, among others.

Electrostatic precipitator (ESP). A type of electronic air cleaner that uses high-voltage wires or points to charge particles via corona discharge and then move the particles transverse to the airflow to grounded collection plates by the imposition of an electric field via the same or secondary plate high voltage electrodes.

Fibrous air filter. See *Air filter*

Fractional efficiency. See *Particle size removal efficiency*

In-duct air cleaner. An air cleaner designed to be installed in an HVAC duct.

In-room air cleaner. A stand-alone device that includes an air cleaner and a blower, or other means to move air through the air cleaner, in a housing. In-room air cleaners typically have an electrical cord and are plugged into an electrical outlet.

In-room air purifier. See *In-Room Air Cleaner*

Mechanical media air filter. An air filter in which particle removal is accomplished via mechanical filtration mechanisms only and not via electrostatic effects.

Media air filter. See *Air Filter*

Most penetrating particle size (MPPS). The size of particles that most easily pass through a filter, whether the filter is infiltration or air purifier system.

Particle size removal efficiency. The fraction or percentage of particles retained by an air cleaner for a given particle-size range.

Particulate air filter. Device for separating solid and/or liquid particles from an airstream passing through the device.

Particulate matter (PM). Solid and/or liquid particles of various sizes.

Penetration. The fraction or percentage of particles that pass through an air cleaner for a given particle-size range.

Portable air purifier. See *In-room air cleaner*

Pressure drop. See *Resistance to airflow*

Removal Efficiency by Particle Size. See *Particle size removal efficiency*

Resistance to airflow. Difference in absolute (static) pressure between two points in an airflow system. This parameter is often called pressure drop.

The preparation of this chapter is assigned to TC 2.4, Particulate Air Contaminants and Particulate Contaminant Removal Equipment.

Resistance to airflow. Difference in absolute (static) pressure between two points in an airflow system. This parameter is often called pressure drop.

Respirable fraction. The subfraction of the inhaled particles that penetrates into the alveolar region of the lung (i.e., includes the respiratory bronchioles, the alveolar ducts and sacs)

Room air cleaner. See *In-room air cleaner*

Room air purifier. See *In-room air cleaner*

Stand-alone air cleaner. See *In-room air cleaner*

2. ATMOSPHERIC AEROSOLS

Atmospheric contaminants are a complex mixture of smokes, mists, fumes, dry granular particles, bioaerosols, and natural and synthetic fibers. When suspended in a gas such as air, this mixture is called an **aerosol**. A sample of atmospheric aerosol usually contains soot and smoke, silica, clay, decayed animal and vegetable matter, organic materials in the form of lint and plant fibers, and metallic fragments. It may also contain living organisms, such as mold spores, bacteria, and plant pollens, which may cause diseases or allergic responses. (Chapter 11 of the 2021 *ASHRAE Handbook—Fundamentals* contains further information on atmospheric contaminants.) A sample of atmospheric aerosol gathered at any point generally contains materials common to that locality, together with other components that originated at a distance but were transported by air currents or diffusion. These components and their concentrations vary with the geography of the locality (urban or rural), season of the year, weather, direction and strength of the wind, and proximity of dust sources.

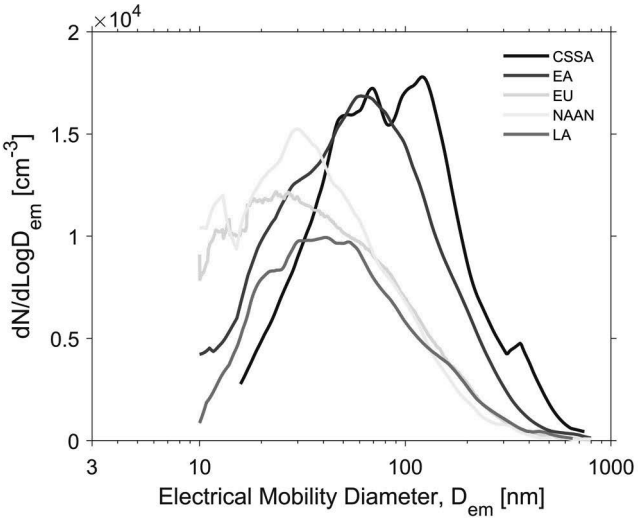

Fig. 1 Mobility Versus Particle Diameter

Median number particle size distributions for each geographical region (CSSA = Central, South, and Southeast Asia; EA = East Asia; EU = Europe; NAAN = North America, Australia, & New Zealand; LA = Latin America) (Wu and Boor 2021)

Aerosol sizes range from 0.01 µm and smaller for freshly formed combustion particles and radon progeny; to 0.1 µm for aged cooking and cigarette smokes; from 0.1 to 10 µm for airborne dust, microorganisms, and allergens; and up to 100 µm and larger for airborne soil, pollens, and allergens.

Number concentrations of atmospheric aerosols generally peak at submicron sizes and decrease rapidly as the particulate size increases above 1 µm. In fact, number concentrations of particles in urban aerosols are predominantly below 0.5 µm, dependent upon geographic location.

For a given size, the concentration can vary by several orders of magnitude over time and by location, particularly near an aerosol source, such as human activities, equipment, furnishings, and pets (Block and Bokalders 2010). This wide range of particulate size and concentration makes it impossible to design one cleaner for all applications.

3. AEROSOL CHARACTERISTICS

The characteristics of aerosols that most affect air filter performance include particle size and shape, mass, concentration, and electrical properties. The most important of these is particle size. Figure 3 in Chapter 11 of the 2021 *ASHRAE Handbook—Fundamentals* gives data on the sizes and characteristics of a wide range of airborne particles that may be encountered.

Particle size in this discussion refers to aerodynamic particle size. Particles less than 0.1 µm in diameter are generally referred to as **ultrafine-mode** or **nanoparticles**, those between 0.1 and 2.5 µm are termed **fine mode**, and those larger than 2.5 µm as **coarse mode**. Whereas ultrafine- and fine-mode particles may be formed together, fine- and coarse-mode particles typically originate by separate mechanisms, are transformed separately, have different chemical compositions, and require different control strategies. Vehicle exhaust is a major source of ultrafine particles. Ultrafines are minimally affected by gravitational settling and can remain suspended for days at a time. Fine-mode particles generally originate from condensation or are directly emitted as combustion products. Many microorganisms (bacteria and fungi) either are in this size range or produce components this size. These particles are less likely to be removed by gravitational settling and are just as likely to deposit on

vertical surfaces as on horizontal surfaces. Coarse-mode particles are typically produced by mechanical actions such as erosion and friction. Coarse particles are more easily removed by gravitational settling, and thus have a shorter airborne lifetime.

For industrial hygiene purposes, particles ≤ 5 μm in diameter are considered **respirable particles (RSPs)** because a large percentage of this size range has been shown to reach the alveolar region of the lungs. A cutoff of 5.0 μm includes 80 to 90% of the particles that can reach the functional pulmonary region of the lungs (James et al. 1991; Phalen et al. 1991). Willeke and Baron (1993) describe a detailed aerosol sampling technique for RSPs, including the use of impactors. See also the discussion in the section on Sizes of Airborne Particles in Chapter 11 of the 2021 *ASHRAE Handbook—Fundamentals*.

In the United States, **particulate matter (PM)** levels in outdoor air are regulated by the Environmental Protection Agency (EPA). Outdoor PM is a complex mixture of small particles and liquid droplets; their effects on health are related to size. Smaller particles have more impact because they penetrate deeper into the respiratory system. Currently, there are two regulated size ranges:

- **PM_{10}.** Inhalable particles with diameters that are generally 10 μm and smaller according to the EPA; typical sources include road dust and industrial emissions
- **$PM_{2.5}$.** Fine inhalable particles with diameters that are generally 2.5 μm and smaller; the main sources are industrial emissions and combustion exhaust from automobiles, power plants, and heating systems

PM_1, which is not regulated, consists of fine and ultrafine particles of less than 1 μm aerodynamic diameter.

The U.S. Clean Air Act requires the EPA to impose both primary standards designed to protect public health, and secondary standards intended to protect against adverse environmental effects. The limits presently in place (Federal Register 2013) are shown in Table 1. There is no filtration requirement for areas of noncompliance.

Bioaerosols are a diverse class of particles of biological origin. They include bacteria, fungal spores, fungal fragments, pollen grains, subpollen particles, viruses, pet- and pest-associated allergens, and plant debris (Fröhlich-Nowoisky et al. 2016). They are of particular concern in indoor air because of their association with allergies and asthma and their ability to cause disease. Chapters 10 and 11 of the 2021 *ASHRAE Handbook—Fundamentals* contain more detailed descriptions of these contaminants.

Bioaerosols range in size from 0.01 to 100 μm. Single bacterial cells are approximately 1 μm or less in aerodynamic diameter; however, they are often transported as larger bacterial cell agglomerates (~2 to 5 μm) or attached to other biological and abiotic particles. Unicellular fungal spores are generally 2 to 5 μm in aerodynamic diameter and multicellular fungal spores are larger than 10 μm (Després et al. 2012; Qian et al. 2012). Fungal fragments are typically less than 1 μm in size (Mensah-Attipoe et al. 2016). Pollen grains range in size from 10 to 100 μm (Després et al. 2012), while subpollen particles span ~0.01 μm to several micrometers in size (Taylor et al. 2004). Individual viruses can be as small as 0.02 to 0.03 μm, but are typically carried on larger particles (Verreault et al. 2008). Pet- and pest-associated allergens are approximately 1 to ≥20 μm in size (O'Meara and Tovey 2000). Virus- or bacteria-containing particles (from human sneezing, coughing, singing, etc.) include saliva/sputum and other compounds from the human respiratory tract, such that these particles will be bigger (often much bigger) than the individual virus or bacterium.

Throughout the COVID-19 pandemic, the terms *droplet*, *droplet nuclei*, *aerosol particle*, etc., were used in different ways by different people, especially across the infectious disease to aerosol science areas. To clearly understand these discussions, determine which use of the words is important in context. However, generally speaking *drop* or *droplet* is used to mean larger pieces of wet saliva/sputum/biological content. Depending on the person and time, this may mean different sizes, including bigger than 5 μm, bigger than 10 μm, or even bigger than 100 μm. When used, *droplet* most often means bigger particles that will fall out of still air very quickly. *Droplet nuclei* is used to mean smaller particles, but the use seems to be less specific. *Aerosols* or *aerosol particles* are used to indicate particles that can stay in the air for many minutes, hours, or longer. In this context, it may mean particles emitted from a person at that size or that dried down from bigger particles.

Table 1 U.S. EPA Standards for Particulate Matter in Outdoor Air

Type of Standard	Time Period Applicable	PM_{10}, μg/m³	$PM_{2.5}$, μg/m³
Primary	24 h	150	35
	1 yr	—	12
Secondary	24 h	150	35
	1 yr	—	15

Source: EPA (2015).

4. AIR-CLEANING APPLICATIONS

Different air-cleaning applications require different degrees of air cleaning effectiveness. In some industrial environments, ventilation removing only the larger dust particles from the airstream may produce acceptable cleanliness of the structure, protection of mechanical equipment, and employee health.

Certain industrial processes may also generate finer particulate contaminants that can impact employee health and may require a higher level of filtration.

In other applications, surface discoloration must be prevented. Unfortunately, the smaller components of atmospheric aerosol are the worst offenders in smudging and discoloring building interiors. Air cleaners or medium- to high-efficiency filters are required to remove smaller particles, especially the respirable fraction, which often must be controlled for comfort and health reasons. In cleanrooms or when radioactive or other dangerous particles are present, high- or ultrahigh-efficiency filters should be selected. For more information on cleanrooms, see Chapter 19 of the 2023 *ASHRAE Handbook—HVAC Applications*.

Major factors influencing filter design and selection include (1) degree of air cleanliness required, (2) specific particle size range or aerosols that require filtration, (3) aerosol concentration, (4) resistance to airflow through the filter, (5) design filter for sealing and face velocity to achieve published performance and to include the capability of HVAC system to push air through it, (6) change-out cycle requirements, (7) energy consumption requirements, (8) special disposal mandates, and (9) resistance to certain conditions (physical, chemical, or biological).

5. MECHANISMS OF PARTICLE COLLECTION

In particle collection, air cleaners made of fibrous media rely on the following five main principles or mechanisms (Figure 2):

Straining or Sieving. The coarsest kind of filtration strains particles through an opening smaller than the particle being removed. It is most often observed as the collection of large particles and lint on the filter surface. The mechanism is not adequate to achieve the filtration of submicrometre aerosols through fibrous matrices, which occurs through other physical mechanisms, as follows.

Inertial Impingement. When particles are large or dense enough that they cannot follow the airstream around a fiber, they cross over streamlines, hit the fiber, and remain there if the attraction is strong enough. With flat-panel and other minimal-media-area filters having high air velocities (where the effect of inertia is most pronounced), the particle may not adhere to the fiber because drag and bounce

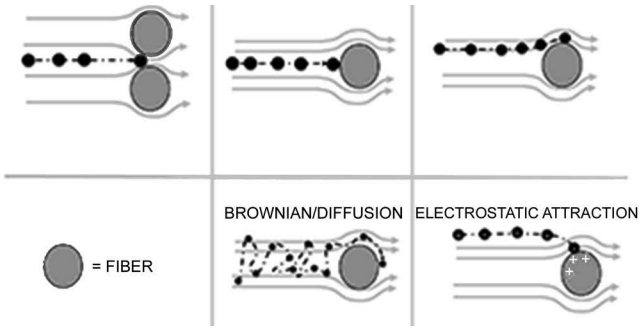

Fig. 2 Collection Mechanisms for Filter Fiber

forces are so high. In this case, a viscous coating (preferably odorless and nonmigrating) is applied to the fiber to enhance retention of the particles. This adhesive coating is critical to metal mesh impingement filter performance. This is also called inertial impaction.

Interception. Particles that follow the airstream close enough to a fiber that the particle contacts the fiber and remains there mainly because of van der Waals forces (i.e., weak intermolecular attractions between temporary dipoles). The adhesion process depends on air velocity through the media being low enough not to dislodge the particles; particles may be dislodged by other particles, causing shedding through the filter with repeated bounces. Interception is the predominant capture mechanism in extended-media filters such as bag and deep-pleated rigid cartridge types.

Diffusion. The path of very small particles is not smooth but erratic and random within the airstream. This is caused by gas molecules in the air bombarding them (Brownian motion), producing an erratic path that brings the particles close enough to a media fiber to be captured by interception. As more particles are captured, a concentration gradient forms in the region of the fiber, further enhancing filtration by diffusion and interception. The effects of diffusion increase with decreasing particle size and media velocity.

Electrostatic Effects. Particle or media electrostatic charge can produce changes in dust collection affected by the electrical properties of the airstream. Some particles may carry a natural charge. Passive electrostatic (without a power source) filter fibers are often electrostatically charged during their manufacture or (in some materials) by blowing dry air through the media. Charges on the particle and media fibers can produce a strong attracting force if opposite. The influence of this mechanism is highest when the media is new and clean. As the filter captures dust on the fibers, the particles will mask the charge, leading to lower collection efficiency.

Electrostatic precipitators, which are a class of electronic air cleaners, capture particles by charging them with high-voltage wires and then capturing the particles on oppositely charged plates. The mechanism is similar to that used with charged media, except the charging of the particles is intentionally induced by the air cleaner and the devices require power to operate.

Ionizers may be used to enhance particle capture by producing charged particles that will stick to a following filter's fibers. This mechanism is similar to that of the charged filters of electronic air cleaners in that oppositely charged particles and collection surfaces are fundamental to the collection of particles. Ionizers are also used to create ions that attach to particles in the air, which in turn leads to agglomeration (particles sticking together to form larger particles that are more easily removed by a filter than the original, smaller particles). Ionizers not immediately followed by a filter may cause charged or agglomerated particles to stick to other surfaces such as walls, floors, drapes, and lungs.

Chemical Effects. Chemical effects can also remove particles from air. Reactive air cleaners (RACs) include a variety of technologies that rely on some form of chemistry to work. They require power to operate. RACs may introduce reactive species into the air that may reduce particles of some chemical contents to CO_2 and water or other intermediary species (e.g., organic particles will react with ozone, whereas aluminosilicates may not). Since the mechanisms vary across the types of devices and are not clearly understood, they are not elucidated here.

6. TYPES OF AIR CLEANERS AND PERFORMANCE

Common air cleaners for particulate removal are broadly grouped as described below. These types of air cleaner exist in both HVAC and in-room styles. Most of the discussion below is aimed at HVAC-type devices, but the technology details are applicable to both. Users of in-room air cleaners (IRAC) should refer to Chapter 66 in the 2023 *ASHRAE Handbook—HVAC Applications* for more details specific to in-room applications.

Common air cleaners can be grouped as follows:

- **Media filters** constructed from fibers in various configurations
- **Electronic air cleaners**, which rely on electrostatic effects for removal efficiency and require supplied power to operate
- Air cleaners that rely on **chemical effects** to remove particles and usually require supplied power to operate
- **Combination air cleaners** that use two or more technologies. In addition to those mentioned previously, they may include gas-phase removal or bioaerosol removal/inactivation technologies such as carbon filters or ultraviolet (UV) lamps

Media Filters

Media filters are typically made from filter media in the form of paper or batting consisting of fibers in various types, sizes, and configurations. The units collect dust directly in and on the fibers at various efficiencies and with varying dust-holding capabilities. They can be static or renewable media devices and do not need separate power sources other than that needed for the HVAC or IRAC fan. The filters are discussed in more detail below, in approximate order of increasing particle removal efficiency.

Panel Filters. Also known as **impingement filters**, these are flat pads. Thus, the media velocity is always equal to the duct velocity. These filters can be constructed from a variety of media, including spun glass, synthetic fibers such as polyester, polyurethane foam, natural fibers, dry plastics, and various metals that may be fibrous or expanded sheets. Using these coarse fiber media, these filters are typically characterized by a low initial pressure drop and efficiencies not above MERV 6.

As filter efficiency increases, resistance to airflow often increases for the same airflow rate. Therefore, to achieve greater filtration efficiencies while maintaining a pressure drop within the design limits of HVAC systems, the media area exposed to the airstream may be increased. These **extended-surface filters** include pleated panels, mini-pleats, bag (or pocket) filters, and compact filters. The products most commonly use nonwoven fiber mats or blankets of varying thicknesses, fiber sizes, and densities.

The most commonly used media for the construction of **pleated panels** include carded and spunbond synthetics such as polyester and polypropylene as well as natural fibers such as cotton. Pleat separation may be maintained through the use of a variety of techniques, including the pleating of an expanded metal mesh layer along with the media, the use of paperboard or polymer combs, hot-melt glue strips, adhesive-coated string, or corrugated metal. New technologies that are becoming more popular include materials such as cellulose and polylactic acid (PLA) fibers, which can be used to meet certified biobased requirements. These filters typically fall into the MERV 7 to MERV 13 efficiency range.

Before 2000, **bag** or **pocket filters** used air-laid micro-fiberglass almost exclusively; however, since then a number of nonwoven synthetic media have been developed that use materials such as polypropylene and polyester. The media are most often constructed of meltblown and spunbond combinations and are almost always charged to achieve a given efficiency at a lower resistance to airflow than uncharged types. The use of nanofibers has recently seen more widespread use for enhancing the efficiency of these products.

The individual pockets may be stitched or heat-sealed around the perimeter. The desired spacing between the media layers forming the pocket is controlled either by a span stitch or media web. This prevents the pocket from "ballooning" and restricting the airflow. The completed pockets are then assembled into a frame parallel to each other in the direction of the airflow. These products are normally offered in the MERV 10 to MERV 16 range.

Compact filters include both **box filters** and **mini-pleat** products. The products cover the same efficiency range as pocket filters; however, as the name implies, they can be used in installations where there is insufficient depth to accommodate a bag filter. Box filters, also referred to as rigid boxes or cells, use the same media as bag filters.

Because of the tight spacing requirements between pleats, special media were developed for mini-pleat products. These include both wet-laid nonwovens as well as synthetics. Spacing between the pleats is physically maintained by use of corrugated aluminum, hot-melt beads, or string spacers. Some hybrid versions use a media that can be embossed for maintaining spacing. These media may be supported by wire mesh or may be laminated to a stiffer nonwoven material (e.g., a spunbond material) to achieve the rigidity requirements and to protect the more fragile efficiency layer from abrasion. In still other designs, the media may be self supporting or, in the case of bag filters, the design uses the airstream to inflate the pockets and maintain spacing.

Extended-surface filters may also be constructed using expanded polytetrafluoroethylene (ePTFE) membranes. These products typically fall into HEPA classifications but can also be found at the very high end of the MERV range. Applications may include semiconductor, microelectronics, pharmaceutical, and gas turbine inlet filtration.

Efficiencies for extended-surface filters are usually higher than those for panel filters. The dust-holding capacities are also generally higher than for impingement filters simply due to the increased media area. As an example, a 610 × 610 × 305 mm deep V-cell product may use up to 18.5 m^2 of media area and have a typical media velocity of 0.05 m/s at 1 m/s system flow. A flat panel filter in the same installation would have a media velocity of 2.5 m/s. Hence a higher efficiency media may exhibit more resistance to airflow, but with significantly more media area the media velocity may be lowered.

Initial resistance on an extended-surface filter varies with the choice of media and filter geometry. Depth in direction of airflow varies from ~25 to 900 mm.

Electret filters require no power in HVAC installations and are composed of electrostatically charged media fibers. Various manufacturing processes are used, many of them producing mats that contain both positively and negatively charged fibers. Charged-fiber filter efficiency is determined by both the normal collection mechanisms of a media filter and the strong local electrostatic effects (related to the amount of electrostatic charge). The effects improve clean filter efficiency over similar uncharged media without increasing resistance to airflow. However, ultrafine-particle dust collected on the fibers usually reduces the efficiency as electrets age. Electret filters are also discussed in ASHRAE *Standard* 52.2, Appendix J.

HEPA (high-efficiency particulate air) and **ULPA** (ultra-low-penetration air) are filters designed to target the MPPS for a given flow rate. The original U.S. MIL standard for efficiency of a HEPA filter specified that it must be a minimum of 99.97% efficient for 0.3 μm particles. There are now a number of differing HEPA filter standards on the market that are described in more detail in section 8 of this chapter. HEPA and ULPA filters are made in extended-surface configurations of deep folds or a mini-pleat style of submicrometer glass fiber paper. Synthetic materials, such as ePTFE and nanofibers, are also common materials for HEPA/ULPA. These are usually combined with a spunbond scrim layer to protect the membrane.

These filters are the standard for cleanroom, nuclear, and toxic particulate applications and are increasingly used in medical and pharmaceutical applications. Traditional HEPA filters for HVAC use are often 300 mm deep and the initial pressure drop can be between 125 and 250 Pa. As such, they are typically not used in residential HVAC systems, where system blowers cannot handle the extra resistance to airflow. Note that there are so-called "bypass HEPA" filter systems on the market that contain a fan and small HEPA filter connected to an HVAC duct so that a portion of the air is drawn through the HEPA filter, with the remainder passing unfiltered down the duct. The overall single-pass efficiency of such a system will necessarily be far less than a HEPA filter. Standards that follow the original HEPA definition of 99.97% efficiency for 0.3 μm diameter particles include

- United States *Military Standard* MIL-STD-282
- United States Department of Energy DOE-STD-3020-2015
- American Society of Mechanical Engineers ASME AG-1
- Institute of Environmental Sciences and Technology IEST-RP-CC001

Alternative HEPA definitions include those found in **ISO 29463-1** (ISO 35H ≥ 99.95% efficient at MPPS, and ISO 40H ≥ 99.99% efficient at MPPS), and the one from **EN-1822-1** (HEPA H13 ≥ 99.75% efficient at MPPS).

Prefiltering. Using less efficient prefilters upstream of extended-surface filters is common and is sometimes justified economically by the potentially longer life of the main filters. Economic considerations include prefilter material cost, changeout labor, and increased fan power. Generally, prefilters should be considered only if they can substantially reduce the part of the dust that may plug the protected filter and extend the final filter's lifetime. A prefilter usually is at least a MERV 8, with 6 as an occasional lower end. They are commonly rated up to MERV 15. They are usually not more than 3 MERVs lower than the final filter. There can be either a two- or three-stage system set up for a HEPA/ULPA filter. A two-stage would have a prefilter in the MERV 11 to 15 range before the HEPA/ULPA. A three-stage would have a MERV 1 to 10 as an initial, a MERV 8 to 15 as a middle, and a HEPA/ULPA as a final.

A single filter gage may be installed when a panel prefilter is placed adjacent to a final filter. Because the prefilter is frequently changed on a schedule, the final filter pressure drop can be read without the prefilter in place every time the prefilter is changed. For maximum accuracy and economy of prefilter use, two gages can be used. Some air filter housings are available with pressure taps between the pre- and final filter tracks to accommodate this arrangement.

Temporary prefilters protecting higher-efficiency filters are worthwhile during construction to capture heavy loads of coarse dust.

HEPA and ULPA filters should always be protected by prefilters.

Removal efficiencies and typical operating conditions for different types of media filters are listed in Table 2.

Electronic Air Cleaners. In the past, the term *electronic air cleaner* (EAC) was somewhat synonymous with the term electrostatic precipitator (ESP). More recently, EAC has been used to describe a wide variety of powered air cleaners, including those that

Table 2 Typical Properties and Operating Conditions for Media filters

		Typical Operating Conditions			
Filter Type	**Typical MERV**	**Initial Resistance to Airflow, Pa**	**Final Resistance to Airflow, Pa**	**Duct Velocity, m/s**	**Media Velocity, m/s**
Panel	1 to 6	13 to 63	125 to 250	1.5 to 2.5	Same as duct velocity
Low-efficiency renewable/ cleanable	4 to 6	100 to 125	125 to 250	1.5 to 2.5	Same as duct velocity
Extended-surface	7 to 16	63 to 250	125 to 375	up to 3	0.03 to 0.5 for intermediate efficiency
Electret	5 to 16	50 to 250	125 to 375	1.5 to 2.5	0.05 to 1
HEPA/ULPA	More efficient than MERV 16	125	500	0.25 to 2.5	0.25 to 0.5

use electrostatic effects to reduce or remove air particulate pollutants and those powered devices aimed at gas-phase pollutants such as ultraviolet photocatalytic oxidation (UVPCO) devices. Electronic air cleaners that use electrostatic effects to remove particles are available in many designs but fall into two major categories: (1) electrostatic, plate-type precipitators and (2) electrically enhanced air filtration. Various types of ionizers also fall into this category.

Corona discharge is used in most electronic air cleaners designed to remove particulates from the air. Corona discharge is a form of electrical discharge in which a small region of plasma is formed at an electrode with a relatively small radius of curvature as compared to the geometry in the rest of the system. A wire and plate are classic examples of such disparate electrodes, although metal points or carbon brushes are also often used as corona electrodes. In such a system, as the electric potential between the electrodes is increased, an electron avalanche will be initiated at or near the sharp electrode, and a small region of plasma (glow corona) will be formed. When properly designed, the voltage is held at that potential and not permitted to increase to the point at which an arc would occur between the electrodes. At the edge of the corona region, ions are formed, which flow along electric field lines to the ground electrode. The space charge created by the ions is typically used to charge particles in electronic air cleaners designed for the removal of particles. A complex series of reactions occurs within the corona plasma and reactive species are formed, most notably ozone. The amount of ozone generated is typically roughly proportional to the amount of current flowing through the discharge electrode, but other factors can influence the amount of ozone produced, including electrode polarity, electrode tip size, and electrode material.

Electrostatic precipitators (ESPs), which require a power source during operation, are electronic air cleaners that create an electric field transverse to the airflow to move charged particles along field lines to grounded plates. Very large single-stage ESPs, in which high-voltage corona wires are suspended between a series of parallel grounded plates, are often used in coal-fired power plants and cement factories. Such ESPs may be 12 m tall and have plate spacings on the order of 300 mm. ESPs designed for HVAC systems, on the other hand, are typically two-stage devices, consisting of a first section containing corona wires and plates, and a second section consisting of alternating high voltage and grounded plates. The second section is more effective at removing smaller particulates due to reduced electrohydrodynamic turbulence in that section.

The first stage of a two-stage ESP is the ionization and particle charging section, in which the small-diameter corona wires, typically at a positive DC voltage between 5 and 25 kV, are suspended equidistant between grounded plates. Ions created by the corona discharge at the wire flow toward the ground plates along electric field lines and charge particles in the airstream. As particles accumulate charge, they are also influenced by the electric field and migrate toward the grounded plates. The largest particles will acquire the most charge and they, along with smaller particles that are already near the plates, will strike the plate and have a high probability of being collected there. The remainder of the charged particles then pass into the second stage, the collection section.

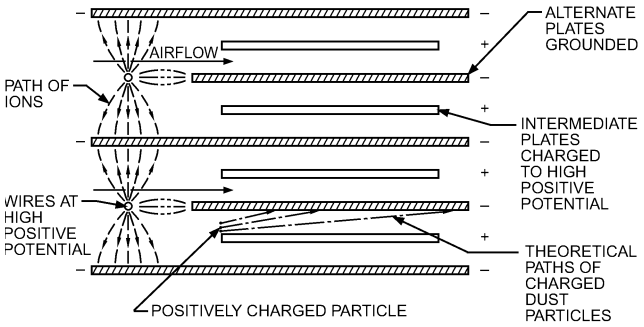

Fig. 3 Cross Section of Plate-Type Precipitator Air Cleaner

The collection section consists of a series of alternating high voltage and grounded parallel plates. The parallel plates set up a uniform electric field transverse to the air flow and the charged particles migrate towards the grounded plate as they move through the section. Voltage differential can be the same as the differential between the sires and plates in the charging section or could be a smaller potential of the plates are spaced more closely together. Once the particles reach the grounded plate, they are removed from the airstream and collected by the plates. Particle retention is a combination of electrical and intermolecular adhesion forces and may be augmented by special oils or adhesives on the plates. Figure 3 shows a typical electrostatic plate-type precipitator cell.

In lieu of positive direct current, a negative potential also functions on generally the same principle, but typically generates more ozone. With voltages of 5 to 25 kV (dc), safety measures are required. A typical arrangement makes the air cleaner inoperative when the doors are removed for cleaning the cells or servicing the power pack. Electronic air cleaners typically operate from a 120 or 240 V (ac) single-phase electrical service. The high voltage supplied to the air cleaner cells is normally created with solid-state power supplies. The electric power consumption ranges from 40 to 85 W per m^3/s of air cleaner capacity.

Electrically Enhanced Air Filtration. Electrically enhanced air cleaners use high voltage to enhance the collection capability of fibrous air filters by polarizing and/or charging the filter fibers. They typically fall into two categories: (1) those that use the polarization effect alone, and 2) those that use ionization charging and polarization. In a polarizing system, the fibrous filter is placed in an electric field strong enough to induce dipoles in/on the fibers. The localized region of charge on the fibers serves to attract particles of the opposite charge and neutral particles with induced dipoles. Although filter enhancement due to polarization alone is typically not as significant as that due to particle or fiber charging, it is a measurable effect (Bergman et al, 1983). In an ionizing electrically enhanced filtration system, the fibers and/or particles are charged

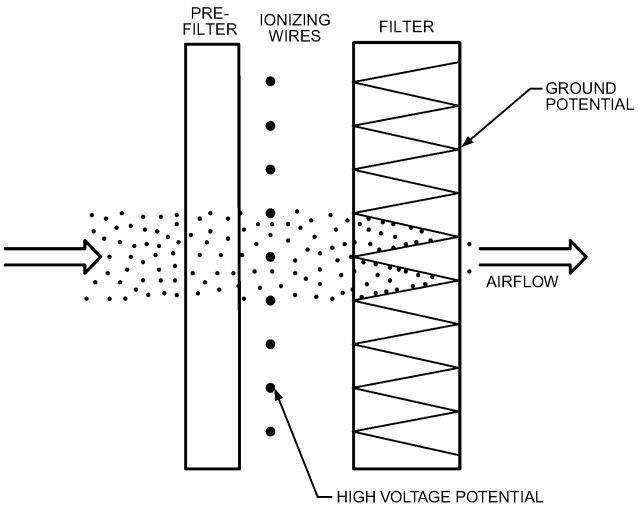

Fig. 4 Electrically Enhanced Air Cleaner with Prefilter

via a corona electrode system and the fibers are also typically polarized. Advantages to doing so include increased efficiency without an increase in resistance to airflow. Figure 4 shows that the air cleaners consist of an ionizing section and a filtration section. The ionizing section has a prefilter to prevent large debris from entering the air filter and to focus the electrostatic field. The air is charged in a high-voltage ionizing section. In the ionization section, the ionizer is connected to a high-voltage power supply and the particulate is charged. The charged particles are collected in the media filter at earth ground potential.

Optional features are often available for electronic air cleaners. Downstream filters collect particulates that agglomerate and blow off the cell plates. These are used mainly where heavy contaminant loading occurs and extension of the cleaning cycle is desired. Cell collector plates may be coated with special oils, adhesives, or detergents to improve both particle retention and particle removal during cleaning. High-efficiency dry extended-media area filters are also used as downstream filters in special designs. The electronic air cleaner used in such a system improves the service life of the dry filter and collects small particles such as smoke.

Ionizers employed independently of an ESP or electrically enhanced filtration system use ions produced by high voltages to charge particles to cause agglomeration resulting in better capture by a filter downstream, or to lead particles to plate out on oppositely charged surfaces such as walls, floors, and people.

A **negative ionizer** uses the principle of particle charging but does not use a collecting section. Particles enter the ionizer of the unit, receive an electrical charge, and then migrate to a grounded surface closest to the travel path.

Space Charge. Particulates that pass through an ionizer and are charged, but not removed, carry the electrical charge into the space. If continued on a large scale, a space charge builds up, which tends to drive these charged particles to walls and interior surfaces. Thus, a low-efficiency electronic air cleaner used in areas of high ambient dirt concentrations (or a malfunctioning unit), can blacken walls faster than if no cleaning device were used (SMACNA, 2010).

Other types of EAC include needlepoint ionization (NPBI), dry hydrogen peroxide (DHP), and photocatalytic oxidation (PCO), which may reduce certain types of particles using chemical reactions with them. Although these EAC lack substantial verification data for efficacy or safety at this point, the COVID-19 crisis has dramatically increased use of EACs. Some EAC technologies with more limited applications before the pandemic have been used in wider applications with exposure to an increased number of occupants. The safety concerns outlined in this chapter apply to both new installations as well as the many devices that were expedited into service for the alleviation of pandemic concerns.

Combining air cleaners involves installing air cleaners in sequence in an HVAC system. For example, as mentioned above, an ESP may be used as a particle coagulator (agglomerator) with a fibrous media filter downstream to catch the agglomerated particles blown off the plates. The benefits of combining different air cleaning processes vary. In addition to combining different particle removal technologies, an air cleaning system may combine particle removal with gas-phase or bioaerosol removal technologies (e.g., a particle filter followed by a carbon bed then a UV lamp system). Care should be taken to be sure that the devices work well together. For example, a filter immediately downstream of an ionizer may lead to better filtration or may limit the ability of the ionizer to charge particles in the rooms.

Combination air cleaners include more than one technology within the unit. These may include, for example, a HEPA and a UV lamp or a MERV 13 filter with a carbon bed. Combination units are most commonly found in IRAC. In some cases, multiple technologies can allow the device to treat more than one type of pollutant, as in the case of a media filter and a carbon bed addressing particles and gases. In others, one or more technologies are used in combination to remove the same pollutant (e.g., filter and ionizer). For combination units, consider the benefits of each technology and the possible interactions between them. The difference between combining air cleaners and combination air cleaners is simply that *combination* air cleaners are sold as a single unit, whereas the *combining* ones are sold separately.

7. AIR CLEANER TEST METHODS

The distinguishing operating characteristics of particle removal air cleaners are particle size removal efficiency, resistance to airflow, service life, and life-cycle cost. Quickly stated, **efficiency** measures the ability of the air cleaner to remove particles from an airstream. Minimum efficiency during the life of the filter is the most meaningful characteristic for most filters and applications. **Resistance to airflow** (or simply resistance) is the static pressure drop differential across the filter at a given face velocity. The term *static pressure differential* is interchangeable with pressure drop and resistance. **Life-cycle cost** is the evaluation of device performance in the application in terms of overall cost, along with filter service life, including element cost, energy consumption, maintenance, disposal, etc. The discussion below introduces relevant test methods from ASHRAE and other organizations. Refer to the actual methods for more details.

Air filter testing is complex, and no individual test adequately describes all filters or air cleaners. Ideally, performance testing of equipment should simulate operation under actual conditions and evaluate the characteristics important to the equipment user. Although the filters are available and tested at higher air velocity, most AHU manufacturers design filter banks to be operated at 2.5 m/s or below. Wide variations in the amount and type of particles in the air being cleaned make evaluation difficult. Another complication is the difficulty of closely relating measurable performance to the specific requirements of users. Recirculated air tends to have a larger proportion of lint than does outdoor air. However, performance tests should strive to simulate actual use as closely as possible.

Air cleaner test methods have been developed by the heating and air-conditioning industry, the automotive industry, the atomic energy industry, and government and military agencies. In 2005, the ISO reactivated technical committee TC 142, Cleaning Equipment for Air and Other Gases, whose scope includes test methods for particle filters of various types and efficiencies, particle filter media, and room air cleaners. ASHRAE has cooperated closely with TC 142,

and several ASHRAE documents have been used in development of TC 142 standards.

General Ventilation (HVAC) Testing

Several tests have become standard in general ventilation applications in the United States. In 1968, the test techniques developed by the U.S. National Bureau of Standards (now the National Institute of Standards and Technology [NIST]) and the Air Filter Institute (AFI) were unified (with minor changes) into a single test procedure, ASHRAE *Standard* 52-1968. Siegel (2002) and Whitby et al. (1956) give details of the original codes. ASHRAE *Standard* 52-1968 was discontinued in 2009 and replaced by ASHRAE Standard 52.2. Other important standards discussed below include ISO 16890, past European standard EN 779, and standards for testing HEPA and ULPA filters.

ASHRAE *Standard* 52.2. ASHRAE *Standard* 52.2-2017 contains **minimum efficiency reporting values (MERVs)** for air cleaner particle size efficiency. In 2008, the standard incorporated arrestance testing from the discontinued ASHRAE *Standard* 52.1. Table 3 provides an approximate cross-reference for air cleaners tested under discontinued ASHRAE *Standards* 52.1 and 52.2. Currently, there is no ASHRAE standard for testing electronic air cleaners; the current industry-accepted test method for electronic air cleaners is AHRI *Standard* 680. This test involves loading the filter with dust that does not contain a conductive component and allows comparison to media filtration.

ASHRAE Particle Size Removal Efficiency (PSE) Test. ASHRAE *Standard* 52.2 prescribes a way to test air-cleaning devices for removal efficiency by particle size while addressing two air cleaner performance characteristics important to users: the ability of the device to remove particles from the airstream and its resistance to airflow. In this method, air cleaner testing is conducted at a specific airflow based on the upper limit of the air cleaner's application range. Airflows are based on specific face velocities between 0.60 and 3.80 m/s, which yields between 0.22 and 1.4 m^3/s for a nominal 610 by 610 mm filter. The test aerosol consists of laboratory-generated potassium chloride particles dispersed in the airstream. Optical particle counters size and count the particles in 12 defined, geometric logarithmic-scale, equally distributed particle size ranges both upstream and downstream for efficiency determinations. The test encompasses 0.3 to 10 μm particles. The clean-filter efficiency test is followed by five dust loadings, using ASHRAE dust, to increase the pressure drop across the filter. Efficiency tests are performed after each dust loading.

A set of particle size removal efficiency performance curves is developed from the test. The minimum efficiency value in each size channel is used as a composite curve representing performance in the range of sizes. Efficiencies on the composite curve are averaged for small, medium, and large particles; these averages are used to determine the MERV of the air cleaner. Since 2020, the same values are also used to calculate PM efficiencies ($PM_{52.2}10$, $PM_{52.2}2.5$, and $PM_{52.2}1$) to meet the needs of those working with PM data. A complete test report includes (1) a summary of the test, (2) removal efficiency curves of the clean devices at each of the loading steps, (3) a composite minimum removal efficiency curve, (4) the MERV, (5) the PM efficiencies, and (6) resistance/pressure drop curves.

In 2008, Appendix J on conditioning was added as an optional part of *Standard* 52.2. If used, this conditioning step replaces the current first (small) dust loading. This step simulates the efficiency drop seen in many charged filters in actual use: the high concentration of 40 to 50 nm aerosol exposes the filter to many particles of a size common in ambient and indoor air. This step does not completely remove the charge on the fibers. When Appendix J is used in a full *Standard* 52.2 test, the nomenclature used to report results is MERV-A (ASHRAE 2008).

ASHRAE 52.2 only official covers media filters in the standard test, so it does not officially include electronic air cleaners. This is largely due to the carbon content of the loading dust that may short out electronic devices and the lack of a consensus non-pressure drop test dust loading endpoint for devices that do not increase noticeably in pressure drop. Still, the procedures for the clean filter and correlation tests may be used to determine the particle size dependent efficiency for these devices as long as the report is labeled a modified test or otherwise not a formal 52.2 test.

Bioaerosol testing was added to ASHRAE 52.2 as an optional appendix to allow standard testing for non-UV-only devices that are HVAC mounted. ASHRAE 185.1 covers bioaerosol removal/inactivation testing for UV devices. The new option within 52.2 uses the same basic techniques but allows them to be applied to devices, including filters, that are not covered by ASHRAE 185.1.

ASHRAE 52.2 Arrestance Test. ASHRAE *Standard* 52.2 defines synthetic test dust as a compounded test dust consisting of (by mass) 72% ISO *Standard* 12 103-A2 fine test dust, 23% powdered carbon, and 5% no. 7 cotton linters. A known amount of the prepared test dust is fed into the test unit at a known and controlled concentration. The amount of dust in the air leaving the test filter is determined by passing the entire airflow through a high-efficiency final filter (≥98%) downstream of the test filter and measuring the gain in filter mass. The synthetic mass **arrestance** is calculated using the masses of the dust captured on the final high-efficiency filter and the total dust fed.

Atmospheric aerosol particles range from a small fraction of a micrometre to tens of micrometres in diameter. The artificially generated dust cloud used in the ASHRAE arrestance method is considerably coarser than typical atmospheric dust. It tests the ability of a filter to remove the largest atmospheric aerosol particles and gives little indication of filter performance in removing the smallest particles. However, where the mass of dust in the air is the primary concern, this is a valid test because most of the mass is contained in the larger particles. Where extremely small particles (such as respirable sizes) are involved, arrestance rating does not differentiate between filters. Arrestance test results are nly used in MERV determination for MERV 1 to 4; for these filters, the arrestance is the only metric beyond the determination that an E3 based on the clean filter data is less than 20%.

ASHRAE 52.2 Dust-Holding Capacity (DHC) Test. Synthetic test dust (as described in the preceding section) is fed to the filter in accordance with ASHRAE *Standard* 52.2 procedures. The pressure drop across the filter (its resistance to airflow) rises as dust is fed. The test normally ends when resistance reaches the maximum operating resistance set by the manufacturer. However, not all filters of the same type retain collected dust equally well. The test, therefore, requires that arrestance be measured at least four times during dust loading and that the test be terminated when two consecutive arrestance values of less than 85%, or one value equal to or less than 75% of the maximum arrestance, have been measured. The ASHRAE **dust-holding capacity** is, then, the integrated amount of dust held by the filter up to the time the dust-loading test is terminated. (See ASHRAE *Standard* 52.2 for more detail.)

ISO *Standard* 16890. ISO 16890, Air Filters for General Ventilation, is a set of standards added to the general ventilation test method arsenal in 2016. It has replaced EN 779 wherever it was specified. This standard uses a similar test procedure to ASHRAE 52.2, but uses an isopropyl alcohol vapor discharge method and includes a unique rating system that relates the measured filter performance to typical urban and rural air pollution conditions. The result is a removal efficiency specified in terms of particulate matter (PM) and shown as ePM. As an example, a filter with rated performance of ISO $ePM_{2.5}$ 75% removes 75% of particles that are 2.5 microns in size or less, as measured by the standard.

This international filtration standard is split into four parts:

- Part 1: Technical specifications, requirements and classification system based upon particulate matter efficiency (ePM)
- Part 2: Measurement of fractional efficiency and air flow resistance
- Part 3: Determination of the gravimetric efficiency and the air flow resistance versus the mass of test dust captured
- Part 4: Conditioning method to determine the minimum fractional test efficiency

EN 779 (Now Replaced by ISO 16890 between 2016 and 2018). CEN developed EN *Standard* 779, Particulate Air Filters for General Ventilation—Requirements, Testing, Marking, in 1993. Its last revision, Particulate Air Filters for General Ventilation—Determination of the Filtration Performance, was approved and published in 2012. Efficiency is reported as an average efficiency after loading with ASHRAE dust. In this latest revision, minimum efficiency requirements for discharged filters are 35% for F7, 55% for F8, and 70% for F9. This is 0.4 mm efficiency, measured on media samples after discharge in liquid isopropyl alcohol (IPA). The test aerosol as specified in the standard is DEHS.

HEPA and ULPA Testing

Penetration Tests. For high-efficiency filters of the type used in cleanrooms and nuclear applications (HEPA or ULPA filters), there are several tests that may be specified, depending on end use. These tests rely on the use of oil-based test aerosols or polystyrene latex spheres (PSL) to challenge the filter.

These tests measure penetration of the test aerosol through the filter under test. The aerosol cloud is fed to the filter, which is held in a special test fixture. Any aerosol that penetrates the body of the filter or leaks through gasket cracks passes into the region downstream from the filter, where it is thoroughly mixed. Air leaving the fixture thus contains the average concentration of penetrating smoke. This concentration, as well as the upstream concentration, is measured by a light-scattering photometer.

Filter penetration *P* (%) is given as

$$P = 100\left(\frac{\text{Downstream concentration}}{\text{Upstream concentration}}\right) \quad (1)$$

Penetration, not efficiency, is usually specified in the test procedure because HEPA filters have efficiencies so near 100% (e.g., 99.97% or 99.99% on 0.30 μm particles). Penetration and efficiency E are related by the equation $E = 100 - P$. For example, a filter penetration of 0.03% can be displayed as having a filter efficiency of 99.97%.

Penetration tests are highly dependent upon three factors:

- **Aerosol Types.** DOP (dioctyl phthalate or bis-[2-ethylhexyl] phthalate) was the original test aerosol as specified by U.S. Military Standard MIL-STD-282, but this aerosol has been replaced by DEHS (di-ethyl-hexyl-sebacate) or PAO (polyalphaolefin, PAO Emery 3004) or equivalents. Polystyrene latex spheres (PSL) are solid aerosols that can be made to a specified size.
- **Particle Size.** Every filter has a most penetrating particle size (MPPS) that is aerosol and velocity dependent, and dependent upon the filter design and filter media in use. Some tests will specify a certain particle size to test, such as 0.1 or 0.3 μm, or they will use MPPS as the particle size to calculate efficiency.
- **Test Velocity.** In general, the lower the velocity that a filter is tested at will improve its filtration efficiency. It is easier for a filter to capture very small particles at slower speeds.

MIL-STD-282. Military *Standard* MIL-STD-282 (Revision B, December 22, 2015) and U.S. Army document 136-300-175A (1965) (replaced by Carlon and Guelta 1992) was first approved in 1956, specifying the use of DOP (dioctyl phthalate, also known as bis-[2-ethylhexyl] phthalate) as the test aerosol. DOP is an oily liquid with a high boiling point. In this method, a smoke cloud of DOP droplets condenses from DOP vapor.

The count median diameter for DOP aerosols is about 0.18 μm, and the mass median diameter is about 0.27 μm with a cloud concentration of approximately 20 to 80 mg/m^3 under properly controlled conditions. The procedure is sensitive to the mass median diameter, and DOP test results are commonly referred to as efficiency at 0.30 μm particle size. This penetration diameter is, of course, velocity dependent.

The DOP smoke cloud is fed to the filter, which is held in a special test fixture. Any smoke that penetrates the body of the filter or leaks through gasket cracks passes into the region downstream from the filter, where it is thoroughly mixed. Air leaving the fixture thus contains the average concentration of penetrating smoke. This concentration, as well as the upstream concentration, is measured by a light-scattering photometer.

IEST *Recommended Practices* RP-CC 001.6 and RP-CC 007.3. The Institute of Environmental Sciences and Technology has published two recommended practices: IEST RP-CC 001.6, HEPA and ULPA Filters, and IEST RP-CC 007.3, Testing ULPA Filters.

ISO 29463. ISO 29463, parts 2 to 5, have replaced EN 1822, parts 2 to 5, for the method of test for very high efficiency filters. EN-1822 part 1 remains for the classification of filters. This standard uses DEHS, PAO, or PSLs to determine filter efficiency at MPPS.

European Standard EN 1822 (Now Replaced by ISO 29463). Introduced in 1998, the EN 1822 filter standard was the first European standard to translate filtration knowledge into a classification system for HEPA filters. This test used DEHS aerosol to determine filter efficiency at MPPS. This standard has been replaced by ISO 19463.

Leakage (Scan) Tests

For HEPA filters, leakage tests are sometimes desirable to show that no small "pinhole" leaks exist or to locate any that may exist so they may be patched. Essentially, this is the same technique as used in the oil aerosol (DOP) penetration test, except that the downstream concentration is measured by scanning the face of the filter and its gasketed perimeter with a moving isokinetic sampling probe. The exact point of smoke penetration can then be located and repaired. This same test (described in IEST RP-CC 001.6) can be performed after the filter is installed. Smoke produced by a portable generator is not uniform in size, but its average diameter can be approximated as 0.6 μm. Particle diameter is less critical for leak location than for penetration measurement. The leak scan test is typically done for filters with 99.99% or higher efficiencies, in applications for which locating and repairing a discrete leak are more important.

In-Situ Testing

ISO 29462. In 2008, ASHRAE published *Guideline* 26 to provide a test method for evaluating filters in place in building HVAC systems. This guideline was adopted without technical change by the ISO and published as ISO *Standard* 29462-2013. Subsequently, ASHRAE decided to withdraw *Guideline* 26.

ISO 29462 presents a method for determining the in-place efficiency of individual particle filters or filter systems installed in building HVAC systems, as long as the filter or system is amenable to testing (e.g., enough space in the HVAC system to install sensors, well-sealed doors, etc.; a checklist is provided). Using a particle counter, particles in several size ranges between 0.3 and 5 μm that are circulating in the HVAC system are measured several times upstream and downstream of the filter to provide statistically robust data. Then, the removal efficiency is calculated by particle size. Pressure drop across the filter, temperature, and relative humidity are

recorded. The test method is theoretically applicable to all filters in HVAC systems. However, it is unlikely to yield statistically significant results for filters with efficiencies lower than MERV 11 because of the size distribution of particles typically found in building HVAC systems.

Note that field data generally show larger uncertainties than measurements made in a laboratory. For filter/filter system tests, this is because of the variety of different HVAC environments and particle types likely to be encountered, and the difficulties in controlling environmental variables during the test. ISO 29462 includes a procedure for reducing uncertainty by subjecting a reference filter to measurement both in the field and in a laboratory.

Respirator Tests

Test standards have been developed in the United States for respirator air filters to receive NIOSH approvals, covered under 42 CFR Part 84. These standards rate respirators as oilproof (P), oil-resistant (R), or not oilproof (N), along with an efficiency rating such as N95.

Environmental Tests

Air cleaners may be subjected to fire, high humidity, a wide range of temperatures, mechanical shock, vibration, and other environmental stress. Several standardized tests exist for evaluating these environmental effects on air cleaners. U.S. Military Standard MIL-STD-282 includes shock tests (shipment rough handling) and filter media water-resistance tests. Several U.S. Atomic Energy Commission agencies (now part of the U.S. Department of Energy) specify humidity and temperature-resistance tests (DOE 1997, 2003).

UL *Standard* 900. This destructive test procedure measures the amount of flame, smoke, or both generated by a filter when subjected to a burner in a test duct. Additionally, to pass, a filter must not generate sparks beyond the discharge length of the test duct.

This procedure does not consider filter performance regarding particle collection at any point of its test life, and pertains to a clean filter only. As filters accumulate particles, the burning, smoke, and spark characteristics change based on the contaminant in the media; thus, UL *Standard* 900 applies *only* to new filters. Once a filter has been put in service, the classification is no longer valid.

UL *Standard* 586. This test was specifically designed to evaluate the performance of a HEPA filter in extreme and rigorous conditions. While being particle challenged, the filter is subjected to extreme cold, heat, and humidity. In addition, there are shock tests simulating shipping and handling stresses to evaluate physical durability, and a flame test on the media. The standard also has some specific construction requirements for various portions of each element.

In 1991, UL *Standard* 586 was required by the Department of Defense for Nuclear material applications. It is an integral part of ASME *Standard* AG-1, Code on Nuclear Air and Gas Treatment.

The UL tests do not evaluate the effect of collected dust on filter flammability; depending on the dust, this effect may be severe. UL *Standard* 867 applies to electronic air cleaners. UL 2998 covers ozone emissions from air cleaners. The standard test is done in a chamber, but there is an option for a single-pass test.

AHRI Standards

The Air-Conditioning, Heating, and Refrigeration Institute published AHRI *Standards* 680 (residential) and 850 (commercial/industrial) for air filter equipment. *Standard* 680 applies to both media and electronic air cleaners, and specifies rating conditions for performance, capacity, and restriction. These standards establish (1) definitions and classification; (2) requirements for testing and rating; (3) specification of standard equipment; (4) performance and safety requirements; (5) proper marking; (6) conformance conditions; and (7) literature and advertising requirements. However, certification of air cleaners is not a part of these standards.

AHAM Standards

Particulate removal air cleaners may also be non-HVAC mounted. In-room air cleaners sometimes include filters that are tested per ASHRAE 52.2 or HEPA standards, but these air cleaners in their entirety are tested per the American Household Appliance Manufactures (AHAM) chamber test. In-room air cleaners and associated standards created by AHAM are discussed in more detail in Chapter 66 in the 2023 *ASHRAE Handbook—HVAC Applications*.

8. SELECTION AND MAINTENANCE

In addition to criteria affecting the degree of air cleanliness, factors such as cost (initial investment, maintenance, and energy effectiveness), space requirements, and airflow resistance have led to the development of a wide variety of air cleaners. Comparisons of different air cleaners can be made from data obtained by standardized test methods.

To evaluate filters and air cleaners properly for a particular application, consider the following factors:

- Types of contaminants present indoors and outdoors
- Sizes and concentrations of contaminants
- Source type, including whether constant or intermittent
- Air cleanliness levels required in the space
- Air filter efficiency needed to achieve cleanliness
- Space available to install and access equipment
- Life-cycle costing, including
  - Operating resistance to airflow (static pressure differential) for HVAC; final resistance to airflow as well as clean-device resistance should be compatible with the fans and other resistance in an HVAC system
  - Power consumption for in-room air cleaners
  - Disposal or cleaning requirements of spent filters/parts
  - Initial cost of selected system
  - Cost of replacement filters or cleaning
  - Cost of warehousing filter stock and change-out labor

Savings (from reduced housekeeping expenses, protection of valuable property and equipment, dust-free environments for manufacturing processes, improved working conditions, and even health benefits) should be credited against the cost of installing and operating an adequate system. The capacity and physical size of the required unit may emphasize the need for low maintenance cost. Operating cost, predicted life, and efficiency are as important as initial cost because air cleaning is a continuing process.

Panel filters do not have efficiencies as high as can be expected from extended-surface filters, but their initial cost and upkeep are generally low. Compared to moving-curtain filters, panel filters of comparable efficiencies require more attention to maintain the resistance within reasonable limits. However, single-stage, face- or side-access, low- to medium-efficiency filters of MERV 6 to 10 from a 50 mm pleat to a 300 mm deep cube, bag, or deep pleated cartridge, require less space with lower initial cost, and have better efficiency. The bag and cartridges generally have a similar service life to that of a roll filter.

If efficiency of MERV 11 or higher is required, extended-surface filters or electronic air cleaners should be considered. The use of very fine glass fiber mats or other materials in extended-surface filters has made these available at the highest efficiency.

Initial cost of an extended-surface filter is lower than for an electronic unit, but higher than for a panel type. Operating and maintenance costs of some extended-surface filters may be higher than for panel types and electronic air cleaners, but efficiencies are always higher than for panel types; the cost/benefit ratio must be considered. Pressure drop of media-type filters is greater than that of electronic types, and slowly increases during their useful life. Advantages include the fact that no mechanical or electrical ser-

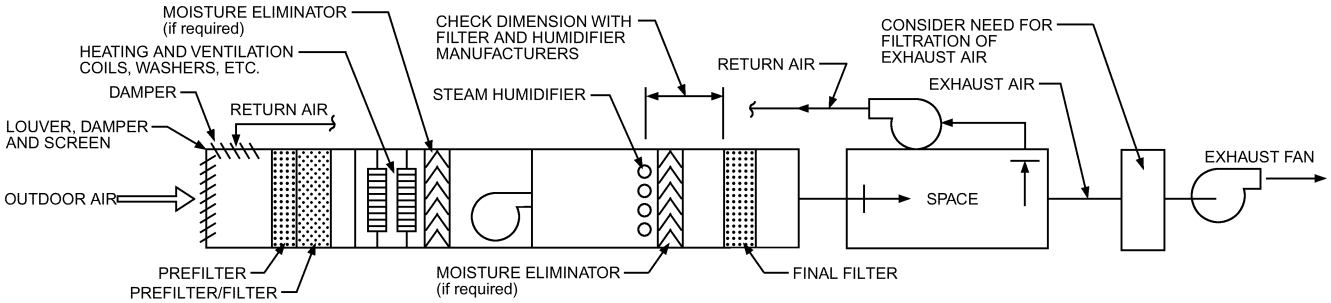

Fig. 5 Typical Filter Locations for HVAC System

vices are required. Choice should be based on both initial and operating costs (life-cycle costs), as well as on the degree of cleaning efficiency and maintenance requirements.

Although electronic air cleaners have higher initial and maintenance costs, they have high initial efficiencies in cleaning atmospheric air, largely because of their ability to remove fine particulate contaminants. System resistance remains unchanged as particles are collected, and efficiency is reduced until the resulting residue is removed from the collection plates to prepare the equipment for further duty. The manufacturer must supply information on maintenance or cleaning. Also, note that electronic air cleaners may not collect particles greater than 10 μm in diameter.

Figure 5 shows where filtration can be placed in an HVAC system. Each area indicates the point of potential need for particulate removal.

The typical contaminants listed in Table 3 appear in the general reporting group that removes the smallest known size of that specific contaminant. The order in which they are listed has no significance, and the list is not complete. The typical applications and typical air cleaners listed are intended to show where and what type of air cleaner could be and/or has been traditionally used. Traditional usage may not represent the optimum choice, so using the table as a selection guide is not appropriate when a specific performance requirement is needed. An air cleaner application specialist should then be consulted and manufacturers' performance curves should be reviewed.

Note that MERV 17 to 20, which were shown in early versions of ASHRAE *Standard* 52.2 to give readers a feeling for where HEPAs could be considered to fit into the MERV scale, were removed because of the confusion when readers assumed these theoretical MERV values existed and tried to use ASHRAE testing procedures for them. ASHRAE 52.2 does not test to these filter levels. For HEPA filters, refer to the ISO or IEST classification system (IEST 2007, 2009; ISO 2012).

Common sense and some knowledge of how air cleaners work help the user achieve satisfactory results. Air cleaner performance varies from the time it is first installed until the end of its service life. Generally, the longer a media-type filter is in service, the higher the efficiency. The accumulation of contaminants begins to close the porous openings, and, therefore, the filter is able to intercept smaller particles. However, there are exceptions that vary with different styles of media-type filters. Electronic air cleaners and charged-fiber media filters start at high efficiency when new (or after proper service, in the case of electronic air cleaners), but their efficiency decreases as contaminants accumulate. Charged media filters may drop as much as 50% of the initial efficiency, especially at lower particle sizes, unless the drop-off effect is countered by significant collection of larger particles and buildup of filter cake to add in collection. Some air cleaners, particularly low-efficiency devices, may begin to shed some collected contaminants after being in service. Testing with standardized synthetic loading dust attempts to predict this, but such testing rarely, if ever, duplicates the air cleaner's performance on atmospheric dust.

The loading rate of all filters depends on the type and concentration of particles in the air being handled and the operating cycle of the system. Media filters may be monitored for resistance to airflow and changed when a predetermined level is reached to minimize filter costs, or they may be changed on a time-based schedule for ease of scheduling. Life-cycle cost (LCC), including energy necessary to overcome the filter resistance (which will vary by fan and other resistance in the HVAC system), should be calculated to evaluate the overall cost of the filtering system.

Residential Air Cleaners

Panel air filters with a MERV 7 or lower, traditionally used for residential applications, may be of spun glass and only filter out the largest of particles. These filters may prevent damage to downstream equipment, but they do little to improve air quality in the residence. MERV 8 or better filters are now recommended. To use higher-MERV filters in residential applications, it is important to be sure the system can handle the pressure drop. If space exists, deeper filters may help reduce pressure drop while increasing the efficiency (and MERV) of filters. Residential architects and contractors should consider providing deeper filter banks (50 to 150 mm during new construction and renovations to allow homeowners greater flexibility in choosing higher-MERV filtration.

In addition to particle removal efficiency, system runtime has a large impact on the effectiveness of air cleaners used in central residential forced-air heating and cooling systems. These systems typically operate only in response to demands for heating or cooling. ASHRAE RP-1691 used building energy modeling combined with an indoor air mass balance model to predict the impacts of various MERV filters on reducing indoor concentrations of $PM_{2.5}$ and UFPs of outdoor origin. Azimi et al. (2016) estimated that low system runtimes mean that even the highest levels of filtration efficiency cannot achieve more than ~50% particle removal in the space, and that effectiveness depends strongly on home vintage, climate zone, and ventilation strategy. Touchie and Siegel (2018) analyzed central residential system runtime data from over 7000 homes in North America and found that the median system runtime was only 18%, with considerable variation between homes. Moreover, at low to average runtimes, it was noted that effectiveness of the filter matters much less because the system does not run enough for a sufficient air volume to pass through the filter and have a substantial impact on particle concentrations. Increasing runtimes (e.g., by operating systems in fan-only mode continuously or for great cycle lengths) can improve filtration effectiveness but will come with an additional energy cost.

VAV Systems

ASHRAE tests on numerous different media-type air cleaners under both constant and variable airflow showed no significant performance differences under different flow conditions, and the air

Table 3 Application Guidelines for MERV Filters

Std. 52.2 Minimum Efficiency Reporting Value (MERV)	Typical Controlled Contaminant	Typical Applications and Limitations	Typical Air Filter/Cleaner Type
16	0.30 to 1.0 µm Particle Size	Hospital inpatient care	**Bag Filters**
	All bacteria	General surgery	Nonsupported (flexible) microfine fiberglass or synthetic media. 300
15	Most tobacco smoke	Smoking lounges	to 900 mm (12 to 36 in.) deep, 6 to 12 pockets.
	Droplet nuclei (sneeze)	Superior commercial	**Box Filters**
14	Cooking oil	buildings	Rigid style cartridge filters 150 to 300 mm
	Most smoke		(6 to 12 in.) deep may use lofted (air laid) or paper (wet laid) media.
13	Insecticide dust		
	Copier toner		
	Most face powder		
	Most paint pigments		
12	1.0 to 3.0 µm Particle Size	Superior residential	Bag Filters
	Legionella	Better commercial	Nonsupported (flexible) microfine fiberglass or synthetic media. 300
11	Humidifier dust	buildings	to 900 mm (12 to 36 in.) deep, 6 to 12 pockets.
	Lead dust	Hospital laboratories	Box Filters
10	Milled flour		Rigid style cartridge filters 150 to 300 mm
	Coal dust		(6 to 12 in.) deep may use lofted (air laid) or paper (wet laid) media.
9	Auto emissions		
	Nebulizer drops		
	Welding fumes		
8	3.0 to 10.0 µm Particle Size	Commercial buildings	Pleated Filters
	Mold	Better residential	Disposable, extended surface, 25 to 125 mm
7	Spores	Industrial workplaces	(1 to 5 in.) thick with cotton-polyester blend media, cardboard frame.
	Hair spray	Paint booth inlet air	Cartridge Filters
6	Fabric protector		Graded density viscous coated cube or pocket filters, synthetic
	Dusting aids		media.
5	Cement dust		Throwaway
	Pudding mix		Disposable synthetic media panel filters.
	Snuff		
	Powdered milk		
4	**>10.0 µm Particle Size**	Minimum filtration	Throwaway
	Pollen	Residential	Disposable fiberglass or synthetic panel filters
3	Spanish moss	Window air conditioners	Washable
	Dust mites		Aluminum mesh, latex coated animal hair, or foam rubber panel
2	Sanding dust		filters
	Spray paint dust		Electrostatic
1	Textile fibers		Self charging (passive) woven polycarbonate
	Carpet fibers		panel filter

Note: A MERV for other than HEPA/ULPA filters also includes a test airflow rate, but it is not shown here because it has no significance for the purposes of this table.

cleaners were not damaged by VAV flow. Low-efficiency air cleaners did show substantial reentrainment for both constant and VAV flow (Rivers and Murphy 2000).

Antimicrobial Treatment of Filter Media

Several varieties and all efficiencies of filters have been treated with antimicrobial additives. The key performance goal is to reduce the growth of microbial organisms in filter components (e.g., the media itself, separators in high-efficiency minipleats, framing components). The intent is not to make the air clean and free of viable microbes, but rather to prevent filter components from becoming the microbial reservoir.

An ASHRAE-funded research project tested low-efficiency filters for microbial reduction for both initial and loaded conditions (Foarde et al. 2000). Under normal use, fibrous air cleaners were found to be unlikely to become a source of microbial contamination to the space, and antimicrobial treatment usually did not increase the filtration efficiency for bioaerosols. The dust cake was found to mask the antimicrobial eliminating contact with the bioaerosols. In the United States, EPA guidelines must be met for the antimicrobial product to be used in air filters.

Maintenance

Various cleaning methods have been recommended for permanent media filters; the most widely used involves washing the filter with steam or water (frequently with detergent).

If maintained properly by regular cleaning, including wiping the wires, ESPs have relatively constant pressure drop and efficiency. If they are not cleaned regularly, dendritic buildup on the wires can reduce the efficiency or the unit and may lead to sparking. Accumulated dust can build up to the point that arcing may occur in the collection section of the air cleaner. This may reduce the collection efficiency, as well as produce unwanted extraneous noise. Dust buildup in the ionizer section can also reduce efficiency.

Plate-type air cleaner cells must be cleaned periodically with detergent and hot water. Some designs incorporate automatic wash systems that clean the cells in place; in others, the cells are re-moved for cleaning. The frequency of cleaning (washing) the cell depends

on the contaminant and the concentration. Industrial applications may require cleaning every 8 h, but a residential unit may only require cleaning every one to three months. The timing of the cleaning schedule is important to keep the unit performing at peak efficiency. For some contaminants, special attention must be given to cleaning the ionizing wires. The air cleaner must be maintained based on the recommendations of the manufacturer.

Electrically enhanced air cleaners have a longer service life between maintenance than plate-type precipitators. Maintenance consists of replacing the filter and cleaning the ionizing section and prefilter.

9. AIR CLEANER INSTALLATION

An air filter must fit into the duct or frame it is installed into, and it must be sealed in to achieve the expected performance. Thus, the size of the filter and method of installation are both critical for particle removal to be achieved. Many air cleaners are available in units of convenient size for manual installation, cleaning, and replacement. A typical unit filter may be a 400 to 650 mm square or rectangle, from 25 to 400 mm in depth, and of either the dry or viscous impingement type. In large systems, the frames in which these units are installed are bolted or riveted together to form a filter bank. Automatic filters are constructed in sections offering several choices of width up to 20 m and generally range in height from 1 to 5 m, in 100 to 150 mm increments. Several sections may be bolted together to form a filter bank.

Several manufacturers provide side-loading access filter sections for various types of filters. Filters are changed from outside the duct, making service areas in the duct unnecessary, thus saving cost and space.

Of course, in-service efficiency of an air filter is sharply reduced if air leaks through the bypass dampers or poorly designed filter-holding frames. Filters must be sealed in so that all the air goes through the filter; bypass will result in lower removal efficiency due to the untreated air. The higher the filter efficiency, the more careful attention must be paid to the rigidity and sealing effectiveness of the frame. For example, a 10% bypass for a 40% efficient filter only results in a 4% loss in removal, whereas an 80% efficiency filter with the same 10% bypass results in 20% less removal. Sealing may be achieved by a simple clamp, pressing into a gasket, a tight fit in a holder, or use of a sealant. In addition, high-efficiency filters must be handled and installed with care. The National Air Filtration Association (NAFA 2006) suggests some precautions needed for HEPA filters.

Air cleaners may be installed in the outdoor-air intake ducts of buildings and residences and in the recirculation and bypass air ducts; however, the prefilters (in a two- or three-stage system) should be placed upstream of heating or cooling coils and other air-conditioning equipment in the system to protect that equipment from dust. Dust in commercial buildings where outdoor air is brought in is likely to be predominantly alumniosilicates, whereas dander is likely to predominate in solely recirculated air such as in residences (Owen et al. 2014). Where high-efficiency filters protect critical areas such as cleanrooms, it is important that filters be installed as close to the room as possible to prevent pickup of particles between the filters and the outlet. The ultimate installation is the unidirectional flow room, in which the entire ceiling or one entire wall becomes the final filter bank.

Although published performance data for all air filters are based on straight-through unrestricted airflow perpendicular to the frame, V-bank designs with 30 to 60° angles are common in commercial applications. Cooling coils are often designed with face velocities not to exceed 2.5 m/s, and filter banks are often specified at lower face velocities such as 1.8 m/s. The use of V-banks allows AHU manufacturers to accommodate such designs while maintaining consistent height and width of adjacent AHU sections. Care should be taken to ensure filters receive even air distribution. Uneven air distribution leads to uneven loading of filters. When filters become unevenly loaded, more air flows through the cleaner areas of the filter, and the higher velocities through the clean areas decrease filter performance.

Failure of air filter installations to give satisfactory results can, in most cases, be traced to faulty installation, improper maintenance, or both. The most important requirements of a satisfactory and efficiently operating air filter installation are as follows:

- The filter must be of ample capacity for the amount of air and dust load it is expected to handle. An overload of 10 to 15% is regarded as the maximum allowable. When air volume is subject to future increase, a larger filter bank should be installed initially.
- The filter must be suited to the operating conditions, such as degree of air cleanliness required, amount of dust in the entering air, type of duty, allowable pressure drop, operating temperature, and maintenance facilities. Where UV lamps are also used, filters of some materials should not be directly irradiated because it may degrade the filter; check with the filter and UV company to determine compatibility.

The following recommendations apply to filters installed with central fan systems:

- Duct connections to and from the filter should change size or shape gradually to ensure even air distribution over the entire filter area. SMACNA standards should be followed for all elbows, junctions, and transitions upstream of the filter bank.

  When installing electrostatic precipitators, duct approaches to and from the air cleaner housing should be arranged so that airflow is distributed uniformly over the face area. Panel prefilters should also be used to help distribute airflow and to trap large particles that might short out or cause excessive arcing in the high-voltage section of the air cleaner cell. Design parameters of air velocity, ionizer field strength, cell plate spacing, depth, and plate voltage must match the application requirements (e.g., contaminant type, particle size, volume of air, required efficiency). Many units are designed for installation into central heating and cooling systems for total air filtration. Other self-contained units are furnished complete with air movers for source control of contaminants in specific applications that need an independent air cleaner.
- Locate the filter far enough from the fan to prevent or reduce reentrainment of particles, especially during start/stop cycles.
- Provide sufficient space in front of (upstream) or behind (downstream of) the filter, or both, depending on its type, to make it accessible for inspection and service. A distance of 500 to 1000 mm is required, depending on the filter chosen.
- Provide conveniently sized access doors to the filter service areas.
- All doors on the clean-air side should be gasketed to prevent infiltration of unclean air. All connections and seams of the sheet-metal ducts on the clean-air side should be airtight. The filter bank must be caulked to prevent bypass of unfiltered air, especially when high-efficiency filters are used.
- Lights should be permanently installed in access sections where personnel are required to enter the AHU for filter replacements and inspections.
- Filters installed close to an outdoor air inlet should be protected from the weather by suitable louvers or an inlet hood.
- In areas with extreme rainfall or where water can drip over or bounce (travel) up in front of the inlet, use drainable track moisture separator sections upstream of the first filter bank. Place a large-mesh wire bird screen in front of the louvers or in the hood. In areas with snowfall potential, care should be taken to ensure that the maximum snow drift accumulation against the exterior

wall does not exceed the height of the outdoor air inlet, because snow may melt and damage filter.
- Filters, other than electronic air cleaners, should consider having permanent indicators (airflow resistance gage) to give notice when the filter reaches its final pressure drop or is exhausted, as with automatic roll media filters. Where pressure drop indicators are not feasible to determine replacement times for filters, a filter replacement schedule shall be established to ensure that filters do not remain in service beyond their loading capabilities.
- Electronic air cleaners should have an indicator or alarm to indicate when high voltage is off or shorted out.

When filters are exposed to UV lighting, filtration media and housing shall be fabricated with UV resistant materials.

Filter Sealing And Installation Techniques

Gasket Seal. The gasket is applied to either the upstream or downstream flange. The gasket is compressed between an opposing mating surface of housing or filter fixing grid.

Gel Seal. The filter frame is provided with an integral gel channel that is filled with a low-outgassing polyurethane-based gel (ISPE 2019). The gel interfaces with an opposing knife edge integral to the housing or filter fixing grid. The gel penetrating knife edge creates a positive seal between the housing and the filters. This technique is most often used in bottom-loading or room side replaceable applications.

Knife Edge Seal. In this case, the filter frame is produced with integral knife edge. The knife edge interfaces with a gel channel that is integral to the housing or filter fixing grid. This technique is preferred in common plenum applications where the weight of the filter and pressure from airflow create a positive seal. No mounting hardware should be required.

10. SAFETY CONSIDERATIONS

Safety ordinances should be investigated when the installation of an air cleaner is contemplated (UL, AFI, NIST). Combustible filtering media may not be allowed by some local regulations. Combustion of dust and lint on filtering media is possible, although the media itself may not burn. This may cause a substantial increase in filter combustibility. Smoke detectors and fire sprinkler systems should be considered for filter bank locations. In some cases, depending on the contaminant, hazardous material procedures must be followed during removal and disposal of the used filter. Bag-in/bag-out (BI/BO) filter housings should be seriously considered in those cases.

Many air filters are efficient collectors of bioaerosols. When provided with moisture and nutrients, the microorganisms can multiply and may become a health hazard for maintenance personnel and building occupants. Moisture in filters can be minimized by preventing (1) entrance of rain, snow, and fog; (2) carryover of water droplets from coils, drain pans, and humidifiers; and (3) prolonged exposure to elevated humidity. Changing or cleaning filters regularly is important for controlling microbial growth.

Good health-safety practices for personnel handling dirty filters include wearing personal protective equipment (PPE), which includes a face mask, nitrile gloves, shoe covers, and safety glasses; and thorough washing upon completion. Old filters should be placed in plastic bags or other containers for safe disposal. Be careful not to shake or drop it, as particles can be released into the air by any sudden movements. Tie and tape the bag shut.

All high-voltage devices (such as electrostatic precipitators) can produce ozone, which is toxic and damaging not only to human lungs, but to paper, rubber, and other materials. When properly designed and maintained, an electronic air cleaner produces an ozone concentration that only reaches a fraction of the limit acceptable for continuous human exposure and is less than that prevalent in many American cities (EPA 1996). Continuous arcing and brush discharge in an electrostatic precipitator may yield an ozone level that is annoying or mildly toxic; this is indicated by a strong ozone odor. Although the nose is sensitive to ozone, only actual measurement of the concentration can determine whether a hazardous condition exists.

It is recommended to use ozone-producing devices that have a certification such as UL 867 or UL 2998 to avoid developing concentrations in excess of the NIOSH Regular Exposure Limit of 100 ppb (or lower if required by a local authority having jurisdiction or other site specific requirements). Real-time ozone monitoring should be used for all equipment not meeting the requirements of UL 2998.

CHAPTER 30

AIR POLLUTION CONTROL AND INDUSTRIAL PROCESS CLEANING

REGULATIONS AND STANDARDS 30.1
PARTICULATE CONTAMINANT CONTROL 30.3
Mechanical Collectors 30.3
Centrifugal Collectors 30.4
Electrostatic Precipitators 30.8
Fabric Filters 30.10
Mist Collectors 30.14
Particulate Scrubbers (Wet Collectors) 30.15
GASEOUS CONTAMINANT CONTROL 30.18
Spray Dry Scrubbing 30.18
Wet-Packed Scrubbers 30.18
Adsorption of Gaseous Contaminants 30.24
Incineration of Gases and Vapors 30.27
AUXILIARY EQUIPMENT 30.28
Ducts 30.28
Dust- and Slurry-Handling Equipment 30.29
Operation and Maintenance 30.29

AIR pollution control and industrial process cleaning perform one or more of the following functions:

- Maintains compliance of an industrial process with the laws or regulations for air pollution
- Reduces nuisance or physical damage from contaminants to individuals, equipment, products, or adjacent properties
- Prepares cleaned gases and airstreams for processes
- Reclaims usable materials, heat, or energy
- Reduces fire, explosion, or other hazards

Equipment that removes particulate matter from a gas stream may also remove or create some gaseous contaminants; on the other hand, equipment that is primarily intended for removal of gaseous pollutants might also remove or create objectionable particulate matter to some degree. In all cases, air pollution control gas-cleaning equipment changes the process stream, and it is therefore essential that the engineer evaluate the consequences of those changes to the plant's overall operation.

Equipment Selection

In selecting air pollution control equipment, plant operations and the use or disposal of materials captured by the gas-cleaning equipment must be considered. Because the cost and efficiency of air pollution control equipment affects manufacturing costs, alternative processes should be evaluated early to minimize the effect equipment may have on the total cost of a product and manufacturing operations. An alternative manufacturing process may reduce the cost of or eliminate the need for gas-cleaning equipment. However, even when gas-cleaning equipment is required, process and system control should minimize load on the collection device.

An industrial process may be changed from dirty to clean by substituting a process material (e.g., switching to a cleaner-burning fuel or pretreating the existing fuel). Equipment redesign, such as enclosing pneumatic conveyors or recycling noncondensable gases, may also clean the process. Occasionally, additives (e.g., chemical dust suppressants used in quarrying or liquid animal fat applied to dehydrated alfalfa before grinding) reduce the potential for air pollution or concentrate the pollutants so that a smaller, more concentrated process stream may be treated.

Gas streams containing contaminants should not usually be diluted with extraneous air unless the extra air is required for cooling or to condense contaminants to make them collectible. The volume of gas to be cleaned is a major factor in the owning and operating costs of control equipment. Therefore, source capture ventilation, where contaminants are kept concentrated in relatively small volumes of air, is generally preferable to general ventilation, where pollutants are allowed to mix into and be diluted by much of the air in a plant space. Chapters 32 and 33 of the 2023 *ASHRAE Handbook—HVAC Applications* address local and general ventilation of industrial environments. Regulatory authorities generally require the levels of emissions to be corrected to standard conditions taking into account temperature, pressure, moisture content, and factors related to combustion or production rate. However, the air-cleaning equipment must be designed using the actual conditions of the process stream as it will enter the equipment.

In this chapter, each generic type of equipment is discussed on the basis of its primary method for gas or particulate abatement. The development of systems that incorporate several of the devices discussed here for specific industrial processes is left to the engineer.

1. REGULATIONS AND STANDARDS

Gas-Cleaning Regulations and Codes

In 1960, only six U.S. states had air pollution programs. By 1970, all 50 states did. This shift occurred due to increased public interest and pressure on legislators to address dense, visible smog in many of the nation's cities, and the health issues thus caused. The Clean Air Act of 1963 was the first federal legislation concerning air pollution control. The Clean Air Amendments of 1970 (CAA 1970) built on and expanded the original legislation's scope, allowing for development of federal and state regulations to protect public health and the environment by limiting emissions from both stationary (industrial) and mobile (vehicle) sources. Most notably, CAA (1970) established the National Ambient Air Quality Standards (NAAQS), National Emissions Standards for Hazardous Air Pollutants (NESHAPs), and New Source Performance Standards (NSPS). During this time, a new Environmental Protection Agency (EPA) was established to consolidate the federal government's many environmental responsibilities under one agency and implement the requirements of the new legislation.

Today, in the United States, industrial gas-cleaning installations that exhaust to the outdoor environment are regulated by the U.S. Environmental Protection Agency (EPA); those that exhaust to the workplace are regulated by the Occupational Safety and Health Administration (OSHA) of the U.S. Department of Labor (DoL). The Mine Safety and Health Administration (MSHA) is also a DoL agency, and solely regulates the mining industry, including underground mines, quarries, and other surface mining sites. Both OSHA

The preparation of this chapter is assigned to TC 5.4, Industrial Process Air Cleaning (Air Pollution Control).

and MSHA have recently published new regulations on silica dusts in the workplace.

The EPA has established Standards of Performance for New Stationary Sources (New Source Performance Standards [NSPSs, GPO) and more restrictive State Implementation Plans (SIP 1991) and local codes as a regulatory basis to achieve air quality standards. Information on the current status of the NSPSs can be obtained through the Semi-Annual Regulatory Agenda, as published in the Federal Register, and through the regional offices of the EPA.

AP-42, Compilation of Air Pollutant Emissions Factors, has been published since 1972 as the primary compilation of the EPA's emissions factor information. It contains emissions factors and process information for more than 200 air pollution source categories (i.e., specific industry sectors or groups of similar emitting sources). The emissions factors were developed and compiled from source test data, material balance studies, and engineering estimates.

The fifth edition of AP-42 was published in January 1995. Supplements and updates are available in volume I, Stationary Point and Area Sources, and on the EPA web site. Additional design information for gas-cleaning equipment can be found in Buonicore and Davis (1992) and Sink (1991).

Where air is not affected by combustion, solvent vapors, and toxic materials, it may be desirable to recirculate the air to the workplace to reduce energy costs or to balance static pressure in a building. High-efficiency fabric or cartridge filters, precipitators, or special-purpose wet scrubbers are typically used in general ventilation systems to reduce particle concentrations to levels acceptable for recirculated air.

The Industrial Ventilation Committee of the American Conference of Governmental Industrial Hygienists (ACGIH) and the National Institute of Occupational Safety and Health (NIOSH) have established criteria for recirculation of cleaned process air to the work area (ACGIH 2010; NIOSH 1978). Fine-particle control by various dust collectors under recirculating airflows has been investigated by Bergin et al. (1989).

Often there are several hazards associated with controlling combustible particulate. The National Fire Protection Association (NFPA) offers several codes and standards to help prevent and reduce dust hazards, fires, and explosions, as discussed in the section on Fires, Explosions, and Hazards. Compliance with these codes and standards can help minimize the risks of dust explosions and protect staff, equipment, and facilities from harm.

Public complaints may occur even when the effluent concentrations discharged to the atmosphere are below the maximum allows emission rates and opacity limits. Thus, in addition to codes or regulations, the plant location, the contaminants involved, and the meteorological conditions of the area must be evaluated.

In most cases, emission standards require a higher degree of gas cleaning than necessary for the economic recovery of process products (if this recovery is desirable). Gas cleanliness is a priority, especially where toxic materials are involved and cleaned gases might be recirculated to the work area.

Measuring Gas Streams and Contaminants

Stack sampling is often required to fulfill requirements of operating and installation permits for gas-cleaning devices, to establish conformance with regulations, and to commission new equipment. Also, it can be used to establish specifications for gas-cleaning equipment and to certify that the equipment is functioning properly. The tests determine the composition and quantity of gases and particulate matter at selected locations along the process stream. The following general principles apply to a stack sampling program:

- The sampling location(s) must be acceptable to all parties who will use the results.
- The sampling location(s) must meet acceptable criteria with respect to temperature, flow distribution and turbulence, and distance from disturbances to the process stream. Exceptions based on physical constraints must be identified and reported.
- Samples that are withdrawn from a duct or stack must represent typical conditions in the process stream. Proper stack traverses must be made and particulate samples withdrawn isokinetically.
- Stack sampling should be performed in accordance with approved methods and established protocols whenever possible.
- Variations in the volumetric flow, temperature, and particulate or gaseous pollutant emissions, along with upset conditions, should be identified.
- A report from stack sampling should include a summary of the process, which should identify any deviations from normal process operations that occurred during testing. The summary should be prepared during the testing phase and certified by the process owner at completion of the tests.
- Disposal methods for waste generated during testing must be identified before testing begins. This is especially critical where pilot plant equipment is being tested because new forms of waste are often produced.
- The regulatory basis for the tests should be established so that the results can be presented in terms of process mass rate, consumption of raw materials, energy use, and so forth.

Analyses of the samples can provide the following types of information about the emissions:

- Physical characteristics of the contaminant: solid dust, liquid mist or "smoke," waxy solids, or a sticky mixture of liquid and solid.
- Distribution of particle sizes: optical, physical, aerodynamic, etc.
- Concentration of particulate matter in the gases, including average and extreme values, and a profile of concentrations in the duct or stack.
- Volumetric flow of gases, including average and extreme values, and a profile of this flow in the duct or stack. The volumetric flow is commonly expressed at actual conditions and at various standard conditions of temperature, pressure, moisture, and process state.
- Chemical composition of gases and particulate matter, including recovery value, toxicity, solubility, acid dew point, etc.
- Particle and bulk densities of particulate matter.
- Handling characteristics of particulate matter, including erosive, corrosive, abrasive, agglomerative, or adhesive/cohesive qualities.
- Flammable or explosive limits.
- Electrical resistivity of deposits of particulate matter under stack and laboratory conditions. These data are useful for assessments of electrostatic precipitators and other electrostatically augmented technology.

EPA Reference Methods. The EPA has developed methods to measure the particulate and gaseous components of emissions from many industrial processes and has incorporated these in the NSPS by reference. Appendix A of the New Source Performance Standards lists the reference methods (GPO, annual). These are updated regularly in the Federal Register. Guidance for using these reference methods can be found in the *Quality Assurance Handbook for Air Pollution Measurement Systems* (EPA-454/B-17-001, January 2017).

In 2004, the EPA promulgated fine particle standards for ambient air quality. Known as PM_{10} and $PM_{2.5}$ Standards, these revised standards focus particulate abatement efforts toward the collection and control of airborne particles smaller than 10 μm and 2.5 μm, respectively. The EPA reviewed the air quality standards for particulate matter (PM) and decided, effective December 18, 2020, to keep the current standards without revision.

Currently, further reductions in allowable $PM_{2.5}$ particulate matter have been submitted for public comment in 2023 and are under

consideration. Fine particles (with aerodynamic particle size smaller than 2.5 μm) are of concern because they penetrate deeply D6830-0into the lungs. With the development of these standards, concern has arisen over the efficiency of industrial gas cleaners at various particle sizes.

Other Test Methods for Reverse-Pulse Filter Fabric Baghouses and Filter Media

ASHRAE Methods. ASHRAE Standard 199 is a testing procedure that measures how well specifically designed dust collectors perform in real-world conditions. The test provides data to compare dust collectors based on their performance data on emissions, pressure drop, compressed air usage, energy consumption, and emission readings. It involves six stages that measure the dust collector's performance for emissions, pressure drop, and compressed air usage. The test is important because it is the first laboratory test method to measure emissions, differential pressure average, and air consumption in pulse-cleaned dust collectors under realistic operating conditions.

ASTM Methods. The EPA has also approved ASTM test methods when cited in the NSPSs or the applicable EPA reference methods. ASTM *Standard* D6830 determines airflow resistance, drag, cleaning requirements, and particulate filtration performance of reverse-pulse-cleaned filter media under specified laboratory conditions. Results of this test are useful in the design, construction, selection, and performance comparison of filter media.

Other Methods. Sometimes, the reference methods must be modified, with the consent of regulatory authorities, to achieve representative sampling under the less-than-ideal conditions of industrial operations. Modifications to test methods should be clearly identified and explained in test reports.

Gas Flow Distribution

The control of gas flow through industrial gas-cleaning equipment is important for good system performance. Because of the large gas flows commonly encountered and the frequent need to retrofit equipment to existing processes, space allocations often preclude gradual expansion and long-radius turns. Instead, elbow splitters, baffles, etc., are used. These components must be designed to limit dust buildup and corrosion to acceptable levels.

2. PARTICULATE CONTAMINANT CONTROL

Particulate collectors may be evaluated for their ability to remove particulate matter from a gas stream and for their ability to reduce the emissions of selected particle sizes. The degree to which particulate matter is separated from a gas stream is known as the efficiency of a collector; the fraction of material escaping collection is the penetration. The reduction of particulate matter in a selected particle size range is known as the fractional efficiency of a particulate collector.

The **efficiency** η of a collector is generally expressed as a percent of the mass flow rate of material entering and exiting the collector.

$$\eta = 100(w_i - w_o)/w_i = 100w_c/w_i \quad (1)$$

where

η = efficiency of collector, %
w_i = mass flow rate of contaminant in gases entering collector
w_o = mass flow rate of contaminant in gases exiting collector
w_c = mass flow rate of contaminant captured by collector

Alternatively, the efficiency of a collector can be expressed in terms of the concentrations of particulate matter entering and exiting the equipment. This approach can be unsatisfactory because of changes that occur in the gas stream due to air leakage in the system, condensation, and temperature and pressure changes.

Table 1 Principal Types of Particulate Control Equipment

Gravity and momentum collectors	• Settling chambers • Louvers and baffle chambers
Centrifugal collectors	• Cyclones and multicyclones • Rotating "centrifugal" mist collectors
Electrostatic precipitators	• Tubular or plate-type, wet or dry, high-voltage (single-stage) precipitators • Plate-type, wet or dry, low-voltage (two-stage) mist and smoke precipitators
Fabric filters	• Baghouses; fabric collectors; cartridge filters • Disposable media filters (for dust and/or mist)
Mist collectors	• Fiber bed filters, panel filters, high-loft bag filters, centrifugal filters, and electrostatic precipitators (ESPs)
Particulate scrubbers	• Spray scrubbers • Impingement scrubbers • Centrifugal-type scrubbers • Orifice-type scrubbers • Venturi scrubbers • Packed towers • Mobile bed scrubbers • Electrostatically augmented scrubbers

Penetration P is usually measured, and the efficiency for a collector calculated, using the following equations:

$$P = 100w_o - w_i \quad (2)$$

with

$$\eta = 100 - P \quad (3)$$

The **fractional efficiency** of a particulate collector is determined by measuring the mass rate of contaminants entering and exiting the collector in selected particle size ranges. Methods for measuring the fractional efficiency of particulate collectors in industrial applications are only beginning to emerge, largely because of the need to compare the fine-particle performance of collectors used under the PM_{10} and $PM_{2.5}$ regulations for ambient air quality.

Measures of performance other than efficiency should also be considered in designing industrial gas-cleaning systems. Table 1 describes some of the main types of particulate control equipment, and Table 2 compares some of these factors for typical equipment. Note that this table contains only nominal values and is no substitute for experience, trade studies, and an engineering assessment of requirements for specific installations.

Table 3 summarizes the types of collectors that have been used in industrial applications.

2.1 MECHANICAL COLLECTORS

Settling Chambers

Particulate matter will fall from suspension in a reasonable time if the particles are larger than about 40 μm. Plenums, dropout boxes, or gravitational settling chambers are thus used for the separation of coarse or abrasive particulate matter from gas streams.

Settling chambers are occasionally used in conjunction with fabric filters or electrostatic precipitators to reduce overall system cost. The settling chamber serves as a precollector to remove coarse particles from the gas stream.

Settling chambers sometimes contain baffles to distribute gas flow and to serve as surfaces for the impingement of coarse particles. Other designs use baffles to change the direction of the gas flow, thereby allowing coarse particles to be thrown from the gas stream by inertial forces.

The fractional efficiency for a settling chamber with uniform gas flow may be estimated by

Table 2 Measures of Performance for Gas-Cleaning Equipment

Type of Particle Collector	Particle Diameter,[a] μm	Max. Loading, g/m³	Collection Efficiency, % by mass	Pressure Loss: Gas, Pa	Pressure Loss: Liquid, kPa	Utilities per m³/s (gas)	Comparative Energy Requirement	Superficial Velocity,[b] m/s	Capacity Limits, m³/s	Space Required (Relative)

Jet	>2	>0.2	90	Provides pressure	345 to 610	7 to 14 L/s	15 to 30	10 to 100	50	Small
Venturi	>0.1	>0.2	95 to 99	2500 to 15 000	70 to 210	0.4 to 1.4 L/s	30 to 300	60 to 210	50	Small

Source: IGCI (1964). Information updated by ASHRAE Technical Committee 5.4.
[a]Minimum particle diameter for which the device is effective.
[b]Average speed of gases flowing through the equipment's collection region.

$$\eta = 100 u_t L / HV \quad (4)$$

where

η = efficiency of collector for particles with settling velocity u_t, %
u_t = settling velocity for selected particles, m/s
L = length of chamber, m
H = height of chamber, m
V = superficial velocity of gases through chamber, m/s

The **superficial velocity** of gases through the chamber is determined from measurements of the volumetric flow of gases entering and exiting the chamber and the cross-sectional area of the chamber. This average velocity must be low enough to prevent reentrainment of the deposited dust; a superficial velocity below 0.3 m/s is satisfactory for many materials.

Typical data on settling can be found in Table 4. Because of air inclusions in the particle, the density of a dust particle can be substantially lower than the true density of the material from which it is made.

Inertial Collectors

Louver and Baffle Collectors. Louvers are widely used to control particles larger than about 15 μm in diameter. The louvers cause a sudden change in direction of gas flow. By virtue of their inertia, particles move away from high-velocity gases and are either collected in a hopper or trap or withdrawn in a concentrated sidestream. The sidestream is cleaned using a cyclone or high-efficiency collector, or it is simply discharged to the atmosphere. In general, the pressure drop across inertial collectors with louvers or baffles is greater than that for settling chambers, but this loss is balanced by higher collection efficiency and more compact equipment.

Inertial collectors are occasionally used to control mist. In some applications, the interior of the collector may be irrigated to prevent reentrainment of dry dust and to remove soluble deposits.

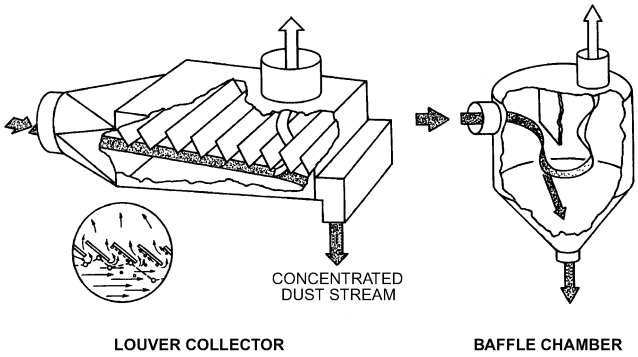

Fig. 1 Typical Louver and Baffle Collectors

Typical louver and baffle collectors are shown in Figure 1.

2.2 CENTRIFUGAL COLLECTORS

Cyclone

Centrifugal collectors are more commonly known as **cyclones** and depend on centrifugal force to move dust particles toward the wall of the collection chamber. Dust-laden air enters the collector tangentially at the top and the flow forms a vortex as it travels down the inside vertical wall or barrel of the cyclone. The tangential forces propel the particles toward the wall. In the whirling airstream, these particles are held against the wall by centrifugal forces, agglomerate, and slide downward toward the cone of the hopper.

The efficiency of a cyclone depends on particle density, shape, and size (aerodynamic size D_p, which is the average of the size

Notes for Table 3

Definitions
N/A: Not applicable because of inefficiency or process incompatibility.
N/U: Not widely used.
Particle size
Fine: 50% in 0.5 to 7 μm diameter range
Medium: 50% in 7 to 15 μm diameter range
Coarse: 50% over 15 μm diameter range
Concentration of particulate matter entering collector (loading)
Light: <4 g/m^3
Moderate: 4 to 10 g/m^3
Heavy: >10 g/m^3

[1] Dust released from bin filling, conveying, weighing, mixing, pressing, forming. Refractory products, dry pan, and screening operations more severe.
[2] Operations found in vitreous enameling, wall and floor tile, pottery.
[3] Grinding wheel or abrasive cutoff operation. Dust abrasive.
[4] Operations include conveying, elevating, mixing, screening, weighing, packaging. Category covers so many different materials that recommendation will vary widely.
[5] Cyclone and high-efficiency centrifugal collectors often act as primary collectors, followed by fabric filters or wet collectors.
[6] Usual setup uses cyclone as product collector followed by fabric filter for high overall collection efficiency.
[7] Dust concentration determines need for dry centrifugal collector; plant location, product value determine need for final collectors. High temperatures are usual, and corrosive gases not unusual. Liquid smoke emissions may be controlled by condensing precipitator systems using low-voltage, two-stage electrostatic precipitators.
[8] Ionizing wet scrubbers are widely used.
[9] Conveying, screening, crushing, unloading.
[10] Remote from other dust-producing points. Separate collector generally used.
[11] Heavy loading suggests final high-efficiency collector for all except very remote locations.
[12] Loadings and particle sizes vary with different drying methods.
[13] Boiler blowdown discharge is regulated, generally for temperature and, in some places, for pH limits; check local environmental codes on sanitary discharge.
[14] Collection for particulate or sulfur control usually requires a scrubber (dry or wet) and a fabric filter or electrostatic precipitator.
[15] Public nuisance from settled wood char indicates collectors are needed.
[16] Hot gases and steam usually involved.
[17] Steam from hot sand, adhesive clay bond involved.
[18] Concentration very heavy at start of cycle.
[19] Heaviest load from airless blasting because of high cleaning speed. Abrasive shattering greater with sand than with grit or shot. Amounts removed greater with sand castings, less with forging scale removal, least when welding scale is removed.
[20] Operations such as car unloading, conveying, weighing, storing.
[21] Special filters are successful.
[22] In addition to grain handling, cleaning rolls, sifters, purifiers, conveyors, as well as storing, packaging operations are involved.
[23] In addition to grain handling, bins, hammer mills, mixers, feeders, conveyors, bagging operations need control.
[24] Primary dry trap and wet scrubbing usual. Electrostatic precipitators are added where maximum cleaning is required.
[25] Air pollution control is expensive for open hearth, accelerating the use of substitute melting equipment, such as basic oxygen process and electric-arc furnace.
[26] Fabric filters have found extensive application for this air pollution control problem.
[27] Cupola control varies with plant size, location, melt rate, and air pollution emission regulations.
[28] Corrosive gases can be a problem, especially in secondary aluminum.
[29] Zinc oxide plume can be troublesome in certain plant locations.
[30] Crushing screening, conveying, storing involved. Wet ores often introduce water vapor in exhaust airstream.
[31] Dry centrifugal collectors are used as primary collectors, followed by a final cleaner.
[32] Collectors usually allow salvage of material and also reduce nuisance from settled dust in plant area.
[33] Salvage value of collected material is high. Same equipment used on raw grinding before calcining.
[34] Coarse abrasive particles readily removed in primary collector types.
[35] Roof discoloration, deposition on autos can occur with cyclones and, less frequently, with dry centrifugal. Heavy-duty air filter sometimes used as final cleaner.
[36] Linty particles and sticky buffing compounds can cause trouble in high-efficiency centrifugals and fabric filters. Fire hazard is also often present.
[37] Unit collectors extensively used, especially for isolated machine tools.
[38] Dust ranges from chips to fine floats, including graphitic carbon.
[39] Coolant mist and thermal smoke, often with solid swarf particulate entrained.
[40] Submicrometre smoke. Arc welding creates mostly dry metal oxide particulate, sometimes with liquid oil smoke. Resistance welding usually creates only liquid oil smoke, unless done at extremely high currents that vaporize some of the metal being welded.
[41] Plasma and laser cutting and welding of clean metals usually creates dry submicrometre smoke, but oily work pieces frequently generate a sticky mix of liquid and solid submicrometre smoke or fume.
[42] Materials involved vary widely. Collector selection may depend on salvage value, toxicity, sanitation yardsticks.
[43] Controlled temperature and humidity of supply air to coating pans makes recirculation from coating pans desirable.
[44] Manufacture of plastic compounds involves operations allied to many in chemical field and vanes with the basic process used.
[45] Operations are similar to woodworking, and collector selection involves similar considerations.
[46] Submicrometre liquid smoke is frequently emitted when plastic and rubber products are heated.
[47] Concentration is heavy during feed operation. Carbon black and other fine additions make collection and dust-free disposal difficult.
[48] Often, no collection equipment is used where dispersion from exhaust stack is good and stack location is favorable.
[49] Salvage of collected material often dictates type of high-efficiency collector.
[50] Fire hazard from some operations must be considered.
[51] Granular-bed filters, at times electrostatically augmented, have occasionally been used in this application.
[52] Bulky material. Storage for collected material is considerable; bridging from splinters and chips can be a problem.
[53] Production sanding produces heavy concentrations of particles too fine to be effectively captured by cyclones or dry centrifugal collectors.
[54] Primary collector invariably indicated with concentration and partial size range involved; when used, wet or fabric collectors are used as final collectors.

range), the exerted force, and the time that the force is exerted on the dust particles. Cyclone efficiency may be estimated from Figure 2.

The parameter D_{pc}, known as the **cut size**, is defined as the diameter of particles collected with 50% efficiency. The cut size may be estimated using the following equation:

$$D_{pc} = \sqrt{\frac{1.4\mu b}{N_e V_i (\rho_p - \rho_g)\pi}} \quad (5)$$

where

D_{pc} = cut size, m
μ = absolute gas viscosity, Pa·s
b = cyclone inlet width, m
N_e = effective number of turns in cyclone; approximately 5 for a high-efficiency cyclone and may be from 0.5 to 10 for other cyclones
V_i = inlet gas velocity, m/s
ρ_p = density of particle material, kg/m^3
ρ_g = density of gas, kg/m^3

Early designers of cyclones realized the correlation between higher efficiencies and greater pressure drops, and made cyclones smaller. To improve cyclonic efficiencies and lower pressure drop, multiple cyclone collectors with vane spinners were developed (Figure 3). Dirty air enters the inlet plenum and is diverted into

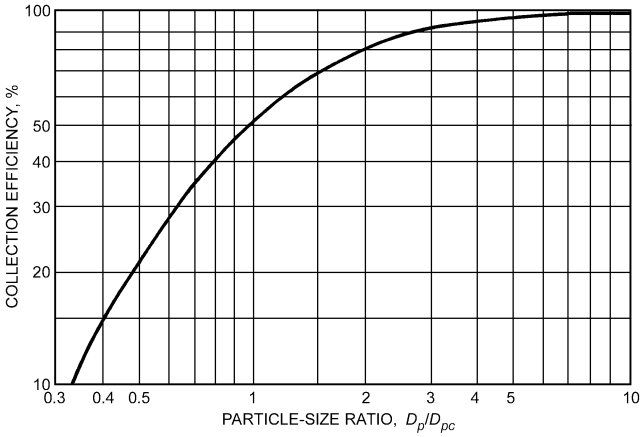

Fig. 2 Cyclone Efficiency

(Lapple 1951)

multiple tubes with turning vanes. These vanes create a centrifugal spin that separates dust from the airstream. The dust slides down the tube into the discharge hopper, while the clean gas rises through the center of the tube and is exhausted from the outlet. These multiple cyclones were often applied in boilers and other high-temperature applications as the only acceptable dust collectors.

Dust-carrying capacities of cyclones have two opposite characteristics. In general, small-diameter cyclones collect dust efficiently even at relatively low loads (0.0002 to 0.014 g/L), but the pressure drop will range from 1.5 to 2.5 kPa. However, at high dust loads, some of the dust outlets may tend to plug. Large-diameter cyclones can handle dust loads in the 0.11 to 0.23 g/L range with low pressure drops (0.37 to 0.75 kPa), but the collector efficiency will be lower at low dust loads because the dust particles may be swept from the walls of the collector before the dust particles can agglomerate. Currently, cyclones are broken down into grades as shown in Table 2.

The progression from low to high efficiency is achieved by reducing the diameter of the cyclone and altering the geometry to meet the airflow, pressure drop, and efficiency of the required application. The progression to ultrahigh efficiency (UHE) is a large leap. A tradeoff exists between separation efficiency and energy consumption. More energy is required in the form of static pressure to overcome the additional resistance of a smaller-diameter and longer-bodied cyclone. Although UHE cyclones can achieve the same level of emissions as filter media dust collectors; the UHE cyclone will cost more upfront; however, with no moving parts, the ease of operation can pay for itself. Like all cyclones, UHE cyclones are not appropriate for all applications and will depend on the dust collected. In additional to dust particle size and density, the particle aerodynamics must be considered (e.g., wood chips will act must differently than lead fines).

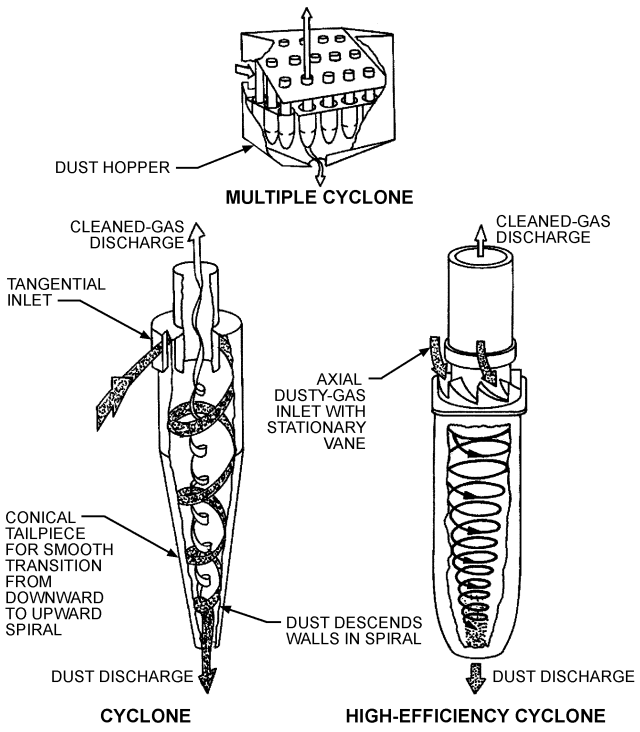

Fig. 3 Typical Cyclone Collectors

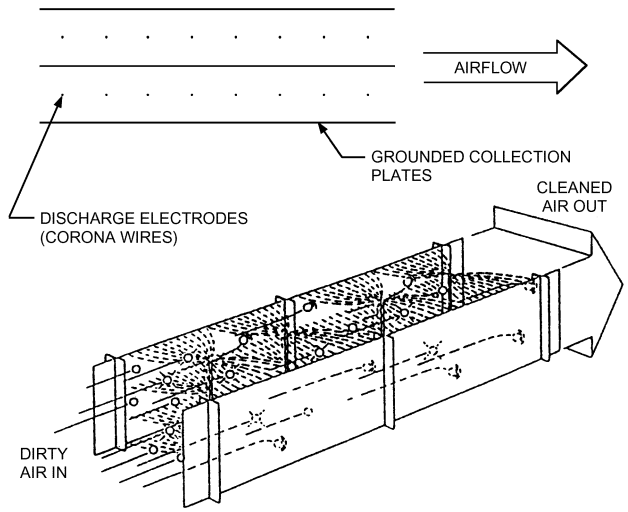

Fig. 4 Typical Single-Stage Electrostatic Precipitator

2.3 ELECTROSTATIC PRECIPITATORS

Electrostatic precipitators use the forces acting on charged particles passing through an electric field to separate those particles from the airstream in which they were suspended. In every precipitator, three distinct functions must be accomplished:

- **Ionization:** charging contaminant particles
- **Collection:** subjecting particles to a precipitating force that moves them toward collecting electrodes
- **Collector cleaning:** removing collected contaminant from precipitator

Units in which ionization and collection are accomplished simultaneously in a single structure are called **single-stage precipitators** (Figure 4). They have widely spaced electrodes (80 to 150 mm) and typically operate with high voltages (20 to 60 kV) but relatively low (rarely as high as 0.43 kV/mm) field gradients.In **two-stage precipitators**, ionization and collection are performed independently in discrete charging and precipitating structures (Figure 5). Because their ionizing and collecting electrodes are closely spaced (18 to 38 mm), two-stage precipitators normally operate with high field gradients (usually more than 0.39 kV/mm) but low voltages (usually 10 kV or less, and never more than 14 kV) (White 1963).

Because of fundamental differences in their ionization processes and practical differences in the way they are usually constructed, high-voltage (single-stage) and low-voltage (two-stage) precipitators are suited for entirely different air-cleaning requirements.

Single-Stage Designs

Figure 6 shows several types of single-stage precipitators. The charging electrodes are located between parallel collecting plates. The gas flows horizontally through the precipitators. High-voltage precipitators collect larger particles better than small particles (they are less efficient at collecting contaminants smaller than 1 to 2 μm). Their precipitation efficiency depends in part on the relative electrical resistivity of the pollutant being collected; most are less efficient when collecting either conductive or highly dielectric contaminants.

Single-stage high-voltage precipitators can easily handle heavy loadings of dry dust. Most are configured to operate continuously (using online vibratory or shaker cleaning). They can continuously collect large quantities (hundreds of kilograms per hour) of airborne materials such as foundry shakeout, cement, ceramics, chemical dusts, fly ash, blast furnace dust and fumes, and paper mill recovery boiler emissions.

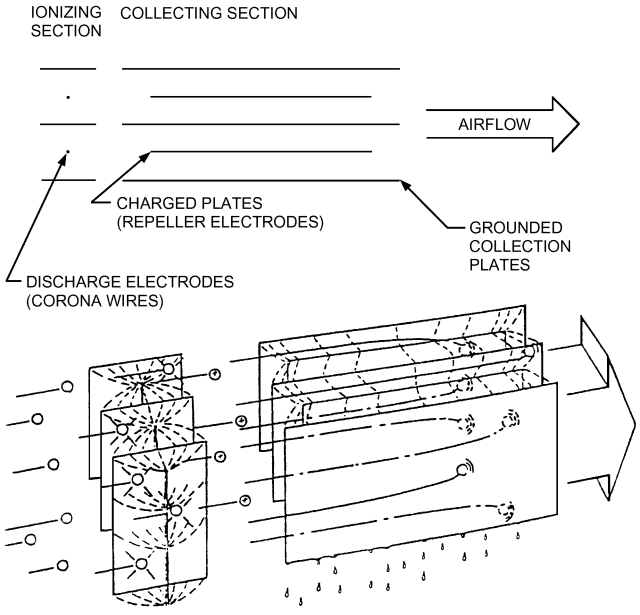

Fig. 5 Typical Two-Stage Electrostatic Precipitators

Although they are rarely used to clean exhaust airflows much smaller than 25 m^3/s, single-stage precipitators can be constructed to handle airflows as large as 1000 m^3/s. Gas velocity through the electrostatic field is ordinarily 0.3 to 2 m/s, with treatment time in the range of 2 to 10 s. Only special-purpose single-stage "wet" precipitators are configured for collection of liquid contaminants.

Single-stage industrial electrostatic precipitators are distinguished from low-voltage two-stage precipitator designs by several attributes:

- Separation between the electrodes is larger to secure acceptable collection and electrode cleaning under the high dust loading and hostile conditions of industrial gas streams.
- Construction is heavy-duty for operation to 450°C and +7.5 kPa.
- They are generally used for exhaust applications where ozone generation is not of concern. Consequently, they may operate with negative ionization, the polarity that gives the maximum electric field strength between the electrodes.
- They are normally custom-engineered and assembled on location for a particular application.

Single-stage precipitators can be designed to operate at collection efficiencies above 99.9% for closely specified conditions. Properties of the dust, such as particle size distribution and a deposit's electrical resistivity, can affect performance significantly, as can variations in gas composition and flow rate.

Two-Stage Designs

Two-stage precipitators are manufactured in two general forms: (1) electronic air cleaners, which are commonly used for light dust loadings in commercial/residential ventilation and air-conditioning service (see Chapter 29); and (2) heavy-duty industrial electrostatic precipitators designed primarily to handle the heavy loadings of submicrometre liquid particulates that are emitted from hot industrial processes and machining operations. Two-stage industrial precipitators often include sumps and drainage provisions that encourage continuous gravity runoff of collected liquids (Beck 1975; Shabsin 1985).

Two-stage precipitators are frequently used in industry to collect submicrometre pollutants that would be difficult (or impossible) to collect in other types of equipment. Two-stage precipitators are frequently sized to handle less than 0.5 m^3/s of air and rarely built to handle more than 25 to 35 m^3/s of contaminated air in one unit. Gas velocity through the collecting fields usually ranges from 1 to 3.5 m/

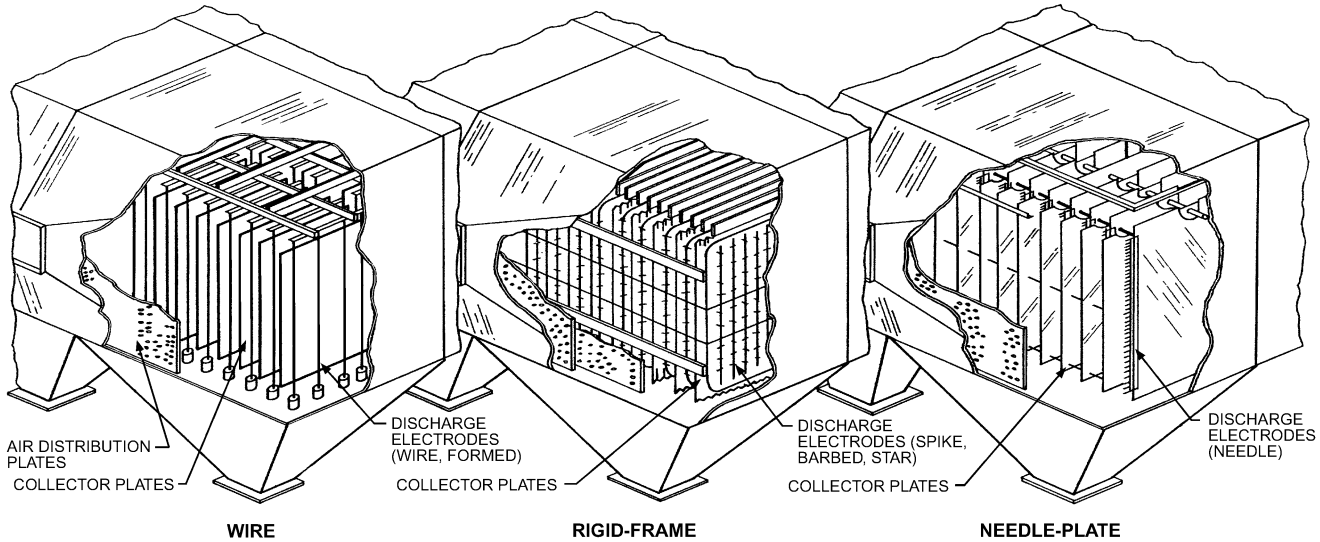

Fig. 6 Typical Single-Stage Precipitators

s, with treatment times per pass of 0.015 to 0.05 s in the ionizing fields and 0.06 to 0.25 s in the collecting fields.

Because gravity drainage of precipitated liquid smoke or fog is a dependable collector-cleaning mechanism, low-voltage two-stage precipitators are most often recommended to collect liquefiable pollutants in which few (or no) solids are entrained.

Since the early 1970s, an important application for low-voltage two-stage electrostatic precipitators has been as the gas-cleaning component of **condensing precipitator systems**. Design of these air pollution control systems (and of similar **condensing filtration systems**) is based on the following principle: although the hot gases or fumes emitted by many processes are not easily filtered or precipitated (because they are in the vapor phase), the condensation aerosol fogs or smokes that form as those vaporized pollutants cool can be efficiently collected by filtration or precipitation (Figure 7). Many condensation aerosol smokes consist of submicrometre liquid droplets, making them a good match for the collecting capability of low-voltage two-stage precipitators (Rossnagel 1973; Sauerland 1976; Thiel 1977).

Low-voltage precipitators can be very effective at collecting the aerosol particles smaller than 1 μm (down to 0.001 to 0.01 μm) that are responsible for most plume opacity and for virtually all blue smoke (blue-tinted) emissions. Condensing precipitator systems may therefore be a good choice for eliminating the residual opacity of blue smoke formed by condensation aerosol plumes from hot processes, dryers, ovens, furnaces, or other exhaust air cleaning devices (Beltran 1972; Beltran and Surati 1976; Thiel 1977).

When condensation aerosol pollutants are odorous in character, precipitation of the submicrometre droplets of odorant can prevent the long-distance drift of odorous materials, possibly eliminating neighborhood complaints that are associated with submicrometre particulate smokes. Odors that have been successfully controlled by precipitation include asphalt fumes, food frying smokes, meat smokehouse smoke, plasticizer smokes, rubber curing smoke, tar, and textile smokes (Chopyk and Larkin 1982; Thiel 1983).

2.4 FABRIC FILTERS

Fabric filters are dry dust collectors that use a stationary medium to capture the suspended dust and remove it from the gas stream. This medium, called fabric, can be composed of a wide variety of materials, including natural and synthetic cloth, glass fibers, and even paper.

Principle of Operation

When contaminated gases pass through a fabric, particles may attach to the fibers and/or other particles and separate from the gas stream. The particles are normally captured near the inlet side of a fabric to form a deposit known as a **dust cake**. In self-cleaning designs, the dust cake is periodically removed from the fabric to prevent excessive resistance to the gas flow. Finer particles may penetrate more deeply into a fabric and, if not removed during cleaning, may blind it.

Surface-loading-type fabrics can help mitigate this effect by not allowing particles to penetrate as deeply into the fabric. Because particles remain on the surface, instead of being embedded into the fabric, the dust cake releases from the fabric more easily during cleaning. Some examples of surface-loading fabrics are polytetrafluoroethylene (PTFE) membrane and nanofiber-coated fabrics.

Self-cleaning fabric filters have several **advantages** over other high-efficiency dust collectors such as electrostatic precipitators and wet scrubbers:

- They provide high efficiency with lower installed cost.
- Particulate matter is collected in the same state in which it was suspended in the gas stream (a significant factor if product recovery is desired).
- Process upsets seldom result in the violation of emission standards. The mass rate of particulate matter escaping collection remains low over the life of the filter media and is insensitive to large changes in the mass-loading of dust entering the collector.

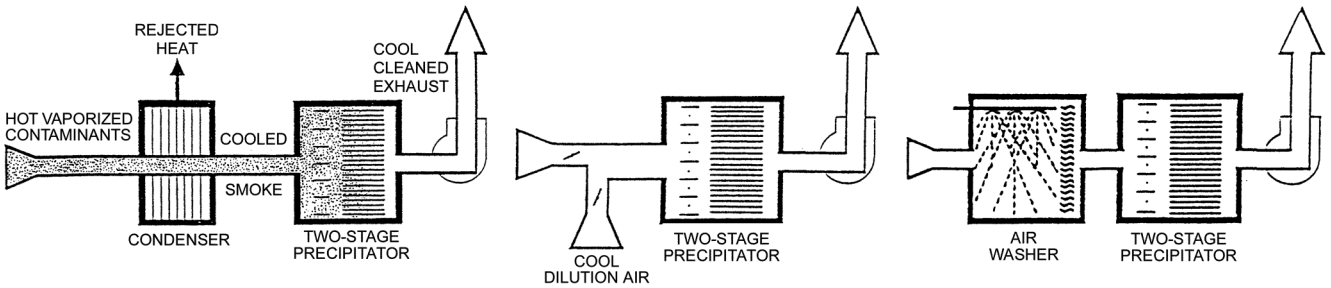
Self-cleaning fabric filter dust collectors also have some **limitations**:

- Liquid aerosols, moist and sticky materials, and condensation blind fabrics and reduce or prevent gas flow. These actions can curtail plant operation.
- Fabric life may be shortened in the presence of acidic or alkaline components in the gas stream.
- Use of fabric filters is generally limited to temperatures below 260°C.
- Should a spark or flame accidently reach the collector, fabrics can contribute to the fire/explosion hazard.
- When a large volume of gas is to be cleaned, the large number of fabric elements (bags, cartridges, or envelopes) required and the maintenance problem of detecting, locating, and replacing a damaged element should be considered. Monitoring equipment can detect leakage in an individual row of filters or an individual bag.

Pressure-Volume Relationships

The size of a fabric filter is based on empirical data on the amount of fabric media required to clean the desired volumetric flow of gas with an acceptable static pressure drop across the media. The appropriate media and conditions for its use are selected by pilot test or from experience with media in similar full-scale installations. These tests provide a recommended range of approach velocities for a specific application.

The **approach velocity** is stated in practical applications as a gas-to-media ratio or filtration velocity (i.e., the velocity at which gas flows through the filter media). The **gas-to-media ratio** is the ratio of the volumetric flow of gases through the fabric filter to the



A. PRINCIPLE OF THE CONDENSING PRECIPITATOR SYSTEM

B. DILUTION-COOLED CONDENSING PRECIPITATOR SYSTEM

C. EVAPORATIVELY COOLED CONDENSING PRECIPITATOR SYSTEM

Fig. 7 Condensing Precipitator Systems for Control of Hot Organic Smokes

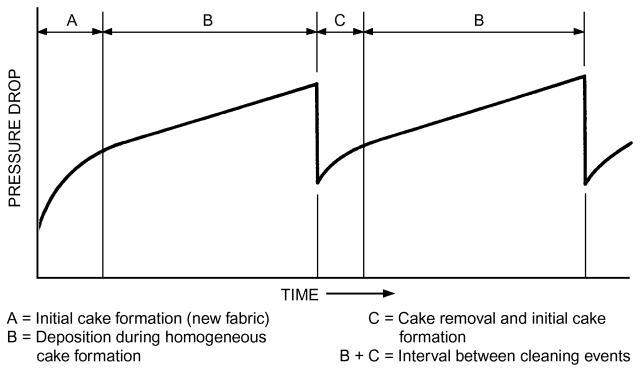


Fig. 8 Time Dependence of Pressure Drop Across Fabric Filter

area of fabric that participates in the filtration. It is the average approach velocity of the gas to the surface of the filter media.

It is difficult to estimate the correlation between pressure drop and gas-to-media ratio for a new installation. However, when flow entering a filter with a dust cake is laminar and uniform, the pressure drop is proportional to the approach velocity:

$$\Delta p = KV_i W = KQW/A \quad (6)$$

where

Δp = pressure drop, Pa
K = specific resistance coefficient, pressure drop per unit air velocity and mass of dust per unit area
V_i = approach velocity or gas-to-media ratio, m/s
W = area density of dust cake, g/m^2
Q = volumetric flow of gases, m^3/s
A = area of cloth that intercepts gases, m^2

Equation (6) suggests that increasing the area of the fabric during initial installation has some advantage. A larger fabric area reduces both the gas-to-media ratio and the thickness of the dust cake, resulting in a decreased pressure drop across the collector and reduced cleaning requirements. A lower gas-to-media ratio generally lowers operational cost for the fabric filter system, extends the useful life of the filter elements, and reduces maintenance frequency and expense. In addition, the lower gas-to-media ratio allows for some expansion of the system and, more importantly, additional surge capacity when upset conditions such as unusually high moisture content occur.

The specific resistance coefficient K is usually higher for fine dusts. The use of a primary collector to remove the coarse fraction seldom causes a significant change in the pressure drop across the collector. In fact, the coarse dust fraction helps reduce operating pressure because it results in a more porous dust cake, which provides better dust cake release.

Figure 8 illustrates the dependence of the pressure drop on time for a single-compartment fabric filter, operating through its cleaning cycle. The volumetric flow, particulate concentration, and distribution of particle sizes are assumed to remain constant. In practice, these assumptions are not usually valid. However, the interval between cleaning events is usually long enough that these variations are insignificant for most systems; between cleaning events, the dependence of pressure drop on time is approximately linear.

The volumetric flow of gases from a process often varies in response to changes in pressure drop across the fabric filter. The degree to which this variation is significant depends on the operating point for the fan and the process requirements.

Fabric Filter Media

Commercially available fabrics, when applied appropriately, will separate 1 μm or larger particles from a gas with an efficiency of 99.9% or better. Particle size is not the major factor influencing efficiency attained from an industrial fabric filter. Most manufacturers of fabric filters will guarantee such efficiencies on applications in which they have prior experience. Lower efficiencies are generally attributed to poor maintenance (torn fabric seams, loose connections, etc.) or the inappropriate selection of lighter/higher-permeability fabrics in an effort to reduce the cost of the collector.

Table 5 Temperature Limits and Characteristics of Fabric Filter Media

	Maximum Continuous Operating Temp., °C	Acid Resistance	Alkali Resistance	Flex Abrasion	Cost Relative to Cotton

[a]These fibers are subject to hydrolysis when they are exposed to hot, wet atmospheres.
[b]DuPont trademark.

Fabric specifications summarize information on such factors as cost, fiber diameter, type of weave, fabric density, tensile strength, dimensional stability, chemical resistance, finish, permeability, and abrasion resistance. Usually, comparisons are difficult, and the supplier must be relied on to select the appropriate material for the service conditions.

Table 5 summarizes experience with the exposure of fabrics to industrial atmospheres. Although higher temperatures are acceptable for short periods, reduced fabric life can be expected with continued use above the maximum temperature. The filter is often protected from high temperatures by thermostatically controlled air bleed-in or collector bypass dampers.

When the gases are moist or the fabric must collect hygroscopic or sticky materials, **synthetic media** are recommended. They are also recommended for high-temperature gases. Polypropylene is a frequent selection. One limitation of synthetic media is greater penetration of the media during the cleaning cycle.

Woven fabrics are generally porous, and effective filtration depends on prior formation of a dust cake. New cloth collects poorly until particles bridge the openings in the cloth. Once the cake is formed, the initial layers become part of the fabric; they are not destroyed when the bulk of the collected material is dislodged during the cleaning cycle.

Cotton and wool fibers in woven media as well as most felted fabrics accumulate an initial dust cake in a few minutes. Synthetic woven fabrics may require a few hours in the same application because of the smoothness of the monofilament threads. Spun threads in the fill direction, when used, reduce the time required to build up the initial dust cake. Felted fabrics contain no straight-through openings and have a reasonably good efficiency for most particulates, even when clean. After the dust cake builds internally, as well as on the fabric's surface, shaking does not make it porous.

Cartridges manufactured from **pleated paper** and various **synthetic microfibers** (usually spun-bonded, not resin-glued, to form a stiff, nonwoven, microporous media) are also fabric filters because they operate in the same general manner as high-efficiency fabrics.

As with cloth filters, the efficiency of the filter is increased by the formation of a dust cake on the medium.

Media used in cartridge type filters is usually manufactured to have many more pores (through which gas flows while being filtered) than do any of the common baghouse fabrics. Initial filtration efficiency of clean new cartridge filters is usually much greater, particularly for submicrometre-sized dust particles, than that of bare baghouse media (before a significant cake of filtered dust forms) because the pores in cartridge media are much smaller than those in baghouse fabrics. Despite having pores approximately one-tenth the diameter of those in the best baghouse felts, both cellulose (paper) and synthetic (most often polyester) cartridge media have so many pores that their permeability to gas flow is considerably greater than that of commonly used polyester felt baghouse media.

Fabric Filter Media Dust Collector Types

Three types of industrial filter media dust collectors are in common use: disposable-media filters, mechanically cleaned dust collectors, and pulse-cleaned dust collectors. Although most commercially available fabric filter systems are currently one of these three types, design variations among competing products can greatly influence the suitability of a particular collector for a specific air-cleaning application.

Disposable Filter Media Dust Collectors. Disposable-fabric (or disposable-media) filter collectors are usually simple, economical units that hold enough fabric or similar media to collect modest quantities of almost any particulate pollutant, including liquids, solids, and sticky or waxy materials, regardless of particle size (at least for particles large than 0.5 to 1 μm). When each filter has accumulated as much material as it can practically hold, it is discarded and replaced with a new element. Both envelope bag arrays and pleated rectangular cartridge elements are popular media forms for use in disposable filter collectors.

When considering using disposable-media filter collectors, serious attention must be given to safe, legal, and ethical disposal of spent and/or contaminated filter elements.

Mechanically Cleaned Dust Collectors. The most common filter cleaning methods for mechanically cleaned dust collectors are shaking the bags and reversing the flow of gas through the bags. Mechanical cleaning of filter media can only occur when the flow of filtering air through the filter is stopped. Typically, the fan flow is stopped momentarily by a damper in one compartment (or the main fan is turned off), making the filter compartment effectively off-line. Then, the cleaning action occurs with no fan flow moving through the compartment. Generally, large installations are compartmented and use off-line cleaning. Other cleaning methods include shake-deflate, a combination of shaker and reverse air cleaning, and acoustically augmented cleaning.

Shaker Collectors. When a single compartment is needed that can be cleaned off-line during shift change or breaks, shaker-type fabric filters are usually the least expensive choice. The fabric medium in a shaker-type fabric filter, whether formed into cylindrical tubes or rectangular envelopes, is mechanically agitated to remove the dust cake. Figures 9 and 10 show typical shaker-type fabric filters using bag and envelope media, respectively.

When the fabric filter cannot be stopped for cleaning, the collector is divided into a number of independent sections that are sequentially taken off-line for cleaning. Because it is usually difficult to maintain a good seal with dampers, relief dampers are often included. The relief dampers introduce a small volume of reverse gas to keep gas flow at the fabric suitable for cake removal. Use of compartments, with their frequent cleaning cycles, does not allow a substantial increase in flow rates over those of a single-compartment unit cleaned periodically. The best situation for fabric reconditioning is when the system is stopped, because even small particles will then fall into the hopper.

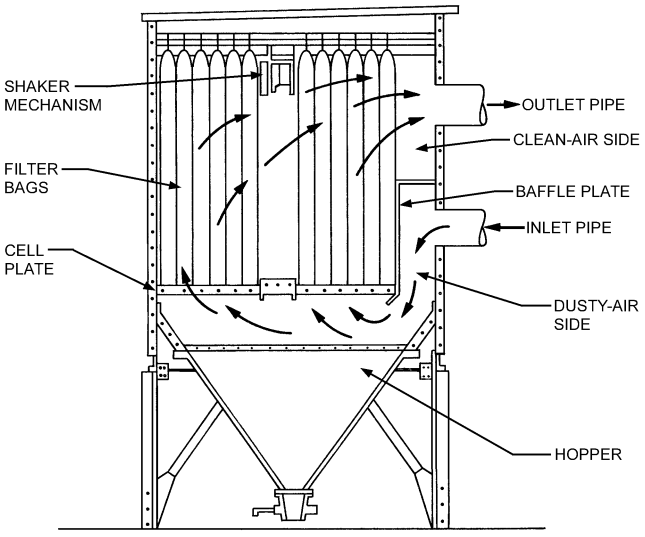

Fig. 9 Bag-Type Shaker Collector

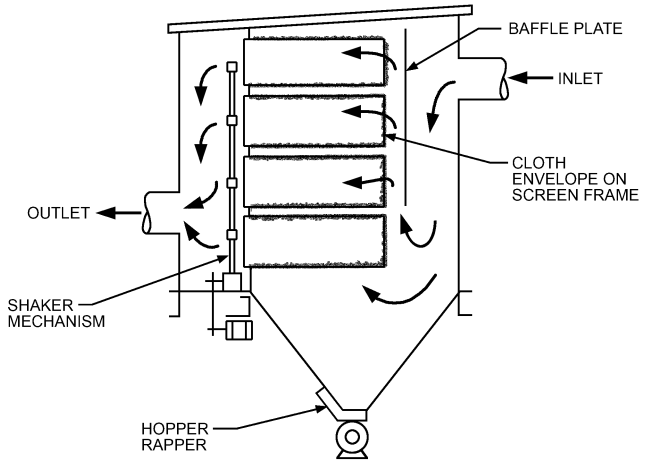

Fig. 10 Envelope-Type Shaker Collector

Figure 11 shows typical pressure diagrams for four- and six-compartment fabric filters that are continuously cleaned with mechanical shakers. Continuously cleaned units have compartment valves that close for the shaking cycle. This diagram is typical for a multiple-compartment fabric filter where individual compartments are cleaned off-line.

The gas-to-media ratio for a shaker-type dust collector is usually in the range of 0.01 to 0.02 m/s; it might be lower where the collector filters particles that are predominantly smaller than 2 μm. The abatement of metallurgical fumes is one example where a shaker collector is used to control particles that are less than 1 μm in size.

The bags are usually 100 to 200 mm in diameter and 3 to 6 m in length, whereas envelope assemblies may be almost any size or shape. For ambient air applications, a woven cotton or polypropylene fabric is usually selected for shaker-type fabric filters. Synthetics are chosen for their resistance to elevated temperature and to chemicals.

Reverse-Flow Collectors. Reverse-flow cleaning is generally chosen when the volumetric flow of gases is very large. This method of cleaning inherently requires a compartmented design because the reverse flow needed to collapse the bags entrains dust

that must be returned to on-line compartments of the fabric filter. Each compartment is equipped with one main shutoff valve and one reverse gas valve (whether the system is blown through or drawn through). A secondary blower and duct system is required to reverse the gas flow in the compartment to be cleaned. When a compartment is isolated for cleaning, the reverse gas circuit increases the volumetric flow and dust loading through the collector's active compartments.

The fabric medium is reconditioned by reversing the direction of flow through the bags, which partially collapse. The cleaning action is illustrated in Figure 12. After cleaning, reintroduction of gas is delayed to allow dislodged dust to fall into the hopper.

Reverse-flow cleaning reduces the number of moving parts in the fabric filter system—a maintenance advantage, especially when large volumetric flows are cleaned. However, the cleaning or reconditioning is less vigorous than other methods, and the residual drag of the reconditioned fabric is higher. Reverse-flow cleaning is particularly suited for fabrics, like glass cloth, that require gentle cleaning.

Reverse-flow bags are usually 200 to 300 mm in diameter and 6 to 10 m long and generally operate at flow velocities in the 0.01 to 0.02 m/s range. As a consequence, reverse-air dust collectors tend to be substantially larger than pulse-jet-cleaned designs of similar capacity.

For ambient air applications, a woven cotton or polypropylene fabric is the usual selection for reverse-flow cleaning. For higher temperatures, woven polyester, glass fiber, or trademarked fabrics are often selected.

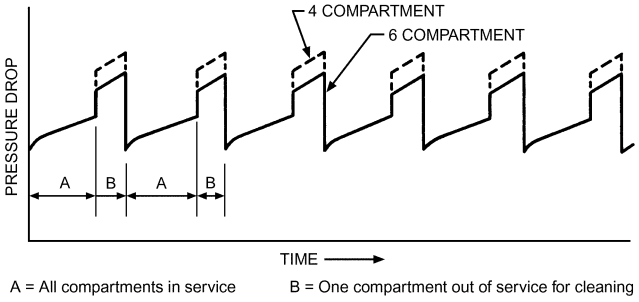

Fig. 11 Pressure Drop Across Shaker Collector Versus Time

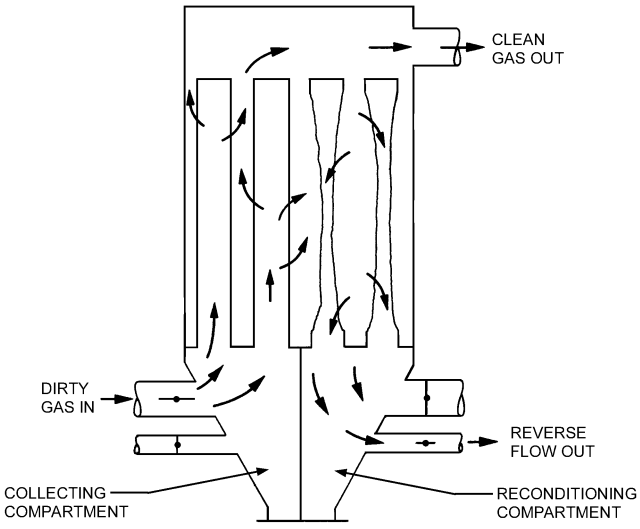

Fig. 12 Draw-Through Reverse-Flow Cleaning of Fabric

Reverse-Air Collectors. These collectors can continuously clean during ongoing industrial processes and without any special compartments. This type of collector became known as an **online cleaning collector**, because it could clean during the industrial process. Filters are cleaned using either a pan, pressure blower, or air pump to blow clean air through a rotating arm exhaust manifold directly above the filter bags. As the clean air manifold rotates, it seals off the filter bags from filtering and back-flushes the filters, with clean air knocking off the accumulated dust. These types of collectors can operate at much higher air-to-cloth ratios than shaker or reverse-flow collectors, and are very effective on a wide range of applications. The disadvantage of this collector type, however, is the multiple drives required to maintain and operate the main exhaust fan, cleaning fan/pump, and rotating arm drive.

Pulse-Cleaned Dust Collectors. These collectors use a common industrial-process resource to clean filters: compressed air. Pulse-cleaned dust collectors (or **pulse-jet**) use a compressed air jet operating for a fraction of a second causes a rapid vibration or ripple in the fabric, which dislodges the accumulated dust cake (Figures 13 and 14). Simultaneously, outflow of both compressed cleaning air and entrained air from the top clean air plenum helps to sweep pulsed-off dust away from the filter surface. The pulse jet design is predominantly used because (1) it is easier to maintain than the reverse-flow mechanism and (2) collectors can be smaller and less costly because the greater useful cleaning energy makes operation with higher filtration velocities practical.

Most pulse jet designs require high-pressure, dry, compressed (up to 700 kPa) air, the cost of which should be considered when air-cleaning systems are designed.

When collecting light or fluffy dust of low bulk density (e.g., arc welding fumes, plasma or laser cutting fumes, finish sanding of wood, fine plastic dusts), serious attention must be given to the direction and velocity at which dust-laden air travels as it moves from the collector inlet to approach the filter media surface. Dusty-air velocity is called **can velocity** and is defined as the actual velocity of airflow approaching the filter surfaces. Can velocity is computed by subtracting the total area occupied by filter elements (bags or cartridges, measured perpendicularly to the direction of gas flow) from

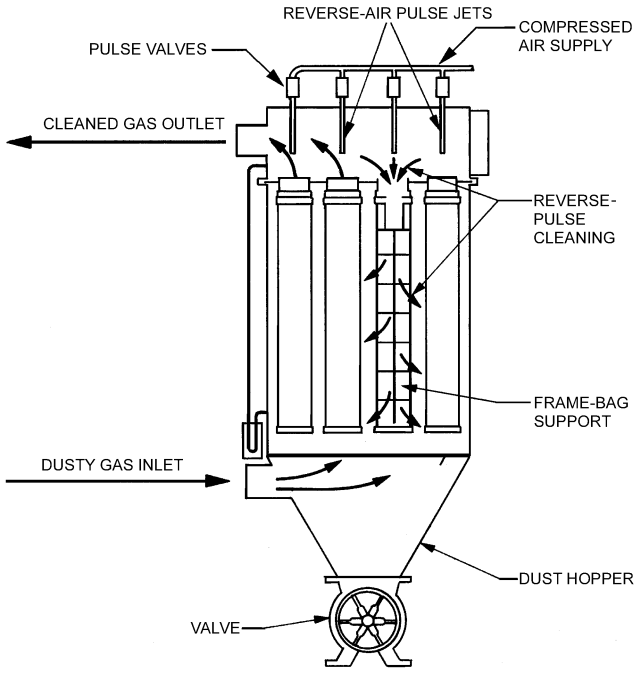

Fig. 13 Typical Pulse-Jet Fabric Filter

the overall cross-sectional area of the collector's dusty-air housing to compute the actual area through which dusty gas flows. The total gas flow being cleaned is then divided by that flow area to yield can velocity:

$$V_c = \frac{Q}{A_h - NA_f} \quad (7)$$

where

V_c = can velocity, m/s
Q = gas flow being cleaned, m^3/s
A_h = cross-sectional area of collector dusty-gas housing, m^2
N = number of filter bags or cartridges in collector
A_f = cross-sectional area, perpendicular to gas flow, of each filter bag or cartridge, m^2

The maximum can velocity in **upflow** collectors (i.e., those in which dusty gas enters through a plenum or hopper beneath the filter elements) is at the bottom end of the filter elements, where the entire gas flow must pass between and around the filters. Unless the maximum can velocity is low enough that pulsed-off dust can fall through the upwardly flowing gas, dust will simply redeposit on filter surfaces. The result is that on-line pulse cleaning cannot function, and the collector must be operated in the downtime pulse mode, with filter cleaning done only when there is no airflow through the collector.

Can velocity is sometimes overlooked when attempting to increase upflow collector capacity with improved fabrics or cartridges. Regardless of the theoretical gas-to-media ratio at which a filter operates, if released dust cannot fall through the rising airflow into the hopper, the collector will not be able to clean itself.

Collector designs in which dusty gas flows **downward** around the filters are much less susceptible to problems caused by high can velocity because the downward gas flow sweeps pulsed-off dust down toward (and into) the bottom dust discharge hopper, from which it can easily be removed.

Types of Pulse Jet Dust Collectors.

- **Baghouses.** Most baghouses (see Figure 13) use flexible cloth or other fabric-like filter media in the shape of long cylindrical bags. The tubular bags are supported by wire cages during normal operation. The reverse-flow pulse breaks up the dust layer on the outside of the bag, and dislodged material eventually falls to a hopper. Filtration velocities for pulse jet designs range from 0.025 to 0.075 m/s for favorable dusts but require greater fabric area for many materials that produce a low-permeability dust cake. Felted fabrics are generally used for these designs because the jet cleaning opens the pores of woven cloth and produces excessive leakage through the filter. Bags in pulse-jet-cleaned systems are rarely more than 160 mm in diameter but can be up to 6 m long. Timed pulses of compressed air flex the bags while blowing collected dust off the media surface. Continuous operation, with no downtime for filter cleaning or dust removal, is common (see Figure 11).
- **Cartridge filters**. These filters (Figure 14) use a nearly identical compressed-air media cleaning system. However, their fabric is relatively rigid material, packaged into pleated cylindrical cartridges. Cartridges are self-supported and much easier to handle and replace than are long tubular baghouse bags. Most cartridges are 325 mm or less in diameter and rarely longer than 760 mm.

  With the pleated media construction, a large filter surface area can be packaged in a relatively small housing to reduce both cost and space required. Most cartridge filter units are not nearly as tall as baghouses having comparable capacity. Pleat depth, spacing, and media material construction are critically important variables that determine the suitability and useful lifetime of particular filter cartridges under the conditions of each specific application.
- **Z-flow pack filters.** These are similar to cartridge filters, but with an even greater density of media. The filter media is corrugated, with alternating ends of the corrugated flutes sealed. Dirty air can enter an open-ended flute that is sealed shut at the other end. The air must pass through the media, and exit via an adjacent flute. The dust contaminant is trapped on the media surface. Z-flow packs use cleaning systems nearly identical to those of cartridge systems.

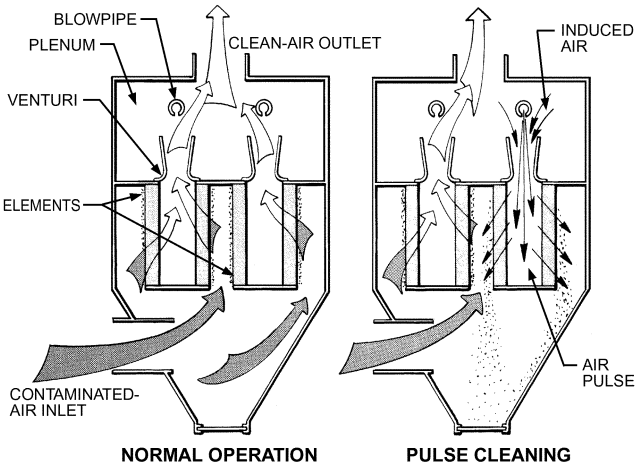

Fig. 14 Pulse Jet Cartridge Filters (Upflow Design with Vertical Filters)

Baghouse, cartridge, and Z-flow pack filter systems are practical only when airborne contaminants consist almost exclusively of dry dust. The presence of any entrained liquid in the airstream usually creates a severe maintenance problem because the filter self-cleaning systems (pulse jet, reverse air, or shaker) become less effective, so the filters become plugged or "blinded" by collected material and fail after only brief operation.

Conservatively selected and carefully applied baghouse, cartridge, and Z-flow filter systems, on the other hand, can easily provide excellent dust collection performance with a filter service life of more than 1 year. They often require very little maintenance, even when handling heavy dust loads in continuous 24 h, 7 day operation.

This chapter cannot adequately cover all the collector design variables and experience-related factors that must be considered when deciding which baghouse or cartridge self-cleaning dust collector design is best suited for each particular application. Engineers making dust collector selections are encouraged to discuss all aspects of each application in detail with all vendors being considered. It is necessary to judge

- The relative expertise of each prospective vendor
- Which dust collector design is most desirable
- How much media surface is needed in each design for each specified gas flow rate
- Which filter media is best suited to the particular application
- In the case of pulse-jet-cleaned cartridge collectors, what pleat spacing and pleat depth will give optimum or acceptable dust cake removal performance under the particular application conditions

2.5 MIST COLLECTORS

Mist collectors are wet filtration systems that separate wet particles out of the airstream and return cleaned air back into the workplace. Various filtration and particle separation technologies exist, including fiber bed filters, panel filters, high loft bag filters, centrifugal filters, and electrostatic precipitators (ESP). Each technology has its advantages and disadvantages depending on what its collecting and filtering out of the air.

Table 6 Common Examples of Mists

Type of Coolant/Lubricant	Typical purpose	Secondary purpose	Mist size typical	Other
Water soluble	Cooling	Lubricating (poor)	1 to 10+ μm	Contain paraffins
Straight Oil (neat)	Lubricating	Cooling (poor)	0.07 to 5 μm	Easily vaporize
Semi-synthetic	Cooling	Cooling	1 to 10+ μm	Water-soluble oil and synthetic chemicals
Synthetic	Cooling	Cooling	1 to 10+ μm	Synthetic chemicals Sticky when dried

Mist Types

There are many types of mists that can be filtered, but the most common are water-soluble coolants, straight oil (neat oil), and semi-synthetic and synthetic coolants (Table 6). Each of these have their own specific purpose, whether the process requires cooling, lubrication, or some combination of both. Although mist collectors filter droplets out of the air, it is very common to also be collecting solid particles along with the mist. Most mist collectors can handle some degree of solid particles, but using prefilters is common to improve the efficiency, maintenance cycles, and overall cost of ownership of the mist collector itself.

Applications

There are many different types of industrial applications that mist collectors can be used on, but in general, they can be grouped into cutting, grinding, forming, and casting. Other applications, such as vacuum pumps and pressurized oil reservoirs, require mist collectors as well, but are less common in the industrial market. Each of these applications uses a different type of coolant or lubricant and the nature of the application generates different size mist particles, higher or lower quantities of mist, higher or lower amounts of dust or swarf, and even burnt lubricants that are sometimes referred as burnt hydrocarbons or smoke.

In applications involving processes such as grinding and lathes, removing dust and swarf is important as well as cooling and lubricating. Leftover material after a cut can cause scratching and impurities in the finished surface. Using water-soluble coolants to flush away the leftover material is typically the most economical solutions for these types of applications. On the other hand, where the smallest/finest mist is needed, straight oils are commonly used because these materials can be put under high pressure and sprayed into the smallest of crevices to provide the best lubrication for fine tool work. Unfortunately, straight oils are not good at cooling and, in tight spaces where heat can be the highest, straight oils will vaporize and in some cases burn. Vaporized oil will condense at 0.07 μm and, if time is not allowed for the fine submicron mist to coalesce, it can act as a thermally generated smoke, penetrating the filtration technology and appearing as if the mist collector is not working or on fire. With today's high-efficiency fiber bed filters and final HEPA polishing filters, this tendency has greatly decreased. Most vaporized oil, after coalescing, will increase to an average 0.7 μm, which can be filtered, coalesced further, and finally drip off high-efficiency medias as large droplets.

Each mist collector technology is best suited for a particular type of application and/or mist challenge. Although most filtration technologies will work for any type of mist, the cost of ownership will be greatly different between the different solutions.

2.6 PARTICULATE SCRUBBERS (WET COLLECTORS)

Wet-type dust collectors use liquid (usually, but not necessarily, water) to capture and separate particulate matter (dust, mist, and fumes) from a gas stream. Some scrubbers operate by spraying the **scrubbing liquid** into the contaminated air. Others bubble air through the scrubbing liquid. In addition, many hybrid designs exist.

Particle sizes, which can be controlled by a wet scrubber, range from 0.3 to 50 μm or larger. Wet collectors can be classified into three categories: (1) **low-energy** (up to 2 kJ/m^3, 0.25 to 1.5 kPa); (2) **medium-energy** (2 to 6 kJ/m^3, 1.5 to 4.5 kPa); and (3) **high-energy** (> 6 kJ/m^3, > 4.5 kPa). Typical wet-scrubber performance is summarized in Table 2.

Wet collectors may be used for collection of most particulates from industrial process gas streams where economics allow for collection of the material in a wet state.

Advantages of wet collectors include

- Constant operating pressure
- No secondary dust sources
- Small spare parts requirement
- Ability to collect both gases and particulates
- Ability to handle high-temperature and high-humidity gas streams, as well as to reduce the possibility of fire or explosion
- Reasonably small space requirements for scrubbers
- Ability to continuously collect sticky and hygroscopic solids without becoming fouled

Disadvantages include

- High susceptibility to corrosion (corrosion-resistant construction is expensive)
- High humidity in discharge gas stream, which may give rise to visible and sometimes objectionable fog plumes, particularly during winter
- Large pressure drops and high power requirement for most designs that can efficiently collect fine (particularly submicrometre) particles
- Possible difficulty or high cost of disposal of waste water or clarification waste
- Rapidly decreasing fractional efficiency for most scrubbers for particles less than 1 μm in size
- Freeze protection required in many applications in colder environments

Principle of Operation

The more important mechanisms involved in the capture and removal of particulate matter in scrubbers are inertial impaction, Brownian diffusion, and condensation.

Inertial impaction occurs when a dust particle and a liquid droplet collide, resulting in the capture of the particle. The resulting liquid/dust particle is relatively large and may be easily removed from the carrier gas stream by gravitation or impingement on separators.

Brownian diffusion occurs when the dust particles are extremely small and have motion independent of the carrier gas stream. These small particles collide with one another, making larger particles, or collide with a liquid droplet and are captured.

Condensation occurs when the gas or air is cooled below its dew point. When moisture is condensed from the gas stream, fogging occurs, and the dust particles serve as condensation nuclei. The dust particles become larger as a result of the condensed liquid, and the probability of their removal by impaction is increased.

Wet collectors perform two individual operations. The first occurs in the **contact zone**, where the dirty gas comes in contact with the liquid; the second is in the **separation zone**, where the liquid that has captured the particulate matter is removed from the gas

stream. All well-designed wet collectors use one or more of the following principles:

- High liquid-to-gas ratio
- Intimate contact between the liquid and dust particles, which may be accomplished by forming large numbers of small liquid droplets or by breaking up the gas flow into many small bubbles that are driven through a bath of scrubbing liquid, to increase the chances that contaminants will be wetted and collected
- Abrupt transition from dry to wet zones to avoid particle build-up where dry gas enters the collectors

For a given type of wet collector, the greater the power applied to the system, the higher the collection efficiency will be (Lapple and Kamack 1955). This is the contacting power theory. Figure 15 compares the fractional efficiencies of several wet collectors, and Figure 16 shows the relationship between the pressure drop across a venturi scrubber and the abatement of particulate matter.

Spray Towers and Impingement Scrubbers

Spray towers and impingement scrubbers are available in many different arrangements. The gas stream may be subjected to a single spray or a series of sprays, or the gas may be forced to impinge on a series of irrigated baffles. Except for packed towers, these types of scrubbers are in the low-energy category; thus, they have relatively low particulate removal efficiency. A typical spray tower and an impingement scrubber are illustrated in Figures 17 and 18, respectively.

The efficiency of a spray tower can be improved by adding high-pressure sprays. A spray tower efficiency of 50 to 75% can be improved to 95 to 99% (for dust particles with size near 2 µm) by pressures in the range of 200 to 700 kPa (gage).

Centrifugal-Type Collectors

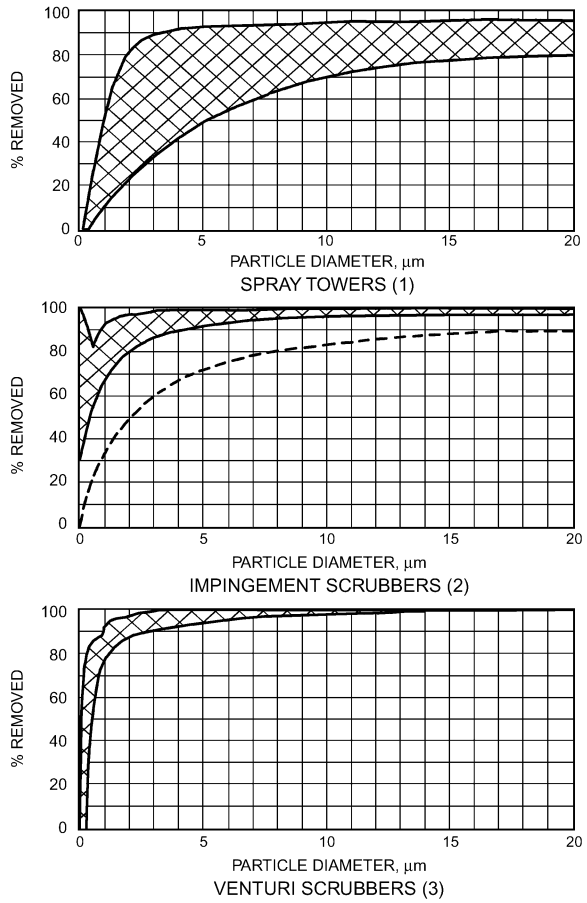
These collectors are characterized by a tangential entry of the gas stream into the collector. They are classed with medium-energy scrubbers. The impingement scrubber shown in Figure 18 is an example of a centrifugal-type wet collector.

Orifice-Type Collectors

Orifice-type collectors are also classified in the medium-energy category. Usually, the gas stream is made to impinge on the surface of the scrubbing liquid and is forced through constrictions where the gas velocity is increased and where the liquid/gaseous/particulate interaction occurs. Water usage for orifice collectors is limited to evaporation loss and removal of collected pollutants. A typical orifice-type wet collector is illustrated in Figure 19.

Venturi Scrubber

A high-energy venturi scrubber passes the gas through a venturi-shaped orifice where the gas is accelerated to 60 m/s or more.



Notes:
1. Efficiency depends on liquid distribution.
2. Upper curve is for packed tower; lower curve is for orifice-type wet collector. Dashed lines indicate performance of low-efficiency, irrigated baffles or rods.
3. Efficiency is directly related to fluid rate and pressure drop.

Fig. 15 Fractional Efficiency of Several Wet Collectors

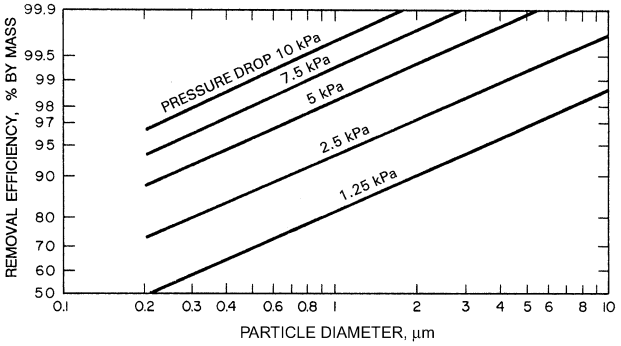


Fig. 16 Efficiency of Venturi Scrubber

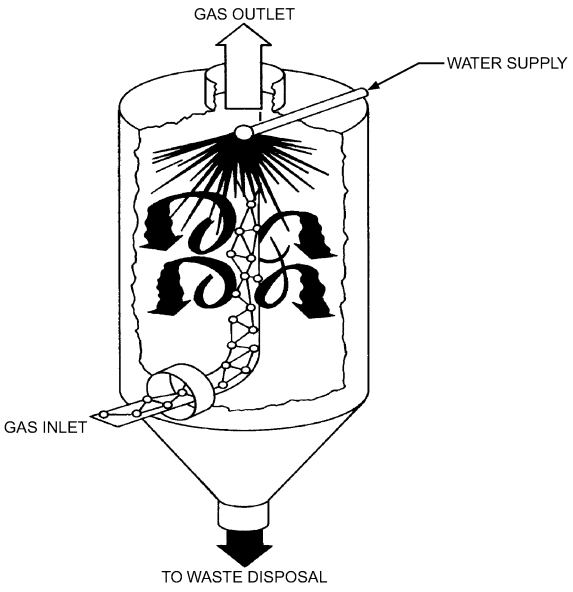

Fig. 17 Typical Spray Tower

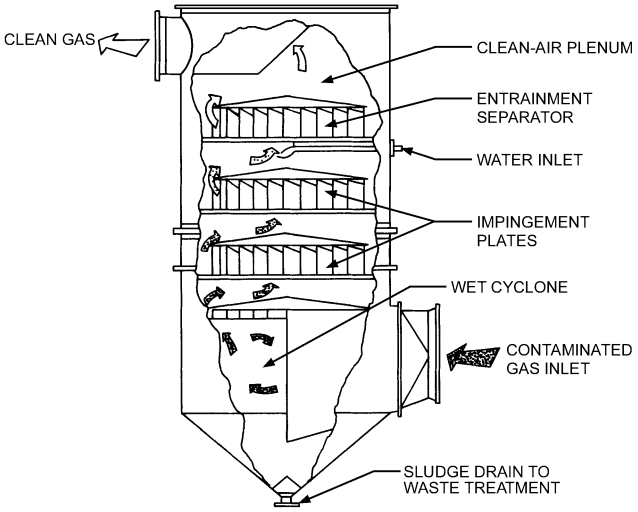

Fig. 18 Typical Impingement Scrubber

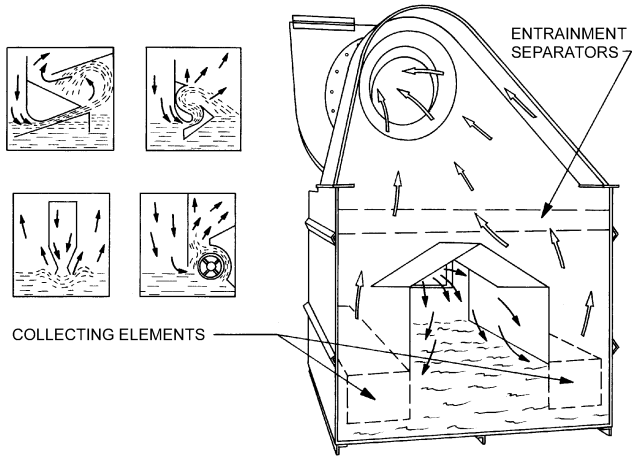

Fig. 19 Typical Orifice-Type Wet Collector

Depending on the design, the scrubbing liquid is added at, or ahead of, the throat. The rapid acceleration of the gas shears the liquid into a fine mist, increasing the chance of liquid-particle impaction. Yung has developed a mathematical model for the performance and design of venturi scrubbers (Semrau 1977). Subsequent validation experiments (Rudnick et al. 1986) demonstrated that this model yields a more representative prediction of venturi scrubber performance than other performance models do.

In typical applications, the pressure drop for gases across a venturi is higher than for other types of scrubber. Water circulation is also higher; thus, venturi systems use water reclamation systems. One example of a venturi scrubber is illustrated in Figure 20.

Electrostatically Augmented Scrubbers

Several gas-cleaning devices combine electrical charging of particulate matter with wet scrubbing. Electrostatic augmentation enhances fine particle control by causing an electrical attraction between the particles and the liquid droplets. Compared to venturi scrubbers, electrostatically augmented scrubbers remove particles smaller than 1 μm at a much lower pressure drop.

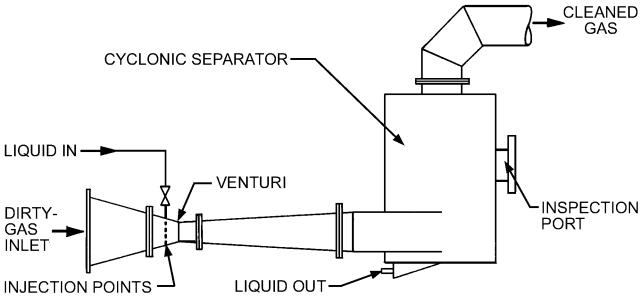

Fig. 20 Typical High-Energy Venturi Scrubber

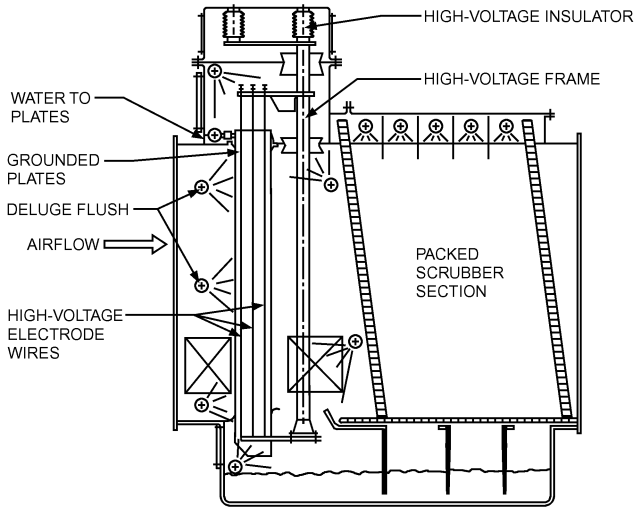

Fig. 21 Typical Electrostatically Augmented Scrubber

There are three generic designs for electrostatic augmentation:

1. Unipolar charged aerosols pass through a contact chamber containing randomly oriented packing elements of dielectric material. A typical electrostatically augmented scrubber of this design is shown in Figure 21.
2. Unipolar charged aerosols pass through a low-energy venturi scrubber.
3. Unipolar charged aerosols pass into a spray chamber where they are attracted to oppositely charged liquid droplets.

Collection efficiencies of 50 to 90% can be achieved in a single particle charging and collection stage, depending on the mass loading of fine particles and the superficial velocity of gases in the collector. Higher collection efficiencies can be obtained by using two or more stages. Removal efficiency of gaseous pollutants depends on the mass transfer and absorption design of the scrubber section.

In most applications of electrostatically augmented scrubbers, the dirty gas stream is quenched by adiabatic cooling with liquid sprays; thus, it contains a large amount of water vapor that wets the particulate contaminants. This moisture provides a dominant influence on particle adhesion and the electrical resistivity of deposits in the collector.

Electrical equipment for particle charging is similar to that for electrostatic precipitators. The scrubber section is usually equipped with a liquid recycle pump, recycle piping, and a liquid distribution system.

3. GASEOUS CONTAMINANT CONTROL

Many industrial processes produce large quantities of gaseous or vaporized contaminants that must be separated from gas streams. These contaminants are usually removed through absorption into a liquid or adsorption onto a solid medium. Incineration of exhaust gas (see the section on Incineration of Gases and Vapors) has also been successfully used to remove organic gases and vapors. Low-vapor-pressure odorous materials that condense to form submicrometre condensation aerosols after being emitted from hot industrial processes can sometimes be successfully controlled by well-designed condensing filter or condensing precipitator submicrometre particulate collection systems (see the section on Two-Stage Designs under Electrostatic Precipitators).

3.1 SPRAY DRY SCRUBBING

Spray dry scrubbing is used to absorb and neutralize acidic gaseous contaminants in hot industrial gas streams. The system uses an alkali spray to react with the acid gases to form a salt. The process heat evaporates the liquid, resulting in a dry particulate that is removed from the gas stream.

Typical industrial applications of spray dry scrubbing are

- Control of hydrochloric acid (HCl) emissions from biological hazardous-waste incinerators
- Control of sulfuric acid and sulfur trioxide emissions from burning high-sulfur coal
- Control of sulfur oxides (SO_x), boric acid, and hydrogen fluoride (HF) gases from glass-melting furnaces.

Principle of Operation

Spray drying involves four operations: (1) atomization, (2) gas droplet mixing, (3) drying of liquid droplets, and (4) removal and collection of a dry product. These operations are carried out in a tower or a specially designed vessel.

In any spray dryer design, good mixing and efficient gas droplet contact are desirable. Dryer height is largely determined by the time required to dry the largest droplets produced by the atomizer. Towers used for acid gas control typically have gas residence times of about 10 s, compared to about 3 s for towers designed for evaporative cooling. The longer residence time is needed because drying by itself is not the primary goal for the equipment. Many of the acid/alkali reactions are accelerated in the liquid state. It is, therefore, desirable to cool the gases to as close as possible to the adiabatic saturation temperature (dew point) without risking condensation in downstream particulate collectors. At these low temperatures, droplets survive against evaporation much longer, thus obtaining a better chance of contacting all acidic contaminants while the alkali compounds are in their most reactive state.

Equipment

The **atomizer** must disperse a liquid containing an alkali compound that will react with acidic components of the gas stream. The liquid must be distributed uniformly in the dryer and mixed thoroughly with the hot gases in droplets of a size that will evaporate before striking a dryer surface.

In typical spray dryers used for acid gas control, the droplets have diameters ranging from 50 to 200 μm. The larger droplets are of most concern because these might survive long enough to impinge on equipment surfaces. In general, a tradeoff must be made between the largest amount of liquid that can be sprayed and the largest droplets that can be tolerated by the equipment. The angular distribution or **fan-out** of the spray is also important. In spray drying, the angle is often 60 to 80°, although both lower and higher angles are sometimes required. The fan-out may change with distance from the nozzle, especially at high pressures.

An important aspect of spray dryer design and operation is the production and control of the gas flow patterns in the drying chamber. Because of the importance of the flow patterns, spray dryers are usually classified on the basis of gas flow direction in the chamber relative to the spray. There are three basic designs: (1) **cocurrent**, in which the liquid feed is sprayed with the flow of the hot gas; (2) **countercurrent**, in which the feed is sprayed against the flow of the gas; and (3) **mixed flow**, in which there is a combined cocurrent and countercurrent flow.

There are several types of atomizers. High-speed rotating **disks** achieve atomization through centrifugal motion. Although disks are bulky and relatively expensive, they are also more flexible than nozzles in compensating for changes in particle size caused by variations in feed characteristics. Disks are also used when high-pressure feed systems are not available. They are frequently used when high volumes of liquid must be spray dried. Disks are not well suited to counterflow or horizontal flow dryers.

Nozzles are also commonly used. These may be subdivided into two distinct types: centrifugal pressure nozzles and two-fluid (or pneumatic) nozzles. In the **centrifugal pressure nozzle**, energy for atomization is supplied solely by the pressure of the feed liquid. Most pressure nozzles are of the swirl type, in which tangential inlets or slots spin the liquid in the nozzle. The pressure nozzle satisfactorily atomizes liquids with viscosities of 300 mPa·s or higher. It is well suited to counterflow spray dryers and to installations requiring multiple atomizers. Capacities up to 1.3 kg/s through a single nozzle are possible. Pressure nozzles have some disadvantages. For example, pressure, capacity, and orifice size are independent, resulting in a certain degree of inflexibility. Moreover, pressure nozzles (particularly those with small passages) are susceptible to erosion in applications involving abrasive materials. In such instances, tungsten carbide or a similarly tough material is mandatory.

In **two-fluid nozzles**, air (or steam) supplies most of the energy required to atomize the liquid. Liquid, admitted under low pressure, may be mixed with the air either internally or externally. Although energy requirements for this atomizer are generally greater than for spinning disks or pressure nozzles, the two-fluid nozzle can produce very fine atomization, particularly with viscous materials.

The density and viscosity of the feed materials and how these might change at elevated temperature should be considered. Some alkali compounds do not form a solution at the concentrations needed for acid gas control. It is not uncommon that pumps and nozzles must be chosen to handle and meter slurries.

Spray dryer systems include metering valves, pumps and compressors, and controls to ensure optimal chemical feed and temperature in the gas-cleaning system.

3.2 WET-PACKED SCRUBBERS

Packed scrubbers are used to remove gaseous and particulate contaminants from gas streams. Scrubbing is accomplished by impingement of particulate matter and/or by absorption of soluble gas or vapor molecules on the liquid-wetted surface of the packing. There is no limit to the amount of particulate capture, as long as the properties of the liquid film are unchanged.

Gas or vapor removal is more complex than particulate capture. The contaminant becomes a solute and has a vapor pressure above that of the scrubbing liquid. This vapor pressure typically increases with increasing concentration of the solute in the liquid and/or with increasing liquid temperature. Contaminant scrubbing continues as long as the partial pressure of contaminant in the gas is above its vapor pressure with respect to the liquid. The rate of contaminant removal is a function of the difference between the partial pressure and vapor pressure, as well as the rate of diffusion of the contaminant.

In most common gas-scrubbing operations, small increases in the superficial velocity of gases through the collector decrease the removal efficiency; therefore, these devices are operated at the highest possible superficial velocities consistent with acceptable contaminant control. Usually, increasing the liquid rate has little effect on efficiency; therefore, liquid flow is kept near the minimum required for satisfactory operation and removal of particulate matter. As the superficial velocity of gases in the collector increases above a certain value, there is a tendency to strip liquid from the surface of the packing and entrain the liquid from the scrubber. If pressure drop is not the limiting factor for operation of the equipment, maximum scrubbing capacity occurs at a gas rate just below the rate that causes excessive liquid reentrainment.

Scrubber Packings

Packings are designed to present a large surface area that will wet evenly with liquid. They should also have high void ratio so that pressure drop will be low. High-efficiency packings promote turbulent mixing of the gas and liquid. Figure 22 illustrates six types of packings that are randomly dumped into scrubbers. Packings are available in ceramic, metal, and thermoplastic materials. Plastic packings are extensively used in scrubbers because of their low mass and resistance to mechanical damage. They offer a wide range of chemical resistance to acids, alkalies, and many organic compounds; however, plastic packing can be deformed by excessive temperatures or by solvent attack.

The relative capacity of tower packings at constant pressure drop can be obtained by calculation from the **packing factor *F***. The gas-handling capacity G of a packing is inversely proportional to the square root of F:

$$G = K/\sqrt{F} \tag{8}$$

where

G = mass flow rate of gases through scrubber
F = packing factor (surface area of packing per unit volume of gently poured material)

The smaller the packing factor of a given packing, the greater will be its gas-handling capacity. Typical packing factors for scrubber packings are summarized in Table 7.

Arrangements of Packed Scrubbers

The four generic arrangements for wet-packed scrubbers are illustrated in Figure 23:

- Horizontal cocurrent scrubber
- Vertical cocurrent scrubber
- Cross-flow scrubber
- Countercurrent scrubber

Cocurrent flow scrubbers can be operated with either horizontal or vertical gas and liquid flows. A **horizontal cocurrent scrubber** depends on the gas velocity to carry the liquid into the packed bed. It operates as a wetted entrainment separator with limited gas and liquid contact time. The superficial velocity of gases in the collector is limited by liquid reentrainment to about 3.3 m/s. A **vertical cocurrent scrubber** can be operated at very high pressure drop (800 to 2450 Pa per metre of packing depth) because there is no flooding limit for the superficial velocity. The contact time in a cocurrent scrubber is a function of bed depth. The effectiveness of absorption processes is lower in cocurrent scrubbers than in the

Table 7 Packing Factor *F* for Various Scrubber Packing Materials

		Nominal Size, mm				
Type of Packing	**Material**	**20**	**25**	**40**	**50**	**80 or 90**

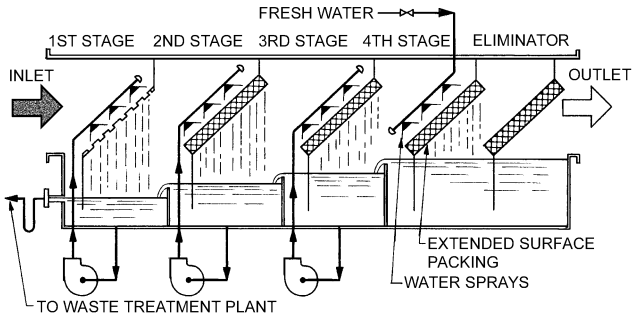

Fig. 25 Horizontal Flow Scrubber with Extended Surface

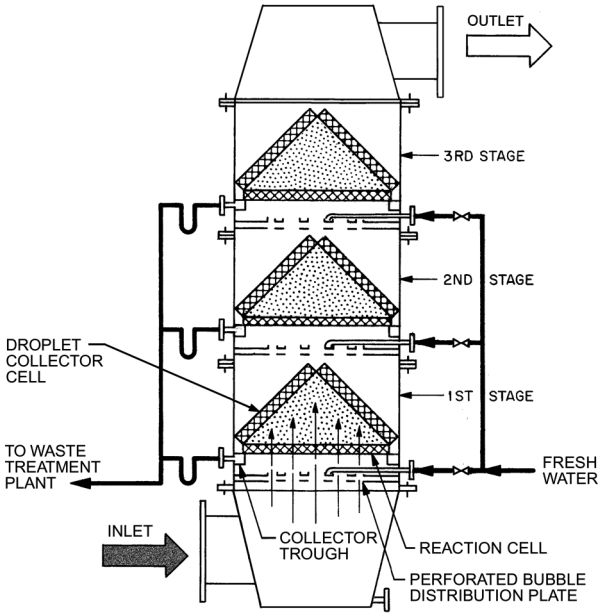

Fig. 26 Vertical Flow Scrubber with Extended Surface

other arrangements because the liquid containing contaminant is in contact with the exit gas stream.

Cross-flow scrubbers use downward-flowing liquid and a horizontally moving gas stream. The effectiveness of absorption processes in cross-flow scrubbers lies between those for cocurrent and countercurrent flow scrubbers.

Countercurrent scrubbers use a downward-flowing liquid and an upward-flowing gas. The gas-handling capacity of countercurrent scrubbers is limited by pressure drop or by liquid entrainment. Contact time can be controlled by the depth of packing used. The effectiveness of absorption processes is maximized because the exiting gas is in contact with fresh scrubbing liquid.

The most broadly used arrangement is the countercurrent packed scrubber. This type of scrubber, illustrated in Figure 24, gives the best removal of gaseous contaminants while keeping liquid consumption to a minimum. The effluent liquid has the highest contaminant concentration.

Extended-surface packings have been used successfully for the absorption of highly soluble gases such as HCl because the required contact time is minimal. This type of packing consists of a woven mat of fine fibers of a plastic material that is not affected by chemical exposure. Figure 25 shows an example of a scrubber consisting of three wetted stages of extended surface packing in series with the gas flow. A final dry mat is used as an entrainment eliminator. If solids are present in the inlet gas stream, a wetted impingement stage precedes the wetted mats to prevent plugging of the woven mats.

Figure 26 shows a scrubber with a vertical arrangement of extended surface packing. This design uses three complete stages in series with the gas flow. The horizontal mat at the bottom of each stage operates as a flooded bed scrubber. The flooded bed is used to minimize water consumption. The two inclined upper mats operate as entrainment eliminators.

Pressure Drop

The pressure drop through a particular packing in countercurrent scrubbers can be calculated from the airflow and water flow per unit area. Charts, such as the one shown in Figure 27, are available from manufacturers of each type and size of packing.

The pressure drop for any packing can also be estimated by using the data on packing factors in Table 7 and the modified generalized pressure drop correlation shown in Figure 28. This correlation was developed for a gas stream substantially of air, with water as the scrubbing liquid. It should not be used if the properties of the gas or liquid vary significantly from air or water, respectively. Countercurrent scrubbers are generally designed to operate at pressure drops between 200 and 530 Pa per metre of packing depth. Liquid irrigation rates typically vary between 3.4 and 13.6 L/s per square metre of bed area.

Absorption Efficiency

The prediction of the absorption efficiency of a packed bed scrubber is much more complex than estimating its capacity because performance estimates involve the mechanics of absorption.

Some of the factors affecting efficiency are superficial velocity of gases in the scrubber, liquid injection rate, packing size, type of packing, amount of contaminant to be removed, distribution and amount of absorbent available for reaction, temperature, and reaction rate for absorption.

Practically all commercial packings have been tested for absorption rate (mass transfer coefficient) using standard absorber conditions: carbon dioxide (CO_2) in air and a solution of caustic soda (NaOH) in water. This system was selected because the interaction of the variables is well understood. Further, the mass transfer coefficients for this system are low; thus, they can be determined accurately by experiment. The values of mass transfer coefficients ($K_G\,a$) for various packings under these standard test conditions are given in Table 8.

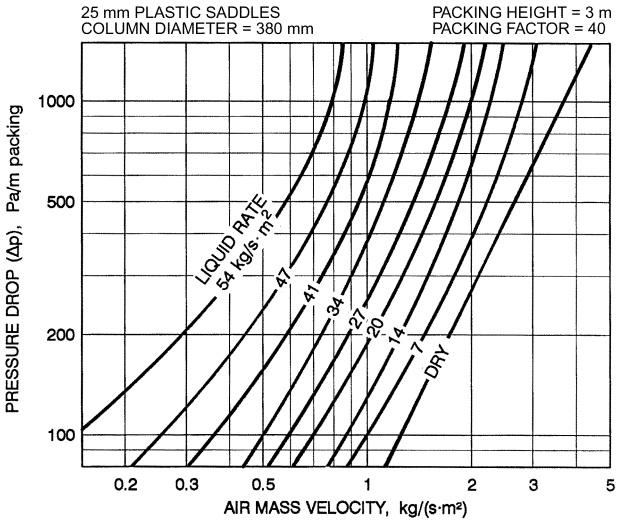

Fig. 27 Pressure Drop Versus Gas Rate for Typical Packing

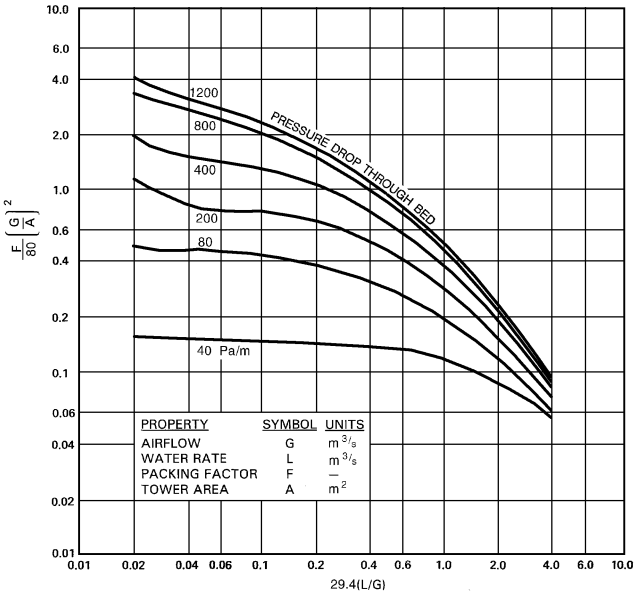

Fig. 28 Generalized Pressure Drop Curves for Packed Beds

The vast majority of wet absorbers are used to control low concentrations (less than 0.005 mole fraction) of contaminants in air. Dilute aqueous solutions of NaOH are usually chosen as the scrubbing fluid. These conditions simplify the design of scrubbers somewhat. Mass transfer from the gas to the liquid is then explained by the **two-film theory**: the gaseous contaminant travels by diffusion from the main gas stream through the gas film, then through the liquid film, and finally into the main liquid stream. The relative influences of the gas and liquid films on the absorption rate depend on the contaminant's solubility in the liquid. Sparingly soluble gases like hydrogen sulfide (H_2S) and CO_2 are said to be liquid-film-controlled; highly soluble gases such as HCl and ammonia (NH_3) are said to be gas-film-controlled. In liquid-film-controlled systems, the mass transfer coefficient varies with the liquid injection rate but is only slightly affected by the superficial velocity of the gases. In gas-film-controlled systems, the mass transfer coefficient is a function of both the superficial velocity of the gases and the liquid injection rate.

In the absence of leakage, the percentage by volume of the contaminant removed from the air can be found from the inlet and outlet concentrations of contaminant in the airstream:

$$\%\ \text{Removed} = 100(1 - Y_o/Y_i) \tag{9}$$

where

Y_i = mole fraction of contaminants entering scrubber (dry gas basis)
Y_o = mole fraction of contaminants exiting scrubber (dry gas basis)

The driving pressure for absorption (assuming negligible vapor pressure above the liquid) is controlled by the logarithmic mean of inlet and outlet concentrations of the contaminant:

$$\Delta p_{\ln} = p\frac{Y_i - Y_o}{\ln(Y_i/Y_o)} \tag{10}$$

where

$\Delta p_{\ln}$ = driving or diffusion pressure acting to absorb contaminants on packing
p = inlet pressure

The rate of absorption of contaminant (mass transfer coefficient) is related to the depth of packing as follows:

$$K_G a = N/HA\Delta p_{\ln} \tag{11}$$

where

N = solute absorbed, mol/s
H = depth of packing, m
A = cross-sectional area of scrubber, m^2

The value of N can be determined from

$$N = G(1 - Y_i - Y_o) \tag{12}$$

where G = mass flow rate of gases through scrubber, mol/s.

Table 8 Mass Transfer Coefficients ($K_G\,a$) for Scrubber Packing Materials

Type of Packing	Material	Nominal Size, mm			
		25	40	50	80 or 90
		$K_G a$, mol/(s·m³·kPa)			
Scalloped saddles	Plastic	0.096		0.063	0.039
Saddles	Ceramic	0.086	0.075	0.063	0.036
Perforated extended saddles	Plastic			0.063	0.039
Raschig rings	Ceramic	0.076	0.066	0.053	
Perforated rings	Metal	0.102	0.082	0.071	0.040
Perforated rings	Plastic	0.087	0.076	0.064	0.039
Large perforated rings	Metal	0.097	0.082	0.074	0.048
Toroidal helix	Plastic	0.096		0.087	

System: CO_2 and NaOH; gas rate: 0.67 kg/(m²·s); liquid rate: 2.7 kg/(m²·s).

The superficial velocity of gases is a function of the unit gas flow rate and the gas density:

$$V = TGM_v/C_1A \quad (13)$$

where

V = superficial gas velocity, m/s
M_v = molar volume, m^3/mol
T = exit gas temperature, K = °C + 273
C_1 = 273 K

By combining these equations and assuming ambient pressure, a graphical solution can be derived for both liquid-film- and gas-film-controlled systems. Figures 29, 30, and 31 show the height of packing required versus percent removal for various mass transfer coefficients at superficial velocities of 0.6, 1.2, and 1.8 m/s, respectively, with liquid-film-controlled systems. Figures 32, 33, and 34 show the height of packing versus percent removal for various mass transfer coefficients at the same three superficial velocities with gas film-controlled systems.

These graphs can be used to determine the height of 50 mm plastic saddles (see Figure 22) required to give the desired percentage of contaminant removal. The height for any other type or size of packing is inversely proportional to the ratio of standard $K_G a$ taken from Table 8. Thus, if 4.0 m packing depth were required for 95% removal of contaminants, the same efficiency could be obtained with a 2.9 m depth of 25 mm plastic perforated rings (Figure 22), at the same superficial velocity and liquid injection rate. However, the pressure drop would be higher for the smaller-diameter packing.

Figures 29 to 34 are useful when the value of the mass transfer coefficient for the particular contaminant to be removed is known. Table 9 contains mass transfer coefficients for 50 mm plastic scalloped saddles in typical liquid-film-controlled scrubbers. These values can be compared with the mass transfer coefficients in Table 10 for the same packing used in gas-film-controlled scrubbers. When the scrubbing liquid is not water, the mass transfer coefficients in these tables can only be used if the amount of reagent in the solution exceeds by at least 33% the amount needed to completely absorb the gaseous contaminant.

When HCl is dissolved in water, there is little vapor pressure of HCl above solutions of less than 8% (by mass) concentration. On the other hand, when NH_3 is dissolved in water, there is an appreciable vapor pressure of NH_3 above solutions, even at low concentrations. The height of packing needed for NH_3 removal, obtained from Figures 32 to 34, is based on the use of dilute acid to maintain the pH of the solution below 7.

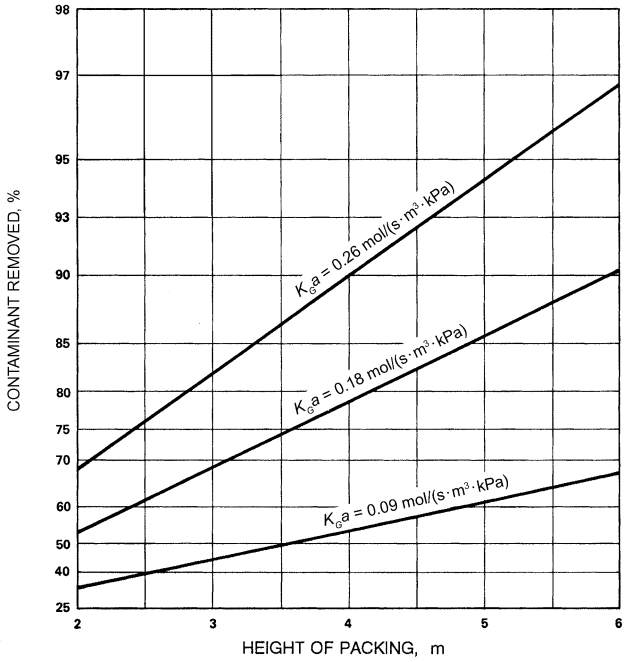

Fig. 30 Contaminant Control at Superficial Velocity = 1.2 m/s (Liquid-Film-Controlled)

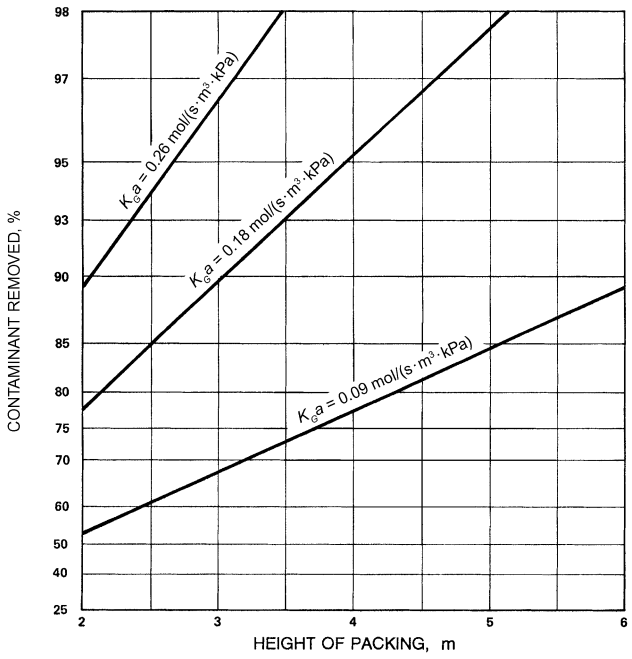

Fig. 29 Contaminant Control at Superficial Velocity = 0.6 m/s (Liquid-Film-Controlled)

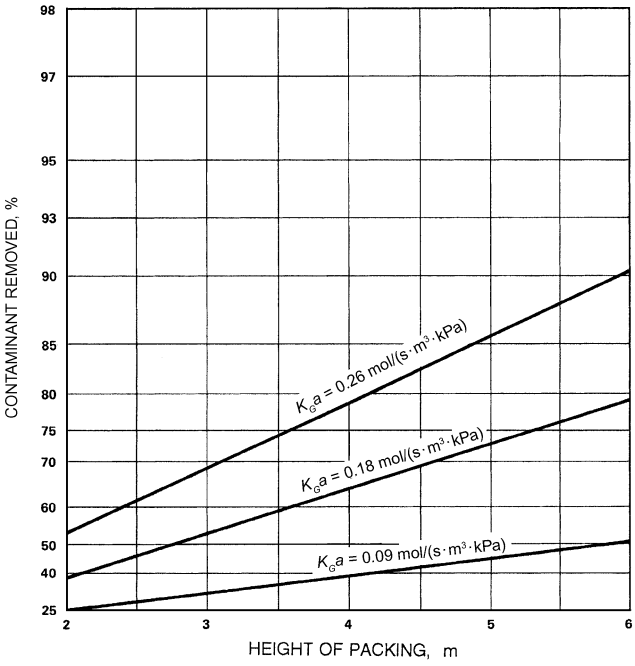

Fig. 31 Contaminant Control at Superficial Velocity = 1.8 m/s (Liquid-Film-Controlled)

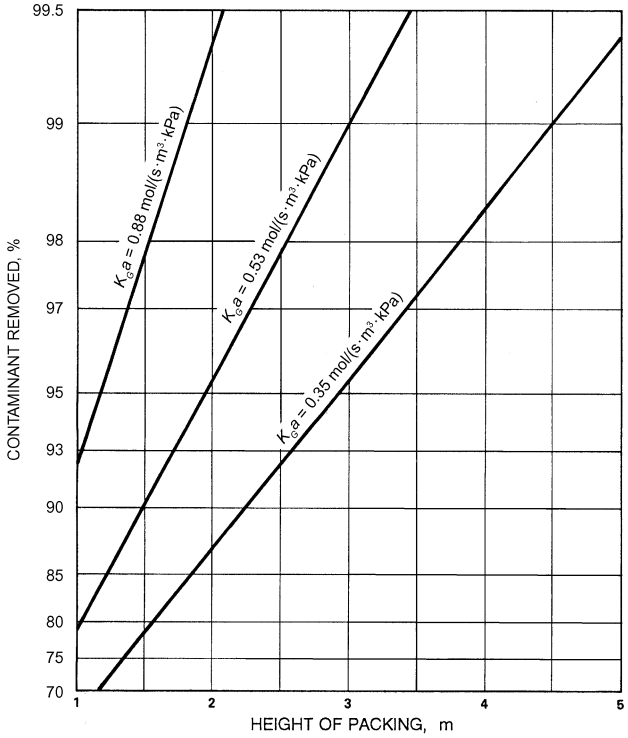

Fig. 32 Contaminant Control at Superficial Velocity = 0.6 m/s (Gas-Film-Controlled)

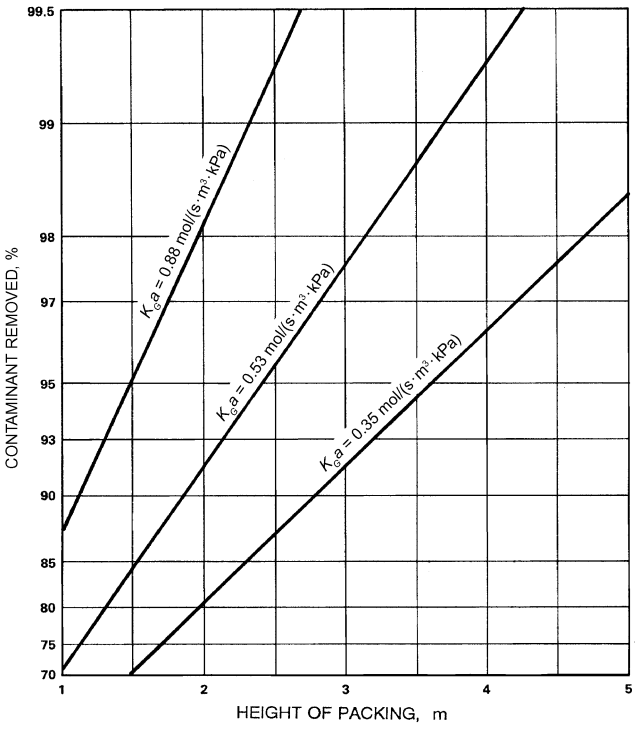

Fig. 33 Contaminant Control at Superficial Velocity = 1.2 m/s (Gas-Film-Controlled)

The following is an example of a typical scrubbing problem.

Example 1. Remove 95% of the HF from air at 30°C. The concentration of HF is 0.0006 mole fraction on a dry gas basis. The concentration of HF in the exhaust gas should not exceed 0.000 030 mole fraction.

The following design conditions apply:

Total volumetric flow of gas G = 2 m³/s
Liquid injection rate = 0.0025 m/s

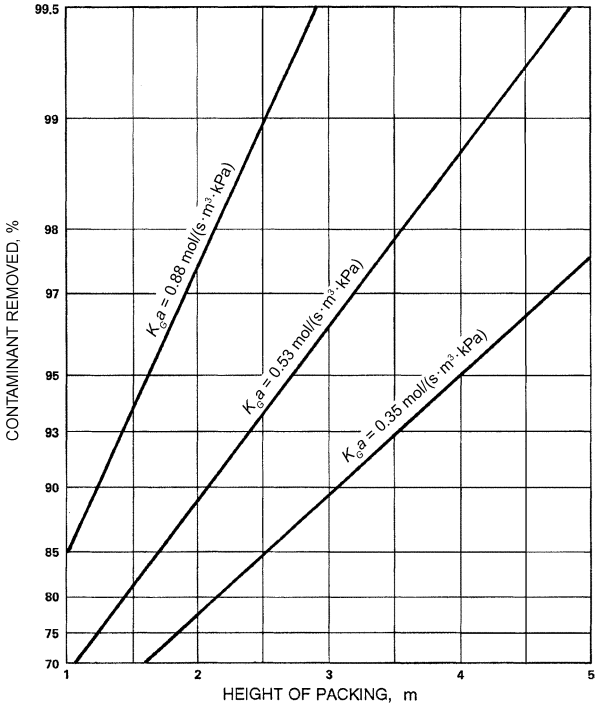

Fig. 34 Contaminant Control at Superficial Velocity = 1.8 m/s (Gas-Film-Controlled)

Table 9 Relative K_Ga for Various Contaminants in Liquid-Film-Controlled Scrubbers

Gas Contaminant	Scrubbing Liquid	K_Ga, mol/(s·m³·kPa)
CO_2	4% (by mass) NaOH	0.088
H_2S	4% (by mass) NaOH	0.26
SO_2	Water	0.13
HCN	Water	0.26
HCHO	Water	0.26
Cl_2	Water	0.2

Table 10 Relative K_Ga for Various Contaminants in Gas-Film-Controlled Scrubbers

Gas Contaminant	Scrubbing Liquid	K_Ga, mol/(s·m³·kPa)
HCl	Water	0.82
HBr	Water	0.26
HF	Water	0.35
NH_3	Water	0.76
Cl_2	8% (by mass) NaOH	0.63
SO_2	11% (by mass) Na_2CO_3	0.52
Br_2	5% (by mass) NaOH	0.22

Note: Data for 250 mm plastic scalloped saddles. Temperatures 16 to 24°C; liquid rate: 0.0068 m/s; gas rate: 1.1 m/s.

Liquid temperature = 20°C
Packed tower diameter = 1.5 m
Packing material is 50 mm polypropylene scalloped saddles

Solution:

Cross-sectional area of absorber

$$A = \pi(1.5/2)^2 = 1.77 \text{ m}^2$$

Total liquid flow rate

$$L = 0.0025 \times 1.77 = 0.00442 \text{ m}^3/\text{s}$$

Packing factor (from Table 7)

$$F = 21$$

Figure 29 may be used to find the pressure drop through the packed tower:

$$x\text{-axis} = 29.4(L/G) = 0.065$$
$$y\text{-axis} = (F/80)(G/A)^2 = 0.335$$

From Figure 28, the pressure drop is about 65 Pa per metre of packing depth.

From Table 10, $K_G a = 0.35$ for HF. From Figure 33, the depth of packing required for 95% removal is 4 m. Thus, the total pressure drop is 4 × 65 = 260 Pa.

General Efficiency Comparisons

Figure 33 indicates that, with $K_G a = 0.35$, 90% removal of HF could be achieved with 3.1 m of packing; this is 23% less packing than needed for 96% removal. Furthermore, with the same superficial velocity, both liquid-film- and gas-film-controlled systems require a 43% increase in absorbent depth to raise the removal efficiency from 80 to 90%.

A comparison of Figures 32 and 33 shows that increasing the superficial velocity by 50% in a gas-film-controlled scrubber requires only a 12% increase in bed depth to maintain equal removal efficiencies. In the liquid-film-controlled system (Figures 29 and 30), increasing the superficial velocity by 50% requires an approximately 50% increase in bed depth to maintain equal removal efficiencies.

Thus, in a gas-film-controlled system, the superficial velocity can be increased significantly with only a small increase in bed depth required to maintain the efficiency. In practical terms, gas-film-controlled scrubbers of fixed depth can handle an overload condition with only a minor loss of removal efficiency. Performance of liquid-film-controlled scrubbers degrades significantly under similar overload conditions. This occurs because the mass transfer coefficient is independent of superficial velocity.

Liquid Effects

Some liquids tend to foam when they are contaminated with particulates or soluble salts. In these cases, the pressure drop should be kept in the lower half of the normal range: 200 to 330 Pa per metre of packing depth.

In the control of gaseous pollution, most systems do not destroy the pollutant but merely remove it from the air. When water is used as the scrubbing liquid, effluent from the scrubber will contain suspended particulate or dissolved solute. Water treatment is often required to alter the pH and/or remove toxic substances before the solutions can be discharged.

3.3 ADSORPTION OF GASEOUS CONTAMINANTS

The surface of freshly broken or heated solids often contains van der Waals (London dispersion) forces that can physically or chemically adsorb nearby molecules in a gas or liquid. The captured molecules form a thin layer on the surface of the solid that is typically one to three molecules thick. Commercial adsorbents are solids with an enormous internal surface area. This large surface area enables them to capture and hold large numbers of molecules. For example, each gram of a typical activated carbon adsorbent contains over 1000 m^2 of internal surface area. Adsorbents are used for removing organic vapors, water vapor, odors, and hazardous pollutants from gas streams.

The most common adsorbents used in industrial processes include activated carbons, activated alumina, silica gel, and molecular sieves. Activated carbons are derived from coal, wood, or coconut shells. They are primarily selected to remove organic compounds in preference to water. The other three common gas-phase adsorbents have a great affinity for water and adsorb it to the exclusion of any organic molecules also present in a gas stream. They are used primarily as gas-drying agents. Molecular sieves also find use in several specialized pollution control applications, including removal of mercury vapor, sulfur dioxide (SO_2), or nitrogen oxides (NO_x) from gas streams. The capacity of a particular activated carbon to adsorb any organic vapor from mass of the organic compound and the temperature of the gas stream. Compounds with a higherrelative molecular mass are usually more strongly adsorbed than those with lower massThe capacity of activated carbon to adsorb any given organic compound increases with the concentration of that compound. Reducing the temperature also favors adsorption. Typical adsorption capacities of an activated carbon for toluene (relative molecular mass 92) and acetone (relative molecular mass 58) are illustrated in Figure 35 for various temperatures and concentrations.

Regeneration. Adsorption is reversible. An increase in temperature causes some or all of an adsorbed vapor to desorb. The temperature of low-pressure steam is sufficient to drive off most of a low-boiling-point organic compound previously adsorbed at ambient temperature. Higher-boiling-point organic compounds may require high-pressure steam or hot inert gas to secure good desorption. Compounds with a very highrelative molecular mass can require reactivation of the carbon adsorber in a furnace at 750°C to drive off all the adsorbed material. Regeneration of the carbon adsorbers can also be accomplished, in some instances, by washing with an aqueous solution of a chemical that will react with the adsorbed organic material, making it water soluble. An example is washing carbon containing adsorbed sulfur compounds with NaOH.

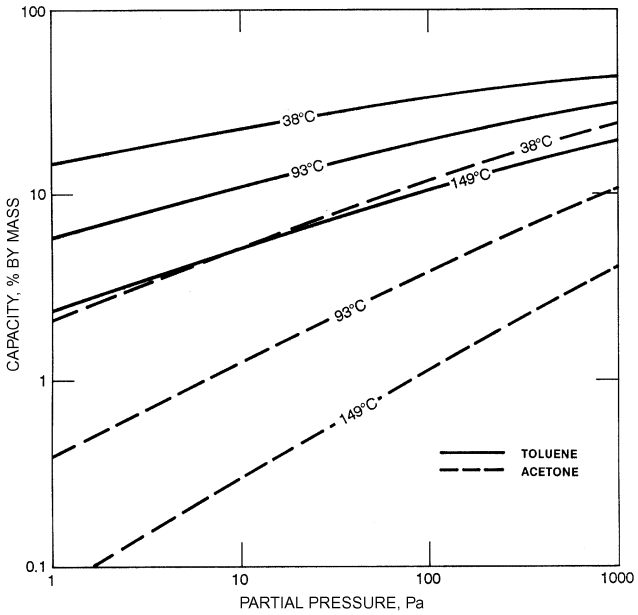

Fig. 35 Adsorption Isotherms on Activated Carbon

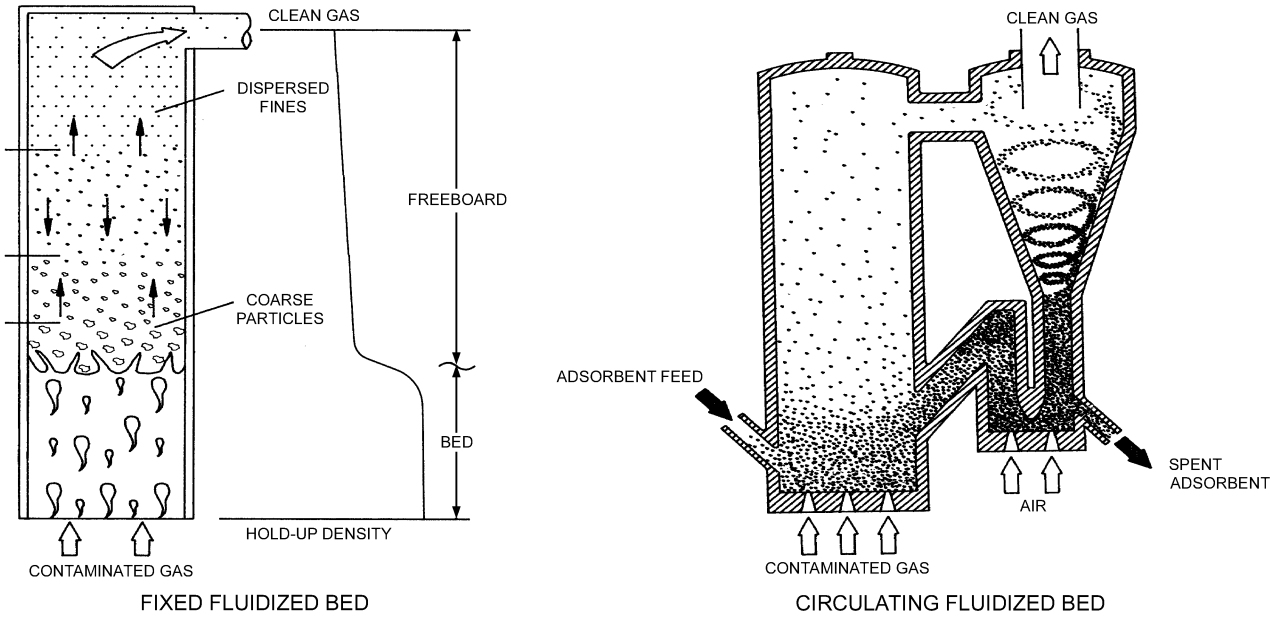

Fig. 36 Fluidized-Bed Adsorption Equipment

The difference between an adsorbent's capacity under adsorbing and desorbing conditions in any application is its **working capacity**. Activated carbon for air pollution control is found in canisters under the hoods of most automobiles. The adsorber in these canisters captures gasoline vapors escaping from fuel aspiration devices (when the engine is stopped) and from the fuel tank's breather vent. Gasoline vapors are desorbed by pulling fresh air through the carbon canister and into the carburetor when the engine is running. Although there is no temperature difference between adsorbing and desorbing conditions in this case, the outdoor airflow desorbs enough gasoline vapors to give the carbon a substantial working capacity.

For applications where only traces of a pollutant must be removed from exhaust air, the life of a carbon bed is very long. In these cases, it is often more economical to replace the carbon than to invest in regeneration equipment. Larger quantities can be returned to the carbon manufacturer for high-temperature thermal reactivation. Regeneration in place by steam, hot inert gas, or washing with a solution of alkali is sometimes practiced.

Impregnated (chemically reactive) adsorbents are used when physical adsorption alone is too weak to remove a particular gaseous contaminant from an industrial gas stream. Through impregnation, the reactive chemical is spread over the immense internal surface area of an adsorbent.

Typical applications of impregnated adsorbent include the following:

- Sulfur- or iodine-impregnated carbon removes mercury vapor from air, hydrogen, or other gases by forming mercuric sulfide or iodide.
- Metal oxide-impregnated carbons remove hydrogen sulfide.
- Amine- or iodine-impregnated carbons and silver exchanged zeolites remove radioactive methyl iodide from nuclear power plant work areas and exhaust gases.
- Alkali-impregnated carbons remove acid gases.
- Activated alumina impregnated with potassium permanganate removes acrolein and formaldehyde.

Equipment for Adsorption

Three types of adsorbers are usually found in industrial applications: (1) fixed beds, (2) moving beds, and (3) fluidized beds (Figure 36).

Fixed beds of regenerable or disposable media are most common. Carbon filter elements are a typical example.

Moving beds use granular adsorbers placed on inclined trays or on vertical frames similar to those used in granular bed particulate collectors. Moving beds offer continuous contaminant control and regeneration. Often, moving bed adsorbers and regeneration equipment are integrated components in a process.

Fluidized beds contain a fine granular adsorber, which is continuously mixed with the contaminated gas by suspension in the process gas stream. The bed may be either "fixed" at lower superficial velocities or highly turbulent and conveying (circulating). Illustrations of these types of fluidized beds are shown in Figure 36.

Solvent Recovery

The most common use of adsorption in stationary sources is in recovering solvent vapors from manufacturing and cleaning processes. Typical applications include solvent degreasing, rotogravure printing, dry cleaning, and the manufacture of such products as synthetic fibers, adhesive labels, tapes, coated copying paper, rubber goods, and coated fabrics.

Figure 37 illustrates the components of a typical solvent recovery system using two carbon beds. One bed is used as an adsorber while the other is regenerated with low-pressure steam. Desorbed solvent vapor and steam are recovered in a water-cooled condenser. If the solvent is immiscible with water, an automatic decanter separates the solvent for reuse. A distillation column is used for water-miscible solvents.

Adsorption time per cycle typically runs from 30 min to several hours. The adsorbing carbon bed is switched to regeneration by (1) an automatic timer shortly before the solvent vapor breaks through from the bed or (2) an organic vapor-sensing control device in the exhaust gas stream immediately after the solvent breaks through from the bed.

Low-pressure steam consumption for regeneration is generally about 2.2 kW per kilogram of solvent recovered (Boll 1976), but it

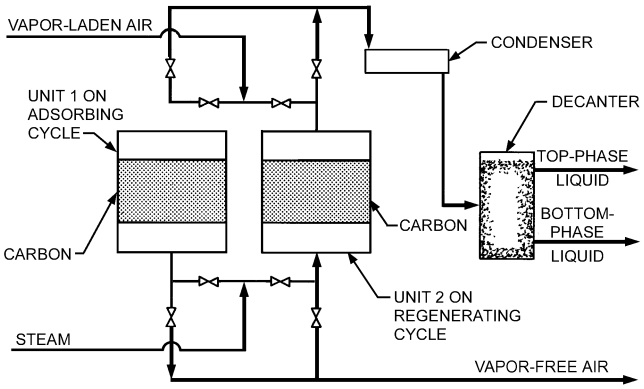

Fig. 37 Schematic of Two-Unit Fixed Bed Adsorber

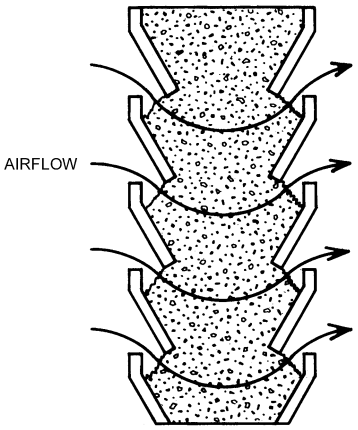

Fig. 38 Moving-Bed Adsorber

can range from 1.3 to over 3 kW per kilogram of solvent recovered, depending on the specific solvent and its concentration in the exhaust gas stream being stripped. Steam with only a slight superheat is normally used, so that it condenses quickly and gives rapid heat transfer.

After steaming, the hot, moist carbon bed is usually cooled and partially dried before being placed back on stream. Heat for drying is supplied by the cooling of the carbon and adsorber, and sometimes by an external air heater. In most cases, it is desirable to leave some moisture in the bed. When solvent vapors are adsorbed, heat is generated. For most common solvents, the heat of adsorption is 90 to 140 J/mol. When high-concentration vapors are adsorbed in a dry carbon bed, this heat can cause a substantial temperature rise and can even ignite the bed, unless it is controlled. If the bed contains moisture, the water absorbs energy and helps to prevent an undue rise in bed temperature. Certain applications may require heat sensors and automatic sprinklers.

Because the adsorptive capacity of activated carbon depends on temperature, it is important that solvent-laden air going to a recovery unit be as cool as is practicable. The exhaust gases from many solvent-emitting processes (such as drying ovens) are at elevated temperatures. Water- or air-cooled heat exchangers must be installed to reduce the temperature of the gas that enters the adsorber.

Solvent at very low vapor concentrations can be recovered in an activated carbon system. The size and cost of the recovery unit, however, depend on the volume of air to be handled; it is thus advantageous to minimize the volume of an exhaust stream and keep the solvent vapor concentration as high as possible, consistent with safety requirements. Insurance carriers specify that solvent vapor concentrations must not exceed 25% of the lower explosive limit (LEL) when intermittent monitoring is used. With continuous monitoring, concentrations as high as 50% of the LEL are permissible.

Solvent recovery systems, with gas-handling capacities up to about 5 m^3/s, are available as skid-mounted packages. Several of these packaged units can be used for larger gas flows. Custom systems can be built to handle 100 m^3/s or more of gas. Materials of construction may be painted carbon steel, stainless steel, Monel, or even titanium, depending on the nature of the gas mixture. The activated carbon is usually placed in horizontal flat beds or vertical cylindrical beds. The latter design minimizes ground space required for the system. Other alternatives are possible; one manufacturer uses a segmented horizontal rotating cylinder of carbon in which one segment is adsorbing while others are being steamed and cooled.

Commercial-scale solvent recovery systems typically recover over 99% of the solvent contained in a gas stream. The efficiency of the collecting hoods at the source of the solvent emission is usually the determining factor in solvent recovery.

Dust filters are generally placed ahead of carbon beds to prevent blinding of the adsorber by dust. Occasionally, the carbon is removed for screening to eliminate accumulated dust and fine particles of carbon.

If the solvent mixture contains high-boiling-point components, the working capacity of activated carbon can decrease with time. This occurs when high-boiling-point organic compounds are only partially removed by low-pressure steam. In this situation, two alternatives should be considered:

1. Periodic removal of the carbon and return to its manufacturer for high-temperature furnace reactivation to virgin carbon activity.
2. Use of more rigorous solvent desorbing conditions in the solvent recovery system. High-temperature steam, hot inert gas, or a combination of electrical heating and application of a vacuum may be used. The last method is selected, for example, to recover lithography ink solvents with high boiling points. Note that this method may not remove all of the high-boiling-point compounds.

Odor Control

Incineration and scrubbing are usually the most economical methods of controlling high concentrations of odorous compounds from equipment such as cookers in rendering plants. However, many odors that arise from harmlessly low concentrations of vapors are still offensive. The odor threshold (for 100% response) of acrolein in air, for example, is only 0.21 ppm, whereas that for ethyl mercaptan is 0.001 ppm and that for hydrogen sulfide is 0.0005 ppm (AIHA 1989; MCA 1968). Activated carbon beds effectively overcome many odor emission problems. Activated carbon is used to control odors from chemical and pharmaceutical manufacturing operations, foundries, sewage treating plants, oil and chemical storage tanks, lacquer drying ovens, food processing plants, and rendering plants. In some of these applications, activated carbon is the sole odor control method; in others, the carbon adsorber is applied to the exhaust from a scrubber.

Odor control systems using activated carbon can be as simple as a steel drum fitted with appropriate gas inlet and outlet ducts, or as complex as a large, vertically moving bed, in which carbon is contained between louvered side panels. A typical moving-bed adsorber is shown in Figure 38. In this arrangement, fresh carbon can be added at the top, and spent or dust-laden carbon is periodically removed from the bottom.

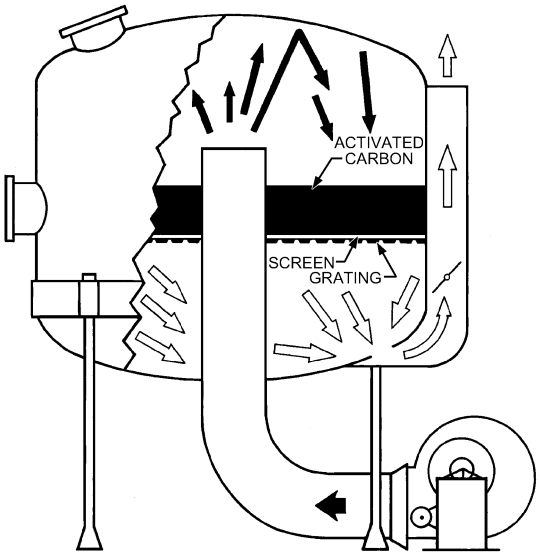

Fig. 39 Typical Odor Adsorber

Figure 39 shows a fixed-bed odor adsorber. Adsorbers of this general configuration are available as packaged systems, complete with motor and blower. Air-handling capacities range from 0.2 to 6 m^3/s.

The life of activated carbon in odor control systems ranges from a few weeks to a year or more, depending on the concentration of the odorous emission.

Applications of Fluidized Bed Adsorbers

The injection of alkali compounds into fluidized bed combustors for control of sulfur-containing compounds is one example of the use of fluidized bed adsorbers. Another example is the control of HF emissions from Søderberg aluminum reduction processes by a fixed or circulating fluidized bed of alumina.

3.4 INCINERATION OF GASES AND VAPORS

Incineration is the process by which volatile organic compounds (VOCs), organic aerosols, and most odorous materials in a contaminated gas stream are converted to innocuous carbon dioxide and water vapor using heat energy. Incineration is an effective means for totally eliminating VOCs. The types of incineration commonly used for air pollution control are thermal and catalytic, sometimes with recuperative or regenerative heat recovery.

To differentiate such air-cleaning systems from liquid and solid waste incinerators, the preferred term to describe such gas and aerosol phase air pollution control systems is now **oxidizers**.

Thermal Oxidizers

Thermal oxidizers, also known as **afterburners** or **direct flame incinerators**, consist of an insulated oxidation chamber in which gas and/or oil burners are typically located. The contaminated gas stream enters the chamber and comes into direct contact with the flame, which provides the heat energy necessary to promote oxidation. Under the proper conditions of time, temperature, and turbulence, the gas stream contaminants are oxidized effectively. The contaminated gas stream enters the combustion chamber near the burner, where turbulence-inducing devices are usually installed. The final contaminant conversion efficiency largely depends on good mixing in the contaminated gas stream and on the temperature of the oxidation chamber.

Supplemental fuel is used for start-up, to raise the temperature of the contaminated gas stream enough to initiate contaminant oxidation. Once oxidation begins, the temperature rises further because of the energy released by combustion of the contaminant. The supplementary fuel feed rate is then modulated to maintain the desired oxidizer operating temperature. Most organic gases oxidize to approximately 90% conversion efficiency if a temperature of at least 650°C and a residence time of 0.3 to 0.5 s are achieved in the oxidation chamber. However, oxidation temperatures are typically maintained in the range of 760 to 820°C with residence times of 0.5 to 1 s to ensure conversion efficiencies of 95% or greater.

Although the efficiency of thermal oxidizers can exceed 95% destruction of the contaminant, the reaction may form undesirable products of combustion. For example, oxidation of chlorinated hydrocarbons causes the formation of hydrogen chloride, which can have an adverse effect on equipment. These new contaminants then require additional controls.

Oxidation systems incorporate primary heat recovery to preheat the incoming contaminated gas stream and, in some cases, provide secondary heat recovery for process or building heating. Primary heat recovery is almost always achieved using air-to-air heat exchangers. Use of a regenerable, ceramic medium for heat recovery has increased due to superior heat recovery efficiency. Secondary heat recovery may incorporate an air-to-air heat exchanger or a waste heat boiler (DOE 1979).

Oxidation systems using conventional air-to-air heat exchangers can achieve up to 80% heat recovery efficiency. Regenerative heat exchanger units have claimed as high as 95% heat recovery efficiency and are routinely operated at 85 to 90%. When operated at these high heat recovery efficiencies and with inlet VOC concentrations of 15 to 25% of the LEL, the oxidation process approaches a self-sustaining condition, requiring very little supplementary fuel.

Catalytic Oxidizers

Catalytic oxidizers operate under the same principles as thermal oxidizers, except that they use a catalyst to promote oxidation. The catalyst allows oxidation to occur at lower temperatures than in a thermal oxidizer for the same VOC concentration. Therefore, catalytic oxidizers require less supplemental fuel to preheat the contaminated gas stream and have lower overall operating temperatures.

A catalytic oxidizer generally consists of a preheat chamber followed by the catalyst bed. Residence time and turbulence are not as important as with thermal oxidizers, but it is essential that the contaminated gas stream be heated uniformly to the required catalytic reaction temperature. The required temperature varies, depending on the catalyst material and configuration.

The temperature of the contaminated gas stream is raised in the preheat chamber by a conventional burner. Although the contaminated gas stream contacts the burner flame, the heat input is significantly less than that for a thermal oxidizer, and only a small degree of direct contaminant oxidation occurs. Natural gas is preferred to prevent catalyst contamination, which could occur with sulfur-bearing fuel oils. However, No. 2 fuel oil units have been operated successfully. The most effective catalysts contain noble metals such as platinum or palladium.

Catalysis occurs at the molecular level. Therefore, an available, active catalyst surface area is important for maintaining high conversion efficiencies. If particulate materials contact the catalyst as either discrete or partially oxidized aerosols, they can ash on the catalyst surface and blind it. This problem is usually accompanied by a secondary pollution problem: odorous emissions caused by the partially oxidized organic compounds.

The greatest concern to users of catalytic oxidizers is **catalyst poisoning or deactivation**. Poisoning is caused by specific gas stream contaminants that chemically combine or alloy with the

active catalyst material. Poisons frequently cited include phosphorus, bismuth, arsenic, antimony, lead, tin, and zinc. The first five materials are considered fast-acting poisons and must be excluded from the contaminated gas stream. Even trace quantities of the fast-acting poisons can cause rapid catalyst deactivation. The last two materials are slow-acting poisons; catalysts are somewhat tolerant of these materials, particularly at temperatures lower than 540°C. However, even the slow poisons should be excluded from the contaminated gas stream to ensure continuous, reliable performance. Therefore, galvanized steel, another possible source of the slow poisons, should not be used for the duct leading to the oxidizer.

Sulfur and halogens are also regarded as catalyst poisons. In most cases, their chemical interaction with the active catalyst material is reversible. That is, catalyst activity can be restored by operating the catalyst without the halogen or sulfur-bearing compound in the gas stream. The potential problem of greater concern with respect to the halogen-bearing compounds is the formation of hydrogen chloride or hydrogen fluoride gas, or hydrochloric or hydrofluoric acid emissions.

Some organic compounds, such as polyester amides and imides, are also poisonous.

Catalytic oxidizers generally cost less to operate than thermal oxidizers because of their lower fuel consumption. With the exception of regenerative heat recovery techniques, primary and secondary heat recovery can be incorporated into a catalytic oxidation system to further reduce operating costs. Maintenance costs are usually higher for catalytic units, particularly if frequent catalyst cleaning or replacement is necessary. Concern over catalyst life has been the major factor limiting more widespread application of catalytic oxidizers.

Applications of Oxidizers

Odor Control. All highly odorous pollutant gases are combustible or chemically changed to less odorous pollutants when they are sufficiently heated. Often, the concentration of odorous materials in the waste gas is extremely low, and the only feasible method of control is oxidation. Odors from rendering plants, mercaptans, and organic sulfides from kraft pulping operations are examples of effluents that can be controlled by incineration. Other forms of oxidation can achieve the same ends (see Chapter 47 of the 2023 *ASHRAE Handbook—HVAC Applications*).

Reduction in Emissions of Reactive Hydrocarbons. Some air pollution control agencies regulate the emission of organic gases and vapors because of their involvement in photochemical smog reactions. Flame afterburning is an effective way of destroying these materials.

Reduction in Explosion Hazard. Refineries and chemical plants are among the factories that must dispose of highly combustible or otherwise dangerous organic materials. The safest method of disposal is usually by burning in flares or in specially designed furnaces. However, special precautions and equipment design must be used in the handling of potentially explosive mixtures.

Adsorption and Oxidation

Alternate cycles of adsorption and desorption in an activated carbon bed are used to concentrate solvent or odor vapors before oxidation. This technique greatly reduces the fuel required for burning organic vapor emissions. Fuel savings of 98% compared to direct oxidation are possible. The process is particularly useful in cases where emission levels vary from hour to hour. This technique is common in metal finishing for automotive and office furniture manufacturing.

Contaminated gas is passed through a carbon bed until saturation occurs. The gas stream is then switched to another carbon bed, and the exhausted bed is shut down for desorption. A hot inert gas, usually burner flue gas, is introduced to the adsorber to drive off concentrated organic vapors and to convey them to an oxidizer. The volume of this desorbing gas stream is much smaller than the original contaminated gas volume, so that only a small oxidizer, operating intermittently, is required (Grandjacques 1977).

4. AUXILIARY EQUIPMENT

4.1 DUCTS

Basic duct design is covered in Chapter 21 of the 2021 *ASHRAE Handbook—Fundamentals*. This chapter covers only those duct components or problems that warrant special concern when handling gases that contain particulate or gaseous contaminants.

Duct systems should be designed to allow thermal expansion or contraction as gases move from the process, through gas-cleaning equipment, and on to the ambient environment. Appropriately designed duct expansion joints must be located in proper relation to sliding and fixed duct supports. Besides withstanding maximum possible temperature, duct must also withstand maximum positive or negative pressure, a partial load of accumulated dust, and reasonable amounts of corrosion. Duct supports should be designed to accommodate these overload conditions as well. Bottom entries into duct junctions create a low-velocity area that can allow contaminants to settle out, thus creating a potential fire hazard. Bottom duct entries should be avoided.

Where gases might condense and cause corrosion or sticky deposits, duct should be insulated or fabricated from materials that will survive this environment. A psychrometric analysis of the exhaust gases is useful to determine the dew point. Surface temperatures should then be held above the dew-point temperature by preheating on start-up or by insulating. Slag traps with clean-out doors, inspection doors where direction changes, and dead-end full-sized caps are required for systems having heavy particulate loading. Special attention should be given to high-temperature duct, where the duct might corrode if insulated or become encrusted when molten particulate impacts on cool, uninsulated surfaces. Water-cooled duct or refractory lining is often used where the high operating temperature exceeds the safe limits of low-cost materials.

Gas flow through ducts should be considered as a part of overall system design. Good gas flow distribution is essential for measurements of process conditions and can lead to energy savings and increased system life. The minimum speed of gases in a duct should be sufficiently high to convey the heaviest particulate fraction with a degree of safety.

Slide gates, balance gates, equipment bypass ducts, and clean-out doors should be incorporated in the duct system to allow for maintenance of key gas-cleaning systems. In some cases, emergency bypass circuitry should be included to vent emissions and protect gas-cleaning equipment from process upsets.

Temperature Controls

Control of gas temperature in a gas-cleaning system is often vital to a system's performance and life. In some cases, gases are cooled to concentrate contaminants, condense gases, and recover energy. In other cases, gas-cleaning equipment, such as fabric filters and scrubbers, can only operate at well-controlled temperatures. Cooling exhaust gases through air-to-air heat transfer has been highly successful in many applications. Controlled evaporative cooling is also used, but it increases the dew point and the danger of acid gas condensation and/or the formation of sticky deposits. However, controlled evaporative cooling to within 28 K of dew point has been used with success. Dilution by injecting ambient air into the duct is expensive because it increases the volumetric flow of gas and, consequently, the size of collector needed to meet gas-cleaning objectives. Water-cooled duct is often used where the gas temperature exceeds the safe limits of the low-cost materials.

For dilution cooling, louver-type dampers are often used to inject ambient air and provide fine temperature control. Controls can be used to provide full modulation of the damper or to provide open or closed operation. Emergency bypass damper systems and bypass duct/stacks are used where limiting excessive temperature is critical.

Fans

Because static pressure across a gas-cleaning device varies depending on conditions, the fan should operate on the steep portion of the fan pressure-volumetric flow curve. This tends to provide less variation in the volumetric flow. An undersized fan has a steeper characteristic than an oversized fan for the same duty; however, it will be noisier.

In the preferred arrangement, the fan is located on the clean gas side of gas-cleaning equipment. Advantages of placing the fan at this point include the following:

- A fan on the clean gas side handles clean gases and minimizes abrasive exposure from the collected product.
- High-efficiency backward-blade and airfoil designs can be selected because accumulation on the fan wheel is not as great a factor.
- Escape of hazardous materials through leaks is minimized.
- The collector can be installed inside the plant, even near the process, because any leakage in the duct or collector will be into the system and will not increase the potential for exposure. However, the fan itself should be mounted outdoors, so that the positive-pressure duct is outside the work environment.

For economic reasons, a fan may be located on the contaminant-laden side of the gas-cleaning equipment if the contaminants are relatively nonabrasive, and especially if the equipment can be located outdoors. This arrangement should be avoided because of the potential for leakage of concentrated contaminants to the environment. In some instances, however, the collector housing design, duct design, and energy savings of this arrangement reduce costs.

Most scrubbers are operated on the suction side of the fan. This not only eliminates leakage of contaminants into the work area, but also allows for servicing the unit while it is in operation. Additionally, such an arrangement minimizes corrosion of the fan. Stacks on the exhaust streams of scrubbers should be arranged to drain condensate rather than allow it to accumulate and reenter the fan.

Fabric filters require special consideration. When new, clean fabric is installed in a collector, the resistance is low, and the fan motor may be overloaded. This overloading may be prevented during start-up by using a temporary throttling damper in the main duct, for example, on the clean side of the filter in a pull-through system. Overloading may also be prevented by using a backward-curved blade (nonoverloading fan) on the clean side of the collector.

4.2 DUST- AND SLURRY-HANDLING EQUIPMENT

Once the particulate matter is collected, new control problems arise from the need to remove, transport, and dispose of material from the collector. A study of all potential methods for handling the collected material, which might be a hazardous waste, must be an integral part of initial system design.

Hoppers

Dust collector hoppers are intended only to channel collected material to the hopper's outlet, where it is continuously discharged. When hoppers are used to store dust, the plates and charging electrodes of electrostatic precipitators can be shorted electrically, resulting in failure of entire electrical sections. Fabric collectors, particularly those that have the gas inlet in the hopper, are usually designed on the assumption that the hopper is not used for storage and that collected waste is continuously removed. High dust levels in the hoppers of fabric collectors often result in high dust reentrainment. This reentrainment causes increased operating pressure and the potential for fabric damage. Excessive dust levels not only expose the system to potentially corrosive conditions and fire/explosion hazards, but also place increased structural demands on the system.

Aside from misuse of hoppers for storage, common problems with dust-handling equipment include (1) plugging of hoppers, (2) blockage of dust valves with solid objects, and (3) improper or insufficient maintenance.

Hopper auxiliaries to be considered include (1) insulation, (2) dust level indicators, (3) rapper plates, (4) vibrators, (5) heaters, and (6) "poke" holes.

Hopper Discharge. Dust is often removed continuously from hoppers by means of rotary valves. Alternative equipment includes the double-flap valve, or vacuum system valves. Wet electrostatic precipitators and scrubbers often use sluice valves and drains to ensure that insoluble particulate remains in suspension during discharge.

Dust Conveyors

Larger dust collectors are fitted with one or more conveyors to feed dust to a central discharge location or to return it to a process. Drag, screw, and pneumatic conveyors are commonly used with dust collectors. Sequential start-up of conveyor systems is essential. Motion switches to monitor operation of the conveyor are useful.

Dust Disposal

Several methods are available for disposal of collected dust. It can be emptied into dumpsters in its as-collected dry form or be pelletized and hauled to a landfill. It can also be converted to a slurry and pumped to a settling pond or to clarification equipment. The advantages and disadvantages of each method are beyond the scope of this chapter, but they should be evaluated for each application.

Slurry Treatment

When slurry from wet collectors cannot be returned directly to the process or tailing pond, liquid clarification and treatment systems can be used for recycling the water to prevent stream pollution. Stringent stream pollution regulations make even a small discharge of bleed water a problem. Clarification equipment may include settling tanks, sludge-handling facilities, and, possibly, centrifuges or vacuum filters. Provisions must be provided for handling and disposal of dewatered sludge, so that secondary pollution problems do not develop.

5. OPERATION AND MAINTENANCE

A planned program for operation and maintenance of equipment is a necessity. Such programs are becoming mandatory because of the need for operators to prove continuous compliance with emission and safety regulations. Good housekeeping and record-keeping will also help prolong the life of the equipment, support a program for positive relations with regulatory and community groups, and aid problem-solving efforts, should nonroutine maintenance or service be necessary.

A typical program includes the following minimum requirements (Stern et al. 1984):

- Central location for filing equipment records, warranties, instruction manuals, etc.
- Lubrication and cleaning schedules
- Planning and scheduling of preventive maintenance (including inspection and major repair)
- Storeroom and inventory system for spare parts and supplies
- Listing of maintenance personnel (including supplier contacts and consultants)

- Costs and budgets for activities associated with operation and maintenance of the equipment
- Storage for special tools and equipment

Industry standards have implemented safety requirements. A typical program includes the following minimum requirements (Stern et al. 1984):

- Using a central location for filing equipment records, warranties, instruction manuals, etc.
- Following lubrication and cleaning schedules
- Planning, scheduling, and performing preventive maintenance (including inspection and major repair)
- Maintaining a storeroom and inventory system for spare parts and supplies

For air pollution control and gas cleaning, the following items are more commonly needed to ensure the system is performing properly. These tasks are performed anywhere from daily to annually, depending on local needs, and can vary depending on the type of system installed:

- Inspections for leaks, moisture, dust accumulation, and abrasion
- System performance checks (operating performance points, discharges, inlets, outlets, system pressures, cleaning systems, airflows, etc.)
- Corrosion and electrical component checks

Corrosion

Because high-temperature gas cleaning often involves corrosive materials, chemical attack on system components must be anticipated. This is especially true if the temperature in a gas-cleaning system falls below the moisture or acid dew point. Housing insulation should be such that the internal metal surface temperature is 11 to 17 K greater than the moisture and/or acid dew point at all times. In applications with fabric filters where alkali materials are injected into the gas stream to react with acid gases, care must be taken to protect the clean side of the housing downstream of the fabric from corrosion.

Fires and Explosions

Air pollution control and industrial gas-cleaning systems often concentrate combustible materials and expose them to environments that are hostile and difficult to control. These environments also make fires difficult to detect and stop. These systems are, therefore, potential fire or explosion hazards (Billings and Wilder 1970; EEI 1980; Frank 1981).

Fires and explosions in industrial process exhaust streams are not generally limited to gas-cleaning equipment. Ignition may take place in the process itself, in the duct, or in exhaust system components other than the gas-cleaning equipment. Once uncontrolled combustion begins, it may propagate throughout the system.

The National Fire Protection Agency (NFPA) maintains the minimum standards for fire and other hazard prevention. The following are the main guidelines applicable to air pollution control and industrial gas cleaning, but it is possible more standards and codes are applicable, depending on the process. NFPA 68 and 69 are standards and guides to system protection; the others address fundamentals and industry specific combustible dust handling and hazard identification. Hazard identification is a requirement per NFPA 652, noting that any facility handling combustible dust perform a dust hazard analysis (DHA), which is a formalized process for identifying and evaluating the fire, deflagration, and explosion hazards associated with the dust and process, as well as providing recommendations on how to manage these.

NFPA 68, Standard on explosion protection by deflagration venting. Focuses on explosion venting on devises and systems that vent combustion gases and pressures resulting from a deflagration within an enclosure in order to minimize structural and mechanical damage.

NFPA 69, Standard on explosion prevention systems. Covers explosion protection of systems when venting is not possible. It incudes several prevention methods such as explosion suppression, deflagration pressure containment, and spark extinguishing systems.

NFPA 660 (Upcoming). Scheduled for release in autumn 2025, this new standard combines previous codes providing both fundamental and industry-specific standards for managing combustible dust, to promote best practices to safeguard facilities from related fires and dust explosions. These previous standards include

- 652, Standard on the fundamentals of combustible dust
- 654, Standard for the prevention of fire and dust explosions from the manufacturing, processing, and handling of combustible particulate solids
- 61, Standard for the prevention of fires and dust explosions in agricultural and food processing facilities
- 484, Standard for combustible metals
- 664, Standard for the prevention of fires and explosions in wood processing and woodworking facilities
- 655, Standard for the prevention of sulfur fires and explosions

NFPA Recommended Practices

- 77. Offers guidance on identifying, evaluating and controlling static electric hazards
- 499. For the classification of combustible dusts and hazardous (classified) locations for electrical installations in chemical process areas

Safety Controls and Interlocks 31.20
Operating Controls 31.21

FUEL-BURNING systems provide a means to mix fuel and air in the proper ratio, ignite it, control the position of the flame envelope within the combustion chamber, and control a fuel flow rate for safe combustion-heat energy release for space conditioning, water heating, and other processes. This chapter covers the design and use of automatic fuel-burning systems. The fuel can be gaseous (e.g., natural or liquefied petroleum gas), liquid (primarily the lighter grades of fuel oil or biodiesel), or solid (e.g., coal, or renewable items such as wood or corn). For discussion of some of these fuels, their combustion chemistry, and thermodynamics, see Chapter 28 of the 2021 *ASHRAE Handbook—Fundamentals*.

1. GENERAL CONSIDERATIONS

1.1 TERMINOLOGY

The following terminology for combustion systems, equipment, and fuel-fired appliances is consistent with usage in gas-fired appliance standards of the American National Standards Institute (ANSI) and Canadian Standards Association, the National Fire Protection Association's *National Fuel Gas Code* (ANSI *Standard* Z223.1/NFPA *Standard* 54), and the Canadian Standards Association's *Natural Gas and Propane Installation Code* (CSA *Standard* B149.1).

Air, circulating. Air distributed to habitable spaces for heating, cooling, or ventilation.

Air, dilution. Air that enters a draft hood or draft regulator and mixes with flue gas.

Air, excess. Air that passes through the combustion chamber in excess of the amount required for complete (stoichiometric) combustion.

Air, primary. Air introduced into a burner that mixes with fuel gas before the mixture reaches the burner ports.

Air, secondary. Air supplied to the combustion zone downstream of the burner ports.

Appliance. Any device that uses a gas, a liquid, or a solid as a fuel or raw material to produce light, heat, power, refrigeration, or air conditioning.

Draft. Negative static pressure, measured relative to atmospheric pressure; thus, positive draft is negative static pressure. Draft is the force (buoyancy of hot flue gas or other form of energy) that produces flow and causes pressure drop through an appliance combustion system and/or vent system. See Chapter 34 for additional information.

Equipment. Devices other than appliances, such as supply piping, service regulators, sediment traps, and vents in buildings.

Flue. General term for passages and conduit through which flue gases pass from the combustion chamber to the outdoors.

Flue gas. Products of combustion plus excess air in appliance flues, heat exchangers, and vents.

Input rate. Fuel-burning capacity of an appliance in kilowatts as specified by the manufacturer. Appliance input ratings are marked on appliance rating plates.

Vent. Passageway used to convey flue gases from appliances or their vent connectors to the outdoors.

Vent gas. Products of combustion plus excess air and dilution air in vents.

1.2 SYSTEM APPLICATION

The following considerations are important in the design, specification, and/or application of systems for combustion of fossil fuels.

Safety. Safety is of prime concern in the design and operation of automatic fuel-burning appliances. For more information, see the sections on Safety and Controls. Appliance standards and installation codes (e.g., ANSI *Standard* Z21.47/CSA *Standard* 2.3 for gas-fired central furnaces and ANSI Z223.1/NFPA 54, *National Fuel Gas Code*, in the United States) provide minimum safety requirements. Appliance manufacturers may include additional safety components to address hazards not covered by appliance standards and installation codes.

Suitability for Application. The system must meet the requirements of the application, not only in heating capacity, but also in its ability to handle the load profile. It must be suitable for its environment and for the substance to be heated.

Combustion System Type. System operation is very much a function of the type of burner(s), means for moving combustion products through the system, proper combustion air supply, and venting of combustion gases to the outdoors.

Efficiency. Efficiency can be specified in various ways, depending on the application. Stack loss and heat output are common measures, but for some applications, transient operation must be considered. In very high-efficiency appliances, heat extraction from combustion products may cool vent gas below its dew point, so condensation of water vapor in the combustion products must be handled, and venting design must consider corrosion by combustion products, as well as their lack of buoyancy.

Operating Control. Heat load or process requirements may occur in batches or may be transient events. The burner control system must accommodate those requirements, and the combustion system must be able to respond to the controls.

The preparation of this chapter is assigned to TC 6.10, Fuels and Combustion.

Emissions. For safety and air quality reasons, combustion products must not contain excessive levels of noxious materials, notably carbon monoxide, oxides of nitrogen, unburned hydrocarbons, and particulate material such as soot.

Fuel Provision. Liquid and solid fuels, liquefied gases, and some gaseous fuels require space for storage. Gaseous and liquid fuels require appropriate piping for the fuel-burning system. Fuel storage and delivery provisions must be of adequate capacity and must be designed to ensure safe operation.

Sustainability. Fuel-burning appliances consume fuel resources and produce combustion products that are emitted to the atmosphere. The effect of these inherent characteristics can be minimized by using highly efficient systems with very low emissions of undesirable substances. (See the section on Efficiency and Emission Ratings.) Appliances using environmentally neutral (nonfossil) fuel, such as biofuels processed from vegetable oils and biomass material (e.g., forestry waste), are available. New technologies are also emerging. Through photosynthesis, biomass chlorophyll captures energy from the sun by converting carbon dioxide from the atmosphere and water from the ground into carbohydrates, complex compounds composed of carbon, hydrogen, and oxygen. When these carbohydrates are burned, they are converted back into carbon dioxide and water, and release the sun's energy. In this way, biomass stores solar energy and is renewable and carbon neutral (UCS 2007).

Venting, Combustion Air Supply, and Appliance Installation. Combustion product gases must be handled properly to ensure safety and satisfactory system operation. Adequate air supply must be provided for combustion and ventilation. Appliances must be located to provide safe clearance from combustible material and for convenient service.

Standards and Codes. Building codes typically require that fuel-burning appliances be design-certified or listed to comply with nationally recognized standards. Appliance construction, safe operation, installation practices, and emissions requirements are often specified. In some locations, codes require special restraint for seismic or high wind conditions.

Cost. The choice of fuel-burning system is often based on it being the least expensive way to provide the heat needed for a process. The basic cost of energy tends to narrow the choices, but the total cost of purchase and ownership should dictate the final decision. Initial cost is the cost of the appliance(s), associated equipment and controls, and installation labor. Operating cost includes the cost of fuel, other utilities, maintenance, depreciation, and various ongoing charges, taxes, fees, etc. Energy cost analysis may indicate that one fuel is best for some loads and seasons, and another fuel is best for other times. Substantial operating cost is incurred if skilled personnel are required for operation and maintenance. Sometimes these costs can be reduced by appliances and control systems that automate operation and allow remote monitoring of system performance and maintenance requirements. Warranties should be considered. See Chapter 38 of the 2023 *ASHRAE Handbook—HVAC Applications* for a thorough discussion of costs.

1.3 SAFETY

All appliance systems must either operate safely or have a way to sense unsafe operation, and safely and promptly shut off the fuel supply before injury or property damage occurs. Safe and unsafe operation sensing and control is generally designed into the combustion control system. Examples of what controls must detect, evaluate, and act on include the following:

- Time to achieve fuel ignition
- Sufficient combustion air and/or flue gas flow rates
- Fuel flow rate (e.g., gas orifice pressure)
- Loss of flame
- Heat exchange operation (e.g., circulating air blower operating speed and timing for furnaces)
- Flame containment (flame rollout)
- Appliance component temperatures
- Loss of control power supply

1.4 EFFICIENCY AND EMISSION RATINGS

Heating capacity may be the primary factor in selecting fuel-burning appliances, but efficiency and emission ratings are often of equal importance to building owners and governmental regulators.

Steady-State and Cyclic Efficiency

Efficiency calculations are discussed in Chapter 28 of the 2021 *ASHRAE Handbook—Fundamentals*. Boiler and furnace efficiencies are discussed in Chapters 32 and 33 of this volume.

Stack Efficiency. Stack efficiency is a widely used rating approach based on measurement of the temperature and composition of gases exhausted by fuel-burning appliances. Knowing the oxygen or carbon dioxide concentration of the flue gases and the fuel's hydrocarbon content provides a measure of stack mass flow. In conjunction with flue gas temperature, these data allow determination of energy loss in the flue gas exiting the stack. The difference between stack loss and energy input is assumed to be useful energy, and stack efficiency is the ratio of that useful energy to energy input, expressed as a percentage. Generally, the rating is applied to steady-state combustion processes. Flue gas carbon dioxide and oxygen concentrations are affected mostly by the fuel's hydrocarbon content and by the appliance's combustion system design. Flue gas temperature is mostly affected by the appliance's heat exchanger design.

Heat Output Efficiency. Some rating standards require actual measurement of heat transferred to the substance being heated. Heat output measurement accounts for all heat losses, not just those in the flue gases. Nonstack heat loss, often called **jacket loss**, is difficult to measure and may be quite small, but can be accounted for by measuring heat output. The ratio of heat output to energy input, expressed as a percentage, is the heat output efficiency.

Load Profile Efficiency. U.S. Federal Trade Commission rules require that some types of residential appliances be rated under protocols that consider load profile. Residential and commercial space-heating furnaces and boilers, for example, are rated by their **annual fuel utilization efficiency (AFUE)**, which considers steady-state efficiency, heat-up and cooldown transients, and off-season energy consumption by gas pilot burners. Residential storage-type water heaters are rated under a protocol that requires measurement of energy consumption over a 24 h period, during which prescribed amounts of heated water are drawn. A water heater **energy factor** $\boldsymbol{E_f}$ is calculated from the measurements. The E_f rating accounts for standby losses (i.e., energy loss through the tank and fittings that does not go into the water). Ratings and discussion of AFUE and energy factors can be found in ASHRAE *Standard* 103 and in product directories by the Gas Appliance Manufacturers Association.

Emissions

Regulated Flue Gas Constituents. Appliance safety standards and environmental regulations specify limits for various substances that may be found in combustion flue gases. Substances most often regulated are carbon monoxide, oxides of nitrogen, and soot. Limits for sulfur oxides, unburned hydrocarbons, and other particulate matter may also be specified. Rules vary with location, type of installation, and type of combustion appliance. Regulations that restrict fuel sulfur content are generally intended to reduce sulfur oxide emissions, which may also reduce particulate emissions under certain conditions.

Flue Gas Concentration Limits. Standards and codes often specify maximum concentration levels permitted in flue gases.

Because flue gases may be diluted by air, requirements invariably specify that measured concentration levels be adjusted by calculation to a standard condition. In appliance certification standards, that condition is typically the air-free level (i.e., what the concentration would be if there were no excess air). Carbon monoxide, for example, is often limited to 400 parts per million air-free. Air quality regulations sometimes specify the maximum level for a fixed degree of excess air. For oxides of nitrogen, the level is often specified in parts per million at 3% oxygen. The calculation, in effect, adds or subtracts dilution air to reach a condition at which oxygen concentration is 3% of the exhaust gas volume.

Emission per Unit of Useful Heat. In some U.S. jurisdictions, regulations for gas-fired residential furnaces and water heaters require that emission of oxides of nitrogen not exceed a specified level in nanograms per joule of useful heat. Measured flue gas emission levels are compared with the benefit in terms of heat output. Under this rating method, high efficiency is rewarded. Regulations for new installations may differ from those for existing systems and may be more stringent.

Mass Released to Atmosphere. Emissions from large fuel-fired appliances are often regulated at the site in terms of mass released to the atmosphere. Limits may be expressed, for example, in terms of kilograms per gigajoule, or megagrams per year.

2. GAS-BURNING APPLIANCES

2.1 GAS-FIRED COMBUSTION SYSTEMS

Gas-burning combustion systems vary widely, the most significant differences being the type of burner and the means by which combustion products are moved through the system. Gas input rate control also has a substantial effect on combustion system design.

Burners

A primary function of a gas burner is mixing fuel gas and combustion air in the proper ratio before their arrival at the flame. In a **partially-aerated burner (Bunsen burner)**, only part of the necessary combustion air is mixed with the gas ahead of the flame. This primary air is typically about 30 to 50% of the stoichiometric air (i.e., that amount of air necessary for complete combustion of the gas). Combustion occurs at the point where adequate secondary air enters the combustion zone and diffuses into the mixture. In most cases, secondary air entry continues downstream of the burner and heat release is distributed accordingly. The total of primary and secondary air typically ranges from 140 to 180% of the stoichiometric air (i.e., 40 to 80% excess air).

Most often, partially aerated burners are **atmospheric** or **natural-draft burners** (i.e., they operate without power assist of any kind), which have the advantage of quiet operation. Fuel gas is injected from a pressurized gas supply through an injector (orifice) to form a gas jet, which propels discharged gas into the burner throat, entraining primary air by viscous shear. Primary air may also be drawn into the burner throat by venturi action. Fuel gas and air are mixed in a mixing tube before their arrival at the burner ports where burning occurs. A typical partially aerated burner is illustrated in Figure 1.

A **premix burner** is a power burner in which all or nearly all of the combustion air is mixed with the fuel gas before arrival at the flame. Because the necessary air is present at the flame front, combustion and heat release take place in a compact zone and there is no need for secondary aeration. Combustion quality (i.e., emission performance) tends to be better than that of partially aerated burners because of inherent mixing advantages, resulting in lower peak temperatures and lower residence times at these temperatures. This especially benefits NO_x emission levels. Premix burners can normally be operated at lower excess air levels (often 15 to 20%) to increase combustion efficiency. Low excess air increases flame temperature, which enhances heat exchange but imposes greater thermal stress on the combustion chamber and its components. Extremely low excess air may result in higher CO and/or NO_x emissions, as with any burner design.

A fan is almost always necessary to force the mixture of gas and air through a premix burner. Airflow is three or four times that through partially aerated burners, and the associated pressure drop is normally too much to be handled by fuel gas entrainment or stack draft. In general, appliances with premix burners are tuned more finely than those with partially aerated burners, to take advantage of their inherent advantages and to ensure reliable operation. A typical premix burner system is illustrated in Figure 2.

Combustion System Flow

In broad terms, flow through the combustion system (i.e., burner, combustion chamber, heat exchanger, and venting) is powered by natural draft and/or by a fan.

In a **natural-draft system**, the low density of hot combustion products creates a buoyant flow through the combustion chamber, heat exchanger, and venting system. The amount of flow through the system is a function of many factors, including chimney height, diameter, flue gas temperature, and friction loss through the appliance and vent system components. For additional information, see Chapter 35.

Fan-assisted combustion systems have become common. A fan pushes or pulls combustion air, flue gas products, and fuel gas through the burner, and combustion products through the combustion chamber and heat exchanger (and, in some cases, the venting). Some fan-assisted systems use atmospheric burners, applying the fan power mainly to force flow through an enhanced heat exchange process. Serpentine heat exchangers, for example, typically require fan assist because they have too much pressure drop to operate in natural-draft mode. In systems with significant burner pressure drop, such as that of a premix burner, fan power is required for the burner as well. Fan-assisted systems can operate with or without pressurizing the vent, depending on the flow rate of the combustion system, flue gas conditions (temperature and buoyancy), resistance of the venting system, and location of an induced-draft fan, if used. For more information, see the discussion of venting in the Applications section.

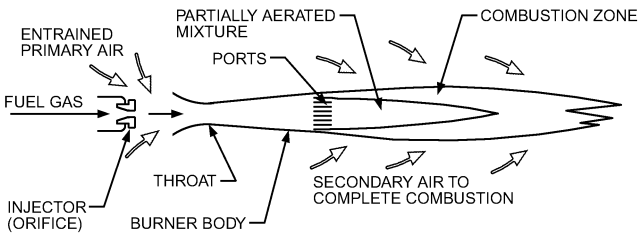

Fig. 1 Partially Aerated (Bunsen) Burner

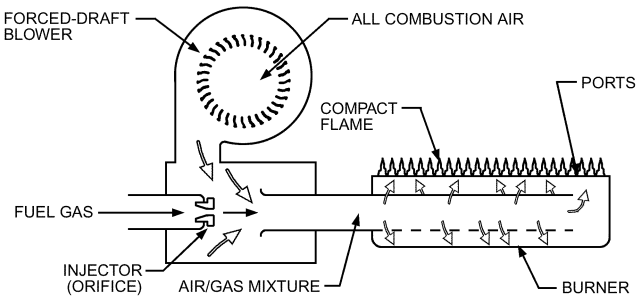

Fig. 2 Premix Burner

Forced-draft systems (Figure 3) use a fan to force air into the combustion chamber and heat exchanger under positive pressure (higher than atmospheric). Often, forced-draft systems also operate with positive pressure in at least part of the vent system.

Induced-draft systems (Figure 4) use a fan in the appliance near the flue collar or vent outlet to pull flue gas through the combustion chamber and heat exchanger. These systems operate with negative pressure at all points before the fan.

Packaged power burners are often used in factory-built heating appliances and in field-assembled installations. These burners include all gas- and air-handling components, along with ignition controls, housing, mechanical means for mounting to the heating appliance, and connection of fuel gas and electric power. They tend to have a gun-type configuration (i.e., gas and air are mixed in an outlet tube with burner head, the latter inserted into the heating appliance's combustion chamber). Packaged power burners may also include special hardware and controls for gas input rate control, and some may include special features to reduce combustion emissions. Flue gas recirculation (i.e., returning some combustion products to the flame) is sometimes used to reduce NO_x production. A typical packaged power burner is shown in Figure 5.

Pulse combustion is a process in which combustion system flow is motivated by low-frequency pressure pulses created in the combustion chamber by cyclic/repetitive self-generating ignition of an air/gas mixture. It provides low emission levels and enhanced heat transfer. The oscillating nature of flow through the system provides a beneficial "scrubbing" effect on heat exchanger surfaces. Additional discussion of pulse combustion is provided in Chapter 28 of the 2021 *ASHRAE Handbook—Fundamentals.*

Ignition

Safety standards and codes specify requirements for ignition and proof of flame presence. Good design practices result in ignition that is immediate, smooth, and complete. Once flame is established, the ongoing presence of the ignition source or the flame itself must be ensured (i.e., flame supervision by the combustion control must detect loss of pilot and/or main flame and immediately shut off fuel gas flow). **Pilot burners** have been used very effectively for decades in appliances such as small residential water heaters and in very large field-assembled installations. The pilot flame may be detected by a temperature sensor (thermocouple) or by various electronic sensing systems. Pilot flames may be continuous or ignited only when there is a demand for heat (**intermittent pilot** operation).

Some types of appliances use **direct ignition**. A **spark igniter** or a **hot surface igniter** is applied directly at the main burner ports to ignite the gas/air mixture. Direct-ignition systems also include a means, usually electronic, to sense presence of the flame.

Ignition system standards and installation codes usually include requirements for other parameters such as flame failure response time, trial for ignition, and combustion chamber purging. For listed or design-certified appliances, applicable requirements have been test-verified by listing or certifying agencies. Other appliances and those installed in some building occupancy classes may be subject to special ignition and flame safety requirements in building and safety codes or by insurance underwriters. (See the section on Controls for more detail.)

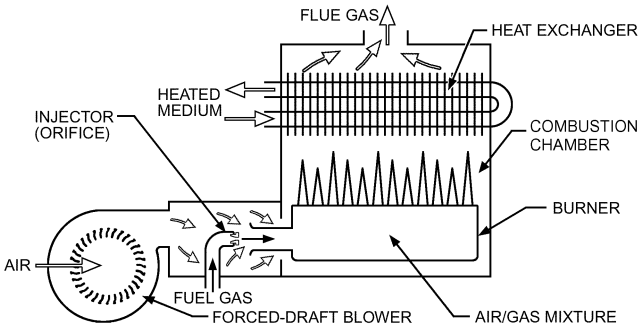

Fig. 3 Forced-Draft Combustion System

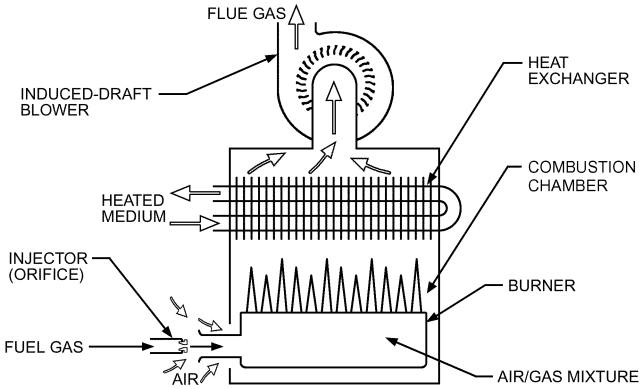

Fig. 4 Induced-Draft Combustion System

Input Rate Control

A wide range of heat input is sometimes required of gas-fired appliances. Space heating, for example, is often done by zones, and must work under a wide range of outdoor conditions. Some water-heating and process applications also require a wide gas input rate range, and transients can be very steep input rate swings. Gas burners with staged or modulating control can be applied to meet these requirements.

Staged systems can be operated at discrete input rate levels, from full rated input to preset lower rates, sometimes with airflow remaining at the full-rate level and sometimes with proportional control of combustion air. Efficiency can be enhanced when combustion air is proportionally controlled, because flame temperature can remain high while the amount of heat exchanger surface per unit of input effectively becomes larger. A common staging approach uses a two-stage gas pressure regulator to change fuel gas pressure at an injector or metering orifice(s). In other designs, staging is accomplished by operating groups of individual burners or combustion chambers, each under control of its own gas valve and, if necessary, having its own ignition control. An extension of this approach is to use multiple individual heating appliances, controlled such that one or more can be called on as needed to meet the demand.

Modulating burner systems vary the input rate continuously, from full rated input to a minimum value. Modulation may be done by a throttling device in the gas burner piping, or with a modulating gas pressure regulator. Modulating systems require special controllers to provide a signal to the gas flow control device that is in some

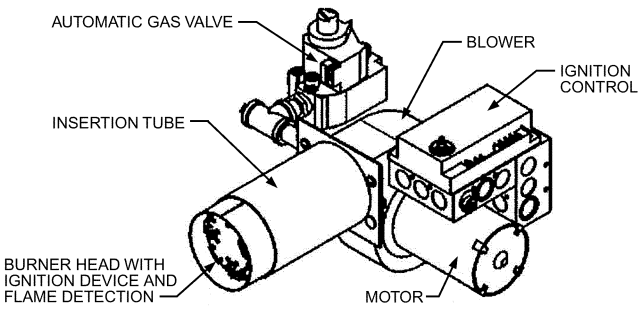

Fig. 5 Packaged Power Burner

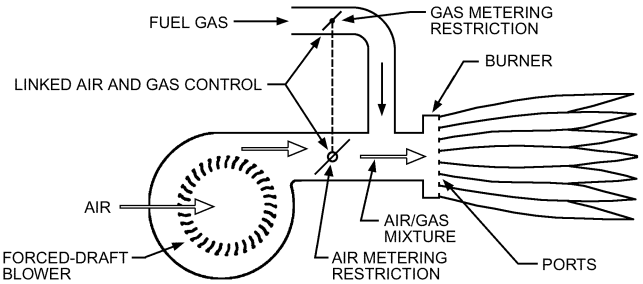

Fig. 6 Combustion System with Linked Air and Gas Flow

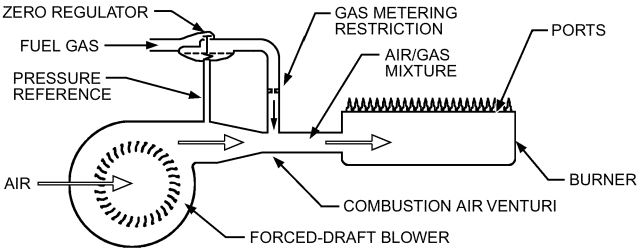

Fig. 7 Pneumatically Linked Gas/Air Ratio Combustion System

way proportional to the demand. As with staged systems, some designs provide commensurate control of combustion air, whereas others control only gas input rate with constant combustion airflow rate. Figure 6 illustrates a system in which combustion air and gas flow rates are throttled and linked.

Pneumatically linked gas/air ratio burner systems, in which combustion air is controlled and gas follows proportionately, are a type of modulating burner system. One such system is shown in Figure 7. In these systems, airflow is controlled by dampers or a variable-speed fan. Combustion air is directed through a restriction (typically a venturi), so that the pressure drop across this restriction increases as a function of air mass flow (in accordance with the Bernoulli Equation). A fuel gas regulator is referenced to the upstream side of this restriction and controls gas flow into the combustion air at a point downstream of the restriction. The regulator set point is fixed (often very close to zero). As airflow increases through the restriction, so does the pressure drop across it. As this happens, the regulator must open further, increasing the gas flow, to maintain its set point. At a regulator set point of zero, the air/fuel ratio is theoretically constant at all firing rates. The regulators typically used in these systems are referred to as **zero-pressure regulators**, **zero governors**, or **negative-pressure regulators**. The air restriction may be located upstream or downstream of the blower. An advantage to placing the venturi at the outlet is that the blower does not handle the combustible gas mixture. Placing the venturi at the blower inlet, however, promotes better mixing. Pneumatically linked systems require a minimum pressure drop across the combustion air restriction for the gas regulator to be able to track the airflow accurately. This requirement typically limits the **turndown ratio** (maximum firing rate divided by minimum firing rate) to approximately 5:1.

Electronically linked gas-air ratio burner systems adjust gas flow to match a variable combustion airflow in a manner similar to pneumatically linked systems; however, measurement of airflow and control of gas flow are by electronic means. Typically, such systems measure airflow using a mass flow sensor and adjust gas flow using a throttling valve operated by a stepper motor (in some cases completely eliminating the need for a gas regulator on the appliance). Oxygen trim and other technologies to infer the actual air/fuel ratio using the combustion air mass flow, along with burner temperature or flame ionization signal, are also coming into commercial use. This technology promises to allow the input and air-fuel ratio to be closely controlled independently of factors, such as altitude, vent length, and even fuel gas composition. In addition, because electronically linked systems do not rely on a minimum combustion air pressure drop to control gas flow, much greater turn-down ratios are theoretically possible than with pneumatic systems.

2.2 RESIDENTIAL APPLIANCES

Boilers

Residential space heating is often done with gas-fired low-pressure steam or hot-water boilers (i.e., steam boilers operating at 100 kPa [gage] or less, or hot-water boilers operating at 1100 kPa [gage] or less with 120°C maximum water temperature). Steam or hot water is distributed to convectors, radiators, floor piping, fan-coils, or other heat transfer devices in the space to be heated. Space temperature control may be by zone, in which case the boiler and distribution system must be able to accommodate reduced-load operation. Burners and combustion systems can be any of the previously described types, and some designs include input rate control. Rules of the U.S. Federal Trade Commission (FTC) and federal law require residential boilers with input rates less than 88 kW to comply with minimum efficiency requirements, following the rating protocol of ASHRAE *Standard* 103. For hot-water boilers, 82% annual fuel utilization efficiency (AFUE) is required; for steam boilers, 80%. For ratings and technical information on rating protocol, see the *AHRI Directory of Certified Product Performance* (ahridirectory.org). Manufacturers' literature also provides technical data and ratings.

Some boilers have low mass and essentially instantaneous response, whereas others have higher water volume and mass, which provides a degree of inherent storage capacity to better handle load change. Both steam and hot-water space-heating boilers are available in models having internal coils for service water heating. These **combination boilers** eliminate the need for a separate water heater, but they must be operated whenever service water may be needed, including times when space heating is not necessary. For a comprehensive discussion of boilers, see Chapter 32.

Forced-Air Furnaces

Central gas-fired, forced-air furnaces are the most common residential space-heating systems in the United States and Canada. Forced-air furnaces are available in configurations for upflow, downflow, and horizontal flow air distribution. Most have induced-draft combustion systems with Bunsen-type burners, and are typically of modular design (i.e., burner and heat exchanger modules are used in multiples to provide appliance models with a range of heating capacities). Some are available with staged or modulated input rate, and some have coordinated control of combustion air and circulating airflow. U.S. federal law require furnaces with firing rates less than 66 kW to meet minimum efficiency ratings; see the National Appliance Energy Conservation Act (NAECA) for details. The recognized rating procedure for furnaces is defined in *Code of Federal Regulations* 10 CFR 430.32, which references ASHRAE *Standard* 103. Federal Trade Commission (FTC) rules require manufacturers to publish AFUE ratings in their literature. In addition, independently certified AFUE ratings are published by organizations such as AHRI (2014). For detailed discussion of furnaces, see Chapter 33.

Water Heaters

In the United States, most residential water heaters are of the storage type (i.e., they have relatively low gas input rates and significant hot-water storage capacity). Typically, a single Bunsen-type burner is applied beneath a flue that rises through the stored

water. Flue gas usually flows by natural draft. ANSI and Canadian Standards Association (CSA) appliance standards limit the input rate of these heaters to 22 kW and require that water heaters manufactured since mid-2003 be designed to be **flammable vapor ignition resistant (FVIR)** because water heaters are often installed in garages and should not be an ignition source in case gasoline or other volatile or flammable substances may be present.

Instantaneous water heaters, often designed for mounting to a wall, are characterized by low water storage capacity and low mass, and have special burners and control systems designed for immediate response to demand for hot water. Burner input rate is typically linked to water flow rate and temperature, often by both hydraulic and electronic mechanisms. Because there is no storage, input rates tend to be higher than for storage heaters, and must be adequate for instantaneous demand. Standby losses of instantaneous water heaters are typically less than those of storage heaters. However, U.S. water use habits favor storage water heaters, which are used more extensively throughout the country.

In the United States, the efficiency of residential storage-type water heaters is based on a Department of Energy (DOE) protocol that requires measurement of energy consumption over a 24 h period, during which prescribed amounts of heated water are drawn. An **energy factor** E_f is calculated from the measurements. The rating accounts for standby losses (i.e., heat lost from stored hot water by conduction and convection through tank walls, flue, and pipe fittings to the environment). Hot-water delivery flow also appears in ratings. For storage heaters, the **first-hour rating** (i.e., volume of water that can be drawn in the first hour of use) is provided. For instantaneous heaters, the **maximum flow rate** in litres per second is provided. See AHRI (2007) for ratings and details about the energy factor.

Combination Space- and Water-Heating Appliances

Residential appliances that provide both space and water heating are available in a variety of configurations. One configuration consists of a specially designed storage water heater that heats and stores water for washing activities or for use as a heat transfer medium in a space-heating fan-coil unit. Another configuration, common in Europe and Asia, is a wall-hung boiler that provides hot water for use in either mode. Storage or instantaneous heating capacity must be adequate to meet user demand for showers or other peak activity. Control systems normally prioritize hot-water consumption requirements over the need for space heating, which is allowed only when the hot-water demand has been satisfied. Descriptions and technical data for these and other configurations are available from manufacturers. Ratings are provided in a special section of AHRI (2007). The method for testing and rating of combination space and water heating appliances is specified in ASHRAE *Standard* 124.

Pool Heaters

Pool heaters are a special type of water heater designed specifically for handling high flow rates of water at relatively low water temperature. Various burner and combustion system approaches are used in pool heaters. Input rate control is not normally incorporated because swimming pools are of very high mass and do not change temperature rapidly. Consult manufacturer and pool industry technical data for pool heater selection and application factors.

Conversion Burners

Conversion burners are complete burner and control units designed for installation in existing boilers and furnaces. Atmospheric conversion burners may have drilled-port, slotted-port, or single-port burner heads. These burners are either upshot or inshot types. Figure 8 shows a typical atmospheric upshot gas conversion burner.

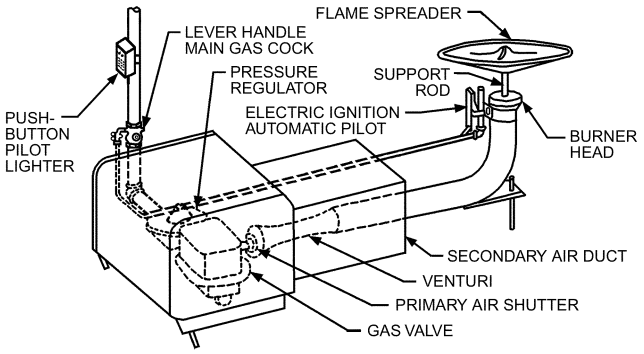

Fig. 8 Typical Single-Port Upshot Gas Conversion Burner

Several power burners are available in residential sizes. These are of gun-burner design and are desirable for furnaces or boilers with restricted flue passages or with downdraft passages.

Conversion burners for domestic application are available in sizes ranging from 12 to 120 kW input, the maximum rate being set by ANSI *Standard* Z21.17/CSA 2.7. However, large gas conversion burners for applications such as apartment building heating may have input rates as high as 260 kW or more.

Successful and safe performance of a gas conversion burner depends on numerous factors other than those incorporated in the appliance, so installations must be made in strict accordance with current ANSI *Standard* Z21.8. Draft hoods conforming to current ANSI *Standard* Z21.12 should also be installed (in place of the dampers used with solid fuel) on all boilers and furnaces converted to burn gas. Because of space limitations, a converted appliance with a breeching over 300 mm in diameter is often fitted with a double-swing barometric regulator instead of a draft hood.

2.3 COMMERCIAL-INDUSTRIAL APPLIANCES

Boilers

Boilers for commercial and industrial application can be very large, both in physical size and input rate. Virtually any requirement for space heating or other process can be met by large boilers or multiple boilers. The heated medium can be water or steam. (See Chapter 32 for extensive discussion.)

Space Heaters

A wide variety of appliances is available for large air-heating applications. Some of them heat air by means of hot-water coils and are used in conjunction with boilers. Some accomplish space heating by means of a fuel-fired heat exchanger. Others fire directly into the heated space.

Forced-air fuel-burning furnaces for commercial and industrial application are essentially like those for residential use, but have larger heating and air-handling capacity. Input rates for single furnaces certified under ANSI *Standard* Z21.47/CSA *Standard* 2.3 may be as high as 117 kW. High capacity can also be provided by parallel (twinned) application of two furnaces. Most manufacturers provide kits to facilitate and address the special safety, mechanical, and control issues posed by twinned application. See manufacturer data and Chapter 33 for additional information about forced-air furnaces and their application.

Duct furnaces are fuel-fired appliances for placement in field-assembled systems with separate air-moving means. Combustion products heat air through heat exchangers mounted in the airstream. The combustion components, heat exchangers, and controls are prepackaged in a cabinet suitable for mounting in a duct system. For proper operation of the duct furnace, the airflow rate must be within

the range specified by the manufacturer. See manufacturer data and Chapter 33 for additional information.

Unit heaters are free-standing appliances for heating large spaces without ductwork. They are often placed overhead, positioned to direct heat to specific areas. Typically, they incorporate fuel-fired heat exchangers and a fan or blower to move air through the exchangers and into the space. However, in some designs the fuel-fired exchangers are replaced by air-heating coils using hot water as the heating medium. Chapter 28 provides further information on unit heaters.

Direct gas-fired makeup-air heaters do not have heat exchangers. They heat large spaces by firing combustion products directly into the space, accompanied by a large quantity of dilution airflow. They have special burners capable of operation in high airflow and controls that allow operation over a wide fuel input rate range. As their name implies, they are used in applications requiring heated makeup air in conjunction with building exhaust systems. (See Chapter 28 for additional information.)

Infrared heaters radiate heat directly to surfaces and objects in a space. Air may be heated by convective heat transfer from the objects. They are suitable for overall heating of a building, but their selection is often based on their ability to radiate heat directly to people in limited areas without intentionally heating items or air in the space, such as in work stations in large open spaces that are not otherwise heated. Indirect infrared heaters use a radiating surface, such as a tube, between the combustion products and the space. Direct infrared heaters use the burner surface, typically a glowing ceramic or metal matrix, as the radiator. Chapter 16 provides additional information. See also manufacturers' data.

Water Heaters

Large-load water-heating applications, such as for large residence buildings, schools and hospitals, restaurants, and industrial processes, require water-heating appliances with correspondingly high fuel input rates, usually in conjunction with substantial hot-water storage. Large tank-type heaters with multiple flues are used in many intermediate-sized applications. They may operate as natural-draft systems, but forced- and induced-draft designs are common. Large applications or those with very high short-term water draw are often handled by means of large unfired storage tanks in conjunction with water-tube or other low-volume, high-input heaters. Fan-assisted combustion systems are increasingly common in those heaters. Premix burners may be used mainly to help meet emissions restrictions. Chapter 51 of the 2023 *ASHRAE Handbook—HVAC Applications* extensively discusses water-heating issues and appliances. ASHRAE *Standards* 118.1 and 118.2 provide methods of testing for rating commercial and residential water heaters, respectively.

Pool Heaters

Fuel-fired pool heaters are available in very large sizes, with fuel input rates ranging to more than 1000 kW. They are designed to handle low-temperature water at high flow rates, and have sensitive temperature controls to ensure swimmer comfort and energy efficiency. Heating pool water with appliances not designed for that purpose can result in severe problems with combustion product condensation, corrosion, and/or scaling. See manufacturers' data for complete information.

2.4 APPLICATIONS

Gas-burning appliances cannot perform as intended unless they are properly installed and set up. Once an appliance of appropriate type, size, and features is selected, the location, fuel supply, air for combustion and ventilation, and venting must be considered and specified correctly. Other factors, notably elevation above sea level, must also be considered and handled.

Location

Listed appliances are provided with rating plate and installation information, with explicit requirements for location. The required clearance to combustible material is particularly important, to eliminate the hazard of fire caused by overheating. Other requirements may be less obvious. Adequate space must be provided for connecting ductwork, piping, and wiring, and for convenient maintenance and service. There must be access to chimneys and vents, and vent terminal locations must comply with specific requirements for safe discharge of combustion products without injury to people or damage to surroundings. Outdoor appliances must be located in consideration of wind effects and similar factors.

Local building codes provide basic rules for unlisted appliances and may impose additional requirements on listed appliances.

Gas Supply and Piping

Natural Gas. Natural gas is usually provided by the local gas utility. Most North American utilities provide substantial and reliable supply pressure, but it is important to verify adequate supply pressure during maximum simultaneous gas consumption by all appliances sharing the supply, and to design adequate supply piping between the utility supply point and the gas-burning appliance. On listed appliances, rating plates specify the minimum supply pressures at which the appliances will operate safely and as intended. This information is also provided in installation instructions, and is available from manufacturers before purchasing appliances.

Gas piping between the utility company meter and the appliance must provide adequate pressure when all concurrent loads operate at their maximum rate. Tables provided in ANSI *Standard* Z223.1/NFPA *Standard* 54 (*National Fuel Gas Code*), CSA *Standard* B149.1, local codes, and elsewhere provide procedures for ensuring adequate pressure. For residential and light commercial services, utility companies typically provide gas at 1.75 kPa. Building distribution piping is usually designed for a full-load pressure drop of less than 75 or 125 Pa. Industrial and large-building applications are often supplied with gas at higher pressures; in that case, the distribution piping can be designed for larger pressure drop, but the end result must supply pressure to an individual appliance within the range required by its manufacturer. A pressure regulator may be required at the appliance to reduce pressure to comply with the rating plate pressure requirement.

Liquefied Petroleum Gas (LPG). LPG can contain a range of gas components. If it is not commercial propane or butane, the actual composition must be ascertained and accommodated. LPG is stored on site as a liquid at moderate pressure; it is vaporized as gas is drawn. A pressure regulator at the tank reduces pressure for distribution to the appliance through piping, subject to the same considerations as for natural gas. In the United States and Canada, normal supply pressure for residential and light commercial applications is 2.75 kPa. Appliance rating plates and installation instructions typically require that supply pressure be maintained at or near that level. Piping must be designed to ensure adequate pressure when concurrent connected loads operate at their maximum input rates.

An important but sometimes overlooked issue is the need to provide heat to vaporize liquefied petroleum in the tank to deliver gas. In most residential applications, heat for vaporization is simply taken from outdoor air through the tank walls. This natural heat source may become inadequate, however, as the air temperature falls, draw rate increases, or tank liquid level falls. Commercial propane and butane have boiling point temperatures of –42°C and 0°C, respectively. As the LPG tank approaches the boiling point temperature, tank pressure falls to the point where the gas cannot be supplied at the required rate. In these cases and in high-demand applications, supplemental heat may be necessary to vaporize LPG. Information on selection and application of vaporization equipment is available from LPG dealers

and distributors, from the National Propane Gas Association, and in various codes and standards.

Air for Combustion and Ventilation

In application of fuel-burning appliances, inadequate provision of air for combustion and ventilation is a serious mistake. In the worst scenario, shortage of combustion air results in incomplete combustion and production of poisonous carbon monoxide, which can kill. Inadequate ventilation of the space in which an appliance is installed can result in high ambient temperatures that stress the appliance itself or other appliances or materials in the vicinity. For those reasons, building codes and manufacturers' installation instructions include requirements for combustion and ventilation air supply. Requirements vary, with several factors having to do with how easily air can get to the appliance from the outdoors. Infiltration is seldom adequate, and it is usually necessary to provide dedicated means for supply of air for combustion and ventilation. In cold regions, take measures to prevent freezing of water pipes and other equipment by cold air in the appliance space. For more information, see Ackerman et al. (1995) and Dale et al. (1997).

Draft Control

Natural-draft appliances typically include a **draft hood** or **diverter** to decouple the combustion system from undesirable draft effects, notably the draft or pull of the chimney. These devices provide a path for dilution air to mix with flue gas before entering the connector between the appliance and the chimney, and to accommodate updraft and downdraft variations that occur in the field because of wind. A **barometric draft control** is a similar device that uses a damper to control the flow of dilution air into the vent. The damper of a barometric draft control can be manually adjusted to regulate the draft imposed on the appliance. Often, this is accomplished with special weights, in conjunction with measurement with a draft gage. Draft controls should be supplied by the appliance manufacturer as part of the appliance combustion controls. See Chapter 35 for design considerations for vent and chimney draft control.

Venting

Safety and technical factors must be considered in venting appliances, including some less obvious considerations. Consequences of incorrect venting are very serious, and can include production of lethal carbon monoxide, spilling of heat and combustion moisture indoors, and deterioration of the vent or chimney caused by condensation of water vapor from vent gas. High-efficiency appliances can produce combustion products at temperatures near or below their dew point. Venting those flue gases requires use of special materials and installation practices, and provision for condensate drainage and disposal.

Comprehensive guidance for design of venting systems is provided in Chapter 35. For many North American gas-fired appliances, however, ANSI *Standard* Z21.47/CSA *Standard* 2.3 and ANSI *Standard* 21.13/CSA *Standard* 4.9 require categorization by the type of vent system necessary for safe and effective operation. Appliances are tested to determine the temperature and pressure of vent gas released into the vent. The categories, which apply only to appliances design-certified as complying with standards having category specifications, are as follows:

Category	Vent Static Pressure	Vent Gas Temperature High Enough to Avoid Excessive Condensate Production in Vent?
I	Nonpositive	Yes
II	Nonpositive	No
III	Positive	Yes
IV	Positive	No

Category I and II appliances with a forced- or induced-draft blower to move combustion air and combustion products through the appliance flue create no pressure at the appliance flue exit (entrance to the venting system), and therefore do not augment draft in the vent.

Most local building codes include vent sizing tables and requirements that must be used for design of venting systems for category I appliances. Those tables are adopted from the *National Fuel Gas Code*, which distinguishes between appliances with draft hoods and appliances having fan-assisted combustion systems without draft hoods. In both cases, vent gases flow into the vent at category I conditions, but there is less dilution air with fan-assisted appliances than with draft-hood-equipped appliances. Vent gas flow and condensation tendencies differ accordingly. The tables specify

- Maximum (NAT Max) input rates for single-appliance vent systems and multiple-appliance vent connectors of given sizes for draft hood-equipped appliances
- Minimum (Fan Min) and maximum (Fan Max) input rates for single-appliance vent systems and multiple-appliance vent connectors of given sizes for fan-assisted appliances
- Maximum (Fan + NAT) input rates for multiple-appliance common vents of given sizes for combinations of draft-hood-equipped and fan-assisted appliance systems
- Maximum (Fan + Fan) input rates for multiple-appliance common vents of given sizes for fan-assisted appliance systems

Category II appliances are rare because it is difficult to vent low-temperature flue gas by its own buoyancy. Category III and IV appliances, with positive vent pressure, are common. Those appliances must be vented in accordance with the manufacturers' installation instructions, and require special venting materials. Category II and IV appliances also require venting designs that provide for collection and disposal of condensate. Condensate tends to be corrosive and may require treatment.

Appliances designed for installation with piping and terminals for both venting of flue gas and intake of combustion air directly to the appliance are called **direct-vent** (and sometimes, erroneously, **sealed combustion**) systems. (Sealed combustion systems take combustion air from outside the space being heated, not necessarily outdoors, and all flue gases are discharged outdoors; this is not a balanced system.) The vent and combustion air intake terminals of direct-vent appliances should be located outdoors, close to each other, so that they form a balanced system that is not adversely affected by winds from various directions. Vent pipe and combustion air intake pipe materials are provided or specified by the appliance manufacturer, and their use is mandatory. A variation in which only vent materials are specified, with combustion air taken directly from inside the conditioned space, is referred to as a **direct-exhaust** system. Most category III and IV systems are direct-vent or direct-exhaust systems.

Unlisted appliances must be vented in accordance with local building codes and the manufacturers' installation instructions. Clearance from vent piping to combustible material, mechanical support of vent piping, and similar requirements are also included in local codes.

Building Depressurization

Appliance operation can be affected by operation of other appliances and equipment in the building that change building pressure with respect to outdoor pressure. Building pressure can be reduced by bathroom and kitchen exhaust fans, cooktop range downdraft exhausters, clothes dryers, fireplaces, other fuel-burning appliances, and other equipment that removes air from the building. If building pressure is significantly lower than outdoor pressure, venting flue gases to the outdoors might be adversely affected and potentially hazardous combustion products may be spilled into the inhabited space, especially from category I and II appliances. Category III and IV appliances are less susceptible to venting and spillage problems,

because these appliances produce pressure to force the flue gases through their vents to the outdoors. In addition, direct-vent appliances of all vent categories take their combustion air directly from the outdoors, which makes them even less susceptible to building depressurization. Wind can produce building depressurization, if building infiltration and exfiltration are unfavorably imbalanced.

Gas Input Rate

Gas input rate is the rate of heat energy input to an appliance, measured in kilowatts.

The unit heating value of the fuel gas is expressed in megajoules per cubic metre. In North America, **higher heating value (HHV)** is commonly used to specify the heat available from gas when combusted. HHV includes all of the heat available by burning fuel gas delivered at 15.0°C and 101.325 kPa (i.e., standard conditions for the gas industry in North America) when combustion products are cooled to 15.0°C and water vapor formed during combustion is condensed at 15.0°C. (*Note*: Standard conditions of 15.0°C and 101.325 kPa [see the section on U.S. Standard Atmosphere in Chapter 1 of the 2021 *ASHRAE Handbook—Fundamentals*] are slightly different from the standard conditions of 60°F [15.56°C] and 14.735 psia [30.00 in. Hg, or 101.594 kPa] used by the gas industry in North America and in the I-P version of this chapter.) See Chapter 28 of the 2021 *ASHRAE Handbook—Fundamentals* for more information on HHV.

In practical laboratory or field situations, fuel gas is not delivered at standard conditions. Determination of appliance input rate must include compensation for the actual temperature and pressure conditions.

In the laboratory, gas input rate is calculated with the following equation:

$$Q = 0.2778\text{HHV} \times \text{VFR} \times \frac{(T_s \times P)}{(T \times P_s)}$$

where

Q = gas input rate, kW

HHV = gas higher heating value at standard temperature and pressure, MJ/m^3

VFR = fuel gas volumetric flow rate at meter temperature and pressure, m^3/h

T_s = standard temperature, 288.15 K (15.0°C + 273.15 K)

P = fuel gas pressure in gas meter, kPa

T = absolute temperature of fuel gas in meter, K (fuel gas temperature in °C + 273.15 K)

P_s = standard pressure, 101.325 kPa

Example 1. Calculate the gas input rate for 38.00 MJ/m^3 HHV fuel gas, 24.0°C fuel gas temperature, 97.788 kPa barometer pressure (300.0 m altitude), 2.8 m^3/h of fuel gas volumetric flow rate clocked at the meter with 1.7 kPa fuel gas pressure in the gas meter.

$$P = B + P_f$$

where

B = local barometric pressure, kPa

P_f = fuel gas pressure in gas meter, kPa

P = 97.788 kPa + 1.7 kPa = 99.488 kPa

T = 24.0°C + 273.15 K = 297.15 K

Thus,

$$Q = \frac{0.2778 \text{ kWh}}{\text{MJ}} \times \frac{38.00 \text{ MJ/m}^3 \times 2.800 \text{ m}^3\text{/h} \times (288.15 \text{ K} \times 99.488 \text{ kPa})}{297.15 \text{ K} \times 101.325 \text{ kPa}}$$

$$= 28.143 \text{ kW gas input rate}$$

In the field, input can be measured in two ways:

- With a gas meter, usually furnished by the gas supplier at the gas entrance point to a building
- By using the appliance burner gas injector (orifice) size and the manifold pressure (pressure drop through the injector [orifice])

Gas input rate is calculated with the following equation, when fuel gas volumetric flow rate is measured using the gas supplier's meter.

$$Q = 0.2778\text{HC} \times \text{VFR}$$

where

Q = gas input rate, kW

0.2778 = conversion factor, MJ/h to kW

HC = local gas heat content, MJ/m^3

VFR = fuel gas volumetric flow rate, m^3/h

Effect of Gas Temperature and Barometric Pressure Changes on Gas Input Rate

In the field, gas temperature is typically unknown, but is sometimes assumed to be a standard temperature such as 15.0°C (15.6°C or 60°F in North America); some meters have built-in temperature compensation to that temperature. Some gas suppliers also tabulate data for both local barometric pressure and local metering pressure. Add the meter gage pressure to the barometric pressure to get a correct fuel-gas absolute pressure. This methodology is used in ANSI Z *Standard* 223.1/NFPA *Standard* 54 (*National Fuel Gas Code*), sections 11.1.1, 11.1.2, and A.11.1.1, and Table A.11.1.1.

Also see the installation codes in the references for methods for using gas meters and for using injector (orifice) size with pressure drop to measure fuel gas flow rate.

Fuel Gas Interchangeability

Gas-burning appliances are normally set up for operation at their rated input with fuel gas of specified properties. Because fuel gases vary greatly, other gases cannot be substituted indiscriminately.

In most gas appliances, input rate is controlled by establishing a specified gas pressure difference (often referred to as **manifold pressure**) across one or more precisely sized orifices. Per the Bernoulli equation, gas velocity through the orifice is proportional to the square root of the pressure difference and inversely proportional to the square root of the density. The input rate also depends on the heat content of the gas and orifice size. Simplified to the basics, it is expressed as follows for particular conditions of temperature and barometric pressure:

$$Q = K \times \text{HHV} \times D_o^2 \sqrt{\frac{P_m}{\text{SG}}} \quad (1)$$

where

Q = input rate, kW

K = constant accounting for measurement units, orifice discharge coefficient, and atmospheric conditions

HHV = gas higher heating value, MJ/m^3

D_o = orifice diameter, mm

P_m = manifold pressure, Pa

SG = gas specific gravity, dimensionless

If a substitute gas is introduced, only the higher heating value and specific gravity change. The orifice diameter, manifold pressure, and factors accounted for in the constant K do not change. Therefore, the new input is directly proportional to the gas higher heating value and inversely proportional to the square root of the specific gravity:

$$\frac{Q_2}{Q_1} = \left(\frac{\text{HHV}_2}{\sqrt{\text{SG}_2}}\right) \Big/ \left(\frac{\text{HHV}_1}{\sqrt{\text{SG}_1}}\right) \quad (2)$$

where subscripts 1 and 2 indicate the original and substitute gases, respectively. The ratio of higher heating value to the square root of the specific gravity has been named the **Wobbe index** W. The units of the Wobbe index are the same as those of the heating value because the specific gravity is dimensionless. Substituting for Wobbe index,

$$\frac{\text{HHV}}{\sqrt{\text{SG}}} = W \tag{3}$$

$$\frac{Q_2}{Q_1} = \frac{W_2}{W_1} \tag{4}$$

$$Q_2 = Q_1 \frac{W_2}{W_1} \tag{5}$$

In other words, when one gas is substituted for another in an appliance and no other changes are made, the input rate changes in proportion to their Wobbe indices. Preservation of input rate does not necessarily ensure proper operation of an appliance, however. Ignition and burning characteristics can differ significantly for gases that have the same Wobbe index. To ensure safe, efficient operation, appliance manufacturers typically limit the range of gases that may be used.

Converting an appliance for use with a gas substantially different from the gas it was originally set up for requires changing the gas-handling components and/or adjustments. Typical natural gas and commercial propane, for example, have Wobbe indices of about 50 and 76 MJ/m^3, respectively. Based on that difference, substituting propane in an unaltered natural gas appliance results in overfiring of the appliance by about 53%, leading to appliance overheating and high production of soot and carbon monoxide. To accommodate the change, it is necessary to change the gas orifice size and, usually, the gas pressure regulator setting to achieve the same gas input rate. Acceptable performance may require additional appliance modifications to avoid other problems (e.g., resonance, poor flame carryover between ganged burners) that manufacturers must identify and resolve. The components necessary for conversion are normally provided by the appliance manufacturer, along with instructions for their installation and checkout of appliance operation.

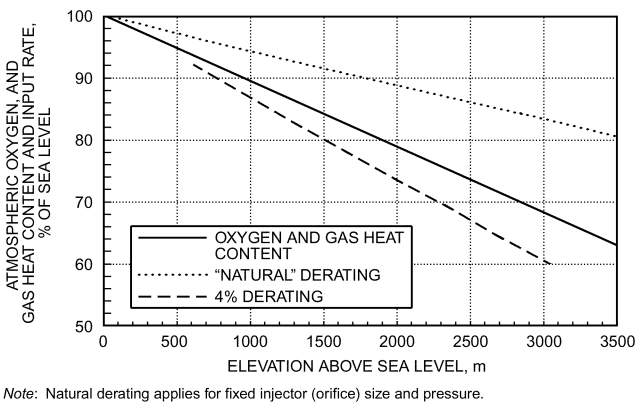
Natural gas is increasingly being transported across oceans as **liquefied natural gas (LNG)**, shipped at high pressure and low temperature in specially designed ships. It is regasified in facilities at the destination, then distributed by utilities in conventional pipelines and service piping. Depending on the characteristics of a utility's existing gas supply, LNG can differ significantly in its mix of various hydrocarbons, inert gases, etc., and its burning characteristics may be of concern relative to the existing gas. Depending on the extent of the difference, a utility may mix it with other components to improve its compatibility with the existing appliance load. The Wobbe index is useful in evaluating the need for such accommodation.

Altitude

When gas-fired appliances are operated at altitudes substantially above sea level, three notable effects occur:

- Oxygen available for combustion is reduced in proportion to the atmospheric pressure reduction
- With gaseous fuels, the heat of combustion per unit volume of fuel gas (gas heat content) is reduced because of reduced fuel gas density in proportion to the atmospheric pressure reduction
- Reduced air density affects the performance and operating temperature of heat exchangers and appliance cooling mechanisms

In addition to reducing the gas heat content of fuel gas, reduced fuel gas density also causes increased gas velocity through flow metering orifices. The net effect is for gas input rate to decrease naturally with increases in altitude, but at less than the rate at which atmospheric oxygen decreases. This effect is one reason that derating is required when appliances are operated at altitudes significantly above sea level. Early research by American Gas Association Laboratories with draft hood-equipped appliances established that appliance input rates should be reduced at the rate of 4% per 305 m above sea level, for altitudes higher than 610 m above sea level (Figure 9).



Note: Natural derating applies for fixed injector (orifice) size and pressure.

Fig. 9 Altitude Effects on Gas Combustion Appliances

Experience with recently developed appliances having fan-assisted combustion systems demonstrated that the 4% rule may not apply in all cases. It is therefore important to consult the manufacturer's listed appliance installation instructions, which are based on both how the combustion system operates and other factors such as impaired heat transfer. Note also that manufacturers of appliances having tracking-type burner systems may not require derating at altitudes above 610 m. In those systems, fuel gas and combustion airflow are affected in the same proportion by density reduction.

In terms of end use, it is important for the appliance specifier to be aware that the heating capacity of appliances is substantially reduced at altitudes significantly above sea level. To ensure adequate delivery of heat, derating of heating capacity must also be considered and quantified.

By definition, fuel gas HHV value remains constant for all altitudes because it is based on standard conditions of 101.325 kPa and 15.0°C (288.15 K). Some fuel gas suppliers at high altitudes (e.g., at Denver, Colorado, at 1525 m) may report fuel gas heat content at local barometric pressure instead of standard pressure. Local gas heat content can be calculated using the following equation:

$$\text{HC} = \text{HHV} \times \frac{B}{P_s}$$

where

HC = local gas heat content at local barometric pressure and standard temperature conditions, MJ/m^3
HHV = gas higher heating value at standard temperature and pressure of 15.0°C (288.15 K) and 101.325 kPa, respectively, MJ/m^3
B = local barometric pressure, kPa (not corrected to sea level: do not use barometric pressure as reported by weather forecasters, because it is corrected to sea level)
P_s = standard pressure = 101.325 kPa

For example, at 1525 m, the barometric pressure is 84.316 kPa. If HHV of a fuel gas sample is 37.5 MJ/m^3 (at standard temperature and pressure), the local gas heat content would be 31.21 MJ/m^3 at 84.316 kPa barometric pressure 1525 m above sea level.

$$\text{HC} = 37.5 \text{ MJ/m}^3 \times 84.316 \text{ kPa}/101.325 \text{ kPa} = 31.21 \text{ MJ/m}^3$$

Therefore, the local gas heat content of a sample of fuel gas can be expressed as 31.21 MJ/m^3 at local barometric pressure of 84.316 kPa and standard temperature or as 37.5 MJ/m^3 (HHV). Both gas heat

contents are correct, but the application engineer must understand the difference to use each one correctly. As described earlier, the local heat content HC can be used to determine appliance input rate.

When gas heat value (either HHV or HC) is used to determine gas input rate, the gas pressure and temperature in the meter must also be considered. Add the gage pressure of gas in the meter to the local barometric pressure to calculate the heat content of the gas at the pressure in the meter. The gas temperature in the meter also affects the heat content of the gas in the meter. The gas heat value is directly proportional to the gas pressure and inversely proportional to its absolute temperature in accordance with the perfect gas laws, as illustrated in the following example calculations for gas input rate with either the HHV or the local heat content.

Example 2. Calculate the gas input rate for 37.5 MJ/m^3 HHV fuel gas, 2.800 m^3/h volumetric flow rate of 24°C fuel gas at 84.316 kPa barometer pressure (1525 m altitude) with 1.700 kPa (gage) fuel gas gage pressure in the gas meter.

HHV Method:

$$Q = 0.2778\text{HHV} \times \text{VFR}_s$$

where

Q = fuel gas input rate, kW
0.2778=conversion factor, MJ/h to kW
HHV= fuel gas higher heating value at standard temperature and pressure, MJ/m^3
VFR_s=fuel gas volumetric flow rate adjusted to standard temperature and pressure, m^3/h
= $\text{VFR}(T_s \times P)/(T \times P_s)$
VFR= fuel gas volumetric flow rate at local temperature and pressure conditions, m^3/h
T_s = standard temperature, 288.15 K (15.0°C + 273.15 K)
P = gas meter absolute pressure, kPa (local barometer pressure + gas pressure in meter relative to barometric pressure)
= 84.316 kPa + 1.700 kPa = 86.016 kPa gas meter absolute pressure
T = absolute temperature of fuel gas, K (fuel gas temperature in °C + 273.15 K)
P_s = standard pressure, 101.325 kPa

Substituting given values into the equation for VFR_s gives

$$\text{VFR}_s = \frac{2.800\ \text{m}^3/\text{h} \times 288.15\ \text{K} \times 86.016\ \text{kPa}}{(24.00°\text{C} + 273.15\ \text{K})101.325\ \text{kPa}} = 2.305\ \text{m}^3/\text{h}$$

Then,

$$Q = 0.2778 \times 37.5\ \text{MJ/m}^3 \times 2.305\ \text{m}^3/\text{h} = 24.012\ \text{kW}$$

Local Gas Heat Content Method: The local gas heat content is simply the HHV adjusted to local gas meter pressure and temperature conditions. The gas input rate is simply the observed volumetric gas flow rate times the local gas heat content.

$$Q = 0.2778\text{HC} \times \text{VFR}$$

where

Q = gas input rate, kW
0.2778=conversion factor, MJ/h to kW
HC = gas heat content at local gas meter pressure and temperature conditions, MJ/m^3
= $\text{HHV}(T_s \times P)/(T \times P_s)$
VFR = fuel gas volumetric flow rate, referenced to local gas meter pressure and temperature conditions, m^3/h
T_s = standard temperature, 288.15 K (15.00°C + 273.15 K)
P = gas meter absolute pressure, kPa (local barometer pressure + gas pressure in gas meter relative to barometric pressure)
P_s = standard pressure = 101.325 kPa
B = local barometric pressure = 84.316 kPa
T = absolute temperature of fuel gas, 297.15 K (24.00°C fuel gas temperature + 273.15 K)

Substituting given values into the equation for HC gives

$$\text{HC} = \frac{37.5 \times 288.15(84.316 + 1.700)}{297.15 \times 101.325} = 30.87\ \text{MJ/m}^3$$

Then,

$$Q = 0.2778 \times 30.87\ \text{MJ/m}^3 \times 2.800\ \text{m}^3/\text{h} = 24.012\ \text{kW}$$

The gas input rate is exactly the same for both calculation methods.

3. OIL-BURNING APPLIANCES

An oil burner is a mechanical device for preparing fuel oil to combine with air under controlled conditions for combustion. Fuel oil is atomized at a controlled flow rate. Air for combustion is generally supplied with a forced-draft fan, although natural or mechanically induced draft can be used. Ignition is typically provided by an electric spark, although gas pilot flames, oil pilot flames, and hot-surface igniters may also be used. Oil burners operate from automatic temperature- or pressure-sensing controls.

Oil burners may be classified by application, type of atomizer, or firing rate. They can be divided into two major groups: residential and commercial/industrial. Further distinction is made based on design and operation; different types include pressure atomizing, air or steam atomizing, rotary, vaporizing, and mechanical atomizing. Unvented, portable kerosene heaters are not classified as residential oil burners or as oil heat appliances.

3.1 RESIDENTIAL OIL BURNERS

Residential oil burners ordinarily consume fuel at a rate of 0.5 to 3.7 mL/s, corresponding to input rates of about 20 to 150 kW. However, burners up to 3.7 mL/s (about 300 kW input) sometimes fall in the residential classification because of basic similarities in controls and standards. (Burners with a capacity of 7.4 mL/s and above are classified as commercial/industrial.) No. 2 fuel oil is generally used, although burners in the residential size range can also operate on No. 1 fuel oil. Burners in the 0.5 to 2.5 mL/s range are used not only for boilers and furnaces for space heating, but also for separate tank-type residential water heaters, infrared heaters, space heaters, and other commercial appliances.

Central heating appliances include warm-air furnaces and steam or hot water boilers. Oil-burning furnaces and boilers operate essentially the same way as their gas counterparts. NFPA *Standard* 31 prescribes correct installation practices for oil-burning appliances.

Steam or hot-water boilers are available in cast iron and steel. In addition to supplying space heating, many boilers are designed to provide hot water using tankless integral or external heat exchangers. Residential boilers designed to operate as direct-vent appliances are available.

Over 95% of residential burners manufactured today are high-pressure atomizing gun burners with retention-type heads (Figure 10). This type of burner supplies oil to the atomizing nozzle at pressures that range from 700 to 2100 kPa. A fan supplies air for combustion, and generally an inlet damper regulates the air supply at the burner. A high-voltage electric spark ignites the fuel by either **constant ignition** (on when the burner motor is on) or **interrupted ignition** (on only to start combustion). Typically, these burners fire into a combustion chamber in which draft is maintained. Increasingly, however, these burners are being fired into applications (including direct-vent and high-efficiency condensing applications) that have a low level of positive combustion chamber pressure.

Modern retention-head oil burners use 3450 rpm motors, and their fans achieve a maximum static pressure of about 750 Pa. Older residential oil burners, which can still be found in the field, used lower-speed motors (1750 rpm) and achieved a maximum static pressure of about 250 to 375 Pa. With higher fan static pressure, burner airflow is less sensitive to variations in appliance draft conditions. Higher-static-pressure burners operate better in applica-

tions with positive combustion chamber pressure. In many cases, these burners can be operated without a flue draft regulator.

Traditionally, oil burners are operated with a fuel pressure of 700 kPa, and burners' nozzles are all rated for firing rate and spray angle at this pressure. Increasingly higher pressures (900 to 1050 kPa) are specified by manufacturers for some burners and applications, to achieve better atomization and combustion performance (Figure 11). Nozzle fuel firing rate increases in proportion to the square root of the fuel pressure.

Oil nozzle line heaters are used in some applications. These are very small electric heaters located adjacent to the nozzle adapter and typically integrated with the burner. These include positive-temperature-coefficient heaters that self-regulate to achieve a fuel temperature in the 50 to 65°C range. Heating fuel in this way improves atomization quality and reduces fuel firing rate.

Electric fuel solenoid valves may be installed in the fuel line between the fuel pump and the nozzle and may be mounted directly on the fuel pump. These valves serve to provide sharp fuel flow starts and stops during cyclic operation and augment the function of the fuel pump and pressure-operated flow control valves. In addition, solenoid valves can be used to achieve pre- and post-purge operation in which the burner motor runs to provide purge airflow through the burner and appliance. The post purge can be useful in reducing nozzle temperatures after shutdown and preventing odors indoors, particularly with non-direct-vent applications.

Pressure-operated valves integrated with oil burner nozzle assemblies are also available. These valves also provide positive fuel cutoff after burner shutdown and avoid after-drip caused by heat transfer from the still-hot combustion chamber to the nozzle assembly and accumulation of fuel vapor pressure in the nozzle assembly and fuel line. When used, these nozzle valves require the fuel pump discharge pressure to be increased, using the integral pump pressure regulator to compensate for the added pressure drop of the valve.

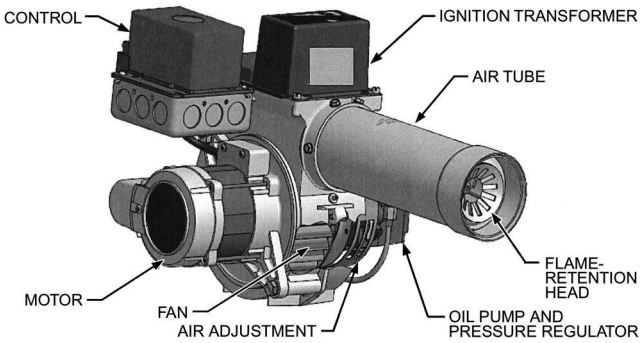


Fig. 10 High-Pressure Atomizing Gun Oil Burner

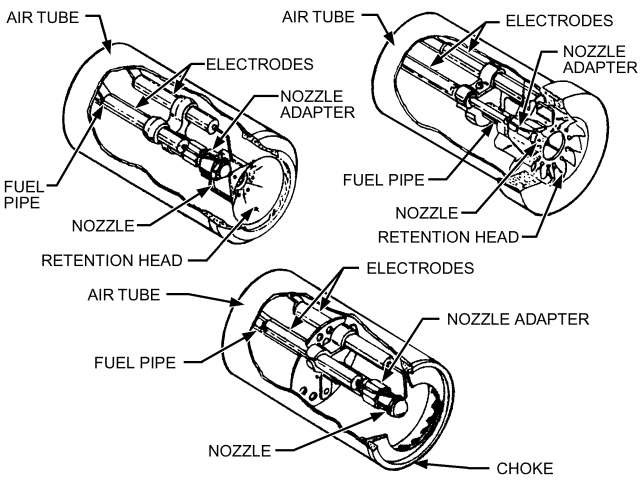

Fig. 11 Details of High-Pressure Atomizing Oil Burner

The following designs are still in operation but are not a significant part of the residential market:

- The low-pressure atomizing gun burner differs from the high-pressure type in that it uses air at a low pressure to atomize oil.
- The pressure atomizing induced-draft burner uses the same type of oil pump, nozzle, and ignition system as the high-pressure atomizing gun burner.
- Vaporizing burners are designed for use with No. 1 fuel oil. Fuel is ignited electrically or by manual pilot.
- Rotary burners are usually of the vertical wall flame type.

Beyond the pressure atomizing burner, considerable developmental effort has been put into advanced technologies such as air atomization, fuel prevaporization, and pulsed fuel flow. Some of these are now used commercially in Europe. Reported benefits include reduced emissions, increased efficiency, and the ability to quickly vary the firing rate. See Locklin and Hazard (1980) for a historical review of technology for residential oil burners. Somewhat more recent developments are described in the *Proceedings of the Oil Heat Technology Conferences and Workshops* (McDonald 1989-2003).

In Europe, there is increasing use of low-NO_x, **blue flame burners** for residential and commercial applications. Peak flame temperatures (and thermal NO_x emissions) are reduced by using high flame zone recirculation rates. In a typical boiler, a conventional yellow flame retention head oil burner has a NO_x emission of 90 to 110 ppm. A blue flame burner emits about 60 ppm. The blue flame burners require flame sensors for the safety control, which responds to the fluctuating light emitted. Blue flame burners are somewhat more expensive than conventional yellow flame burners. See Butcher et al. (1994) for additional discussion of NO_x and small oil burners.

3.2 COMMERCIAL/INDUSTRIAL OIL BURNERS

Commercial and industrial oil burners are designed for use with distillate or residual grades of fuel oil. With slight modifications, burners designed for residual grades can use distillate fuel oils.

The commercial/industrial burners covered here have atomizers, which inject the fuel oil into the combustion space in a fine, conical spray with the apex at the atomizer. The burner also forces combustion air into the oil spray, causing an intimate and turbulent mixing of air and oil. Applied for a predetermined time, an electrical spark, a spark-ignited gas, or an oil igniter ignites the mixture, and sustained combustion takes place. Safety controls are used to shut down the burner upon failure to ignite.

All of these burners can almost completely burn the fuel oil without visible smoke when they are operated with excess air as low as 20% (approximately 12% CO_2 in the flue gases). Atomizing oil burners are generally classified according to the method used for atomizing the oil, such as pressure atomizing, return-flow pressure atomizing, air atomizing, rotary cup atomizing, steam atomizing, mechanical atomizing, or return-flow mechanical atomizing. Descriptions of these burners are given in the following sections, together with usual capacities and applications. Table 1 lists approximate size range, fuel grade, and usual applications. All burners described are available as gas/oil (dual-fuel) burners.

Pressure-Atomizing Oil Burners

This type of burner is used in most installations where No. 2 fuel oil is burned. The oil is pumped at pressures of 700 to 2100 kPa through a suitable burner nozzle orifice that breaks it into a fine mist

Table 1 Classification of Atomizing Oil Burners

Type of Oil Burner	Heat Range, MW	Flow Volume, mL/s	Fuel Grade	Usual Application
Pressure-atomizing	0.02 to 2	0.5 to 50	No. 2 (less than 25 mL/s)	Boilers Warm-air furnaces
			No. 4 (greater than 25 mL/s)	Appliances
Return-flow pressure-atomizing or modulating pressure-atomizing	1 and above	25 and above	No. 2 and heavier	Boilers Warm-air furnaces
Air-atomizing	0.02 to 0.3	0.5 to 7	No. 2 and heavier	Boilers Warm-air furnaces
Horizontal rotary cup	0.2 to 10	5 to 30	No. 2 for small sizes	Boilers
			No. 4, 5, or 6 for larger sizes	Large warm-air furnaces
Steam-atomizing (register-type)	3.5 and above	85 and above	No. 2 and heavier	Boilers
Mechanical atomizing (register-type)	3.5 and above	85 and above	No. 2 and heavier	Boilers Industrial furnaces
Return-flow mechanical atomizing	13 to 50	310 to 1260	No. 2 and heavier	Boilers

and swirls it into the combustion space as a cone-shaped spray. Combustion air from a fan is forced through the burner air-handling parts surrounding the oil nozzle and is directed into the oil spray.

For smaller-capacity burners, ignition is usually started by an electric spark applied near the discharge of the burner nozzle. For burner capacities above 20 mL/s, a spark-ignited gas or an oil igniter is used.

Pressure-atomizing burners are designated commercially as forced-draft, natural-draft, or induced-draft burners. The forced-draft burner has a fan and motor with capacity to supply all combustion air to the combustion chamber or furnace at a pressure high enough to force the gases through the heat-exchange equipment without the assistance of an induced-draft fan or a chimney draft. Mixing of the fuel and air is such that a minimum of refractory material is required in the combustion space or furnace to support combustion. The natural-draft burner requires a draft in the combustion space.

Burner range, or variation in burning rate, is changed by simultaneously varying the oil pressure to the burner nozzle and regulating the airflow by a damper. This range is limited to about 1.6 to 1 for any given nozzle orifice. Burner firing mode controls for various capacity burners differ among manufacturers. Usually, larger burners have controls that provide variable heat inputs. If burner capacity is up to 16 mL/s, a staged control is typically used; if it is up to 25 mL/s, a **modulation control** is typically used. In both cases, the low burning rate is about 60% of the full-load capacity of the burner.

For pressure-atomizing burners, no preheating is required for burning No. 2 oil. No. 4 oil must be preheated to about 38°C for proper burning. When properly adjusted, these burners operate well with less than 20% excess air (approximately 12% CO_2); no visible smoke (approximately No. 2 smoke spot number, as determined by ASTM *Standard* D2156); and only a trace of carbon monoxide in the flue gas in commercial applications. In these applications, the regulation of combustion airflow is typically based on smoke level or flue gas monitoring using analyzers for CO, O_2, or CO_2.

Burners with lower firing rates used to power appliances, residential heating boilers, or warm-air furnaces are usually set up to operate to about 50% excess air (approximately 10% CO_2).

Good operation of these burners calls for (1) a relatively constant draft (either in the furnace or at the breeching connection, depending on the burner selected), (2) clean burner components, and (3) good-quality fuel oil that complies with the appropriate specifications.

Return-Flow Pressure-Atomizing Oil Burners

This burner is a modification of the pressure-atomizing burner; it is also called a modulating-pressure atomizer. It has the advantage of a wide load range for any given atomizer: about 3 to 1 turndown (or variation in load) as compared to 1.6 to 1 for the straight pressure atomizing burner.

This wide range is accomplished by means of a return-flow nozzle, which has an atomizing swirl chamber just ahead of the orifice. Good atomization throughout the load range is attained by maintaining a high rate of oil flow and high pressure drop through the swirl chamber. The excess oil above the load demand is returned from the swirl chamber to the oil storage tank or to the suction of the oil pump.

The burning rate is controlled by varying oil pressure in both the oil inlet and oil return lines. Except for the atomizer, load range, and method of control, the information given for the straight pressure-atomizing burner applies to this burner as well.

Air-Atomizing Oil Burners

Except for the nozzle, this burner is similar in construction to the pressure-atomizing burner. Atomizing air and oil are supplied to individual parts within the nozzle. The nozzle design allows the oil to break up into small droplet form as a result of the shear forces created by the atomizing air. The atomized oil is carried from the nozzle through the outlet orifice by the airflow into the furnace.

The main combustion air from a draft fan is forced through the burner throat and mixes intimately with the oil spray inside the combustion space. The burner igniter is similar to that used on pressure-atomizing burners.

This burner is well suited for heavy fuel oils, including No. 6, and has a wide load range, or turndown, without changing nozzles. Turndown of 3 to 1 for the smaller sizes and about 6 or 8 to 1 for the larger sizes may be expected. Load range is varied by simultaneously varying the oil pressure, the atomizing air pressure, and the combustion air entering the burner. Some designs use relatively low atomizing air pressure (35 kPa and lower); other designs use air pressures up to 520 kPa. The burner uses from 16 to 58 L of compressed air per litre of fuel oil (on an air-free basis).

Because of its wide load range, this burner operates well on modulating control.

No preheating is required for No. 2 fuel oil. The heavier grades of oil must be preheated to maintain proper viscosity for atomization. When properly adjusted, these burners operate well with less than 15 to 25% excess air (approximately 14 to 12% CO_2, respectively, at full load); no visible smoke (approximately No. 2 smoke spot number); and only a trace of carbon monoxide in the flue gas.

Horizontal Rotary Cup Oil Burners

This burner atomizes the oil by spinning it in a thin film from a horizontal rotating cup and injecting high-velocity primary air into the oil film through an annular nozzle that surrounds the rim of the atomizing cup.

The atomizing cup and frequently the primary air fan are mounted on a horizontal main shaft that is motor-driven and rotates at constant speed (58 to 100 r/s) depending on the size and make of the burner. The oil is fed to the atomizing cup at controlled rates from an oil pump that is usually driven from the main shaft through a worm and gear.

A separately mounted fan forces secondary air through the burner windbox. Secondary air should not be introduced by natural draft. The oil is ignited by a spark-ignited gas or an oil-burning igniter (pilot). The load range or turndown for this burner is about 4 to 1, making it well suited for operation with modulating control. Automatic combustion controls are electrically operated.

When properly adjusted, these burners operate well with 20 to 25% excess air (approximately 12.5 to 12% CO_2, respectively, at full load), no visible smoke (approximately No. 2 smoke spot number), and only a trace of carbon monoxide in the flue gas.

This burner is available from several manufacturers as a package comprising burner, primary air fan, secondary air fan with separate motor, fuel oil pump, motor, motor starter, ignition system (including transformer), automatic combustion controls, flame safety equipment, and control panel.

Good operation of these burners requires relatively constant draft in the combustion space. The main assembly of the burner, with motor, main shaft, primary air fan, and oil pump, is arranged for mounting on the boiler front and is hinged so that the assembly can be swung away from the firing position for easy access.

Rotary burners require some refractory in the combustion space to help support combustion. This refractory may be in the form of throat cones or combustion chamber liners.

Steam-Atomizing Oil Burners (Register Type)

Atomization is accomplished in this burner by the impact and expansion of steam. Oil and steam flow in separate channels through the burner gun to the burner nozzle. There, they mix before discharging through an orifice, or series of orifices, into the combustion chamber.

Combustion air, supplied by a forced-draft fan, passes through the directing vanes of the burner register, through the burner throat, and into the combustion space. The vanes give the air a spinning motion, and the burner throat directs it into the cone-shaped oil spray, where intimate mixing of air and oil takes place.

Full-load oil pressure at the burner inlet is generally some 700 to 1050 kPa, and the steam pressure is usually kept higher than the oil pressure by about 170 kPa. Load range is accomplished by varying these pressures. Some designs operate with oil pressure ranging from 1050 kPa at full load to 70 kPa at minimum load, resulting in a turndown of about 8 to 1. This wide load range makes the steam atomizing burner suited to modulating control. Some manufacturers provide dual atomizers within a single register so that one can be cleaned without dropping load.

Depending on the burner design, steam atomizing burners use from 0.1 to 0.6 kg of steam to atomize a litre of oil. This corresponds to 0.5 to 3.0% of the steam generated by the boiler. Where no steam is available for start-up, compressed air from the plant air supply may be used for atomizing. Some designs allow use of a pressure atomizing nozzle tip for start-up when neither steam nor compressed air is available.

This burner is used mainly on water-tube boilers, which generate steam at 1050 kPa or higher and at capacities above 3500 kW input.

Oils heavier than grade No. 2 must be preheated to the proper viscosity for good atomization. When properly adjusted, these burners operate well with 15% excess air (14% CO_2) at full load, without visible smoke (approximately No. 2 smoke spot number), and with only a trace of carbon monoxide in the flue gas.

Mechanical Atomizing Oil Burners (Register Type)

Mechanical atomizing, as generally used, describes a technique synonymous with pressure atomizing. Both terms designate atomization of the oil by forcing it at high pressure through a suitable stationary atomizer.

The mechanical atomizing burner has a windbox, which is a chamber into which a fan delivers combustion and excess air for distribution to the burner. The windbox has an assembly of adjustable internal air vanes called an air register. Usually, the fan is mounted separately and connected to the windbox by a duct.

Oil pressure of 600 to 6000 kPa is used, and load range is obtained by varying the pressure between these limits. The operating range or turndown for any given atomizer can be as high as 3 to 1. Because of its limited load range, this type of burner is seldom selected for new installations.

Return-Flow Mechanical Atomizing Oil Burners

This burner is a modification of a mechanical atomizing burner; atomization is accomplished by oil pressure alone. Load ranges up to 6 or 8 to 1 are obtained on a single-burner nozzle by varying the oil pressure between 700 and 7000 kPa.

The burner was developed for use in large installations such as on ships and in electric generating stations where wide load range is required and water loss from the system makes use of atomizing steam undesirable. It is also used for firing large hot-water boilers. Compressed air is too expensive for atomizing oil in large burners.

This is a register burner similar to the mechanical atomizing burner. Wide range is possible by using a return-flow nozzle, which has a swirl chamber just ahead of the orifice or sprayer plate. Good atomization is attained by maintaining a high rate of oil flow and a high pressure drop through the swirl chamber. Excess oil above the load demand is returned from the swirl chamber to the oil storage tank or to the oil pump suction. Control of burning rate is accomplished by varying the oil pressure in both the oil inlet and the oil return lines.

3.3 DUAL-FUEL GAS/OIL BURNERS

Dual-fuel, combination gas/oil burners are forced-draft burners that incorporate, in a single assembly, the features of the commercial/industrial-grade gas and oil burners described in the preceding sections. These burners have controls to ensure that the burner flame relay or programmer cycles the burner through post- and prepurge before starting again on the other fuel. Burner manufacturers for larger boilers design the special mechanical linkages needed to deliver the correct air/fuel ratios at full fire, low fire, or any intermediate rate. Smaller burners may have straight **on/off** firing. Larger burners may have low-fire starts on both fuels and use a common flame scanner. Smaller dual-fuel burners usually include pressure atomization of the oil. Air atomization systems are included in large oil burners.

Dual-fuel burners often have automatic changeover controls that respond to outdoor temperature. A special temperature control, located outdoors and electrically interlocked with the dual-fuel burner control system, senses outdoor temperature. When the outdoor temperature drops to the outdoor control set point, the control changes fuels automatically after putting the burner through post- and prepurge cycles. A manual fuel selection switch can be retained as a manual override on the automatic feature. These control systems require special design and are generally provided by the burner manufacturer.

The dual-fuel burner is fitted with a gas train and oil piping that is connected to a two-pipe oil system following the principles of the preceding sections. An oil reserve must be maintained at all times for automatic fuel changeover.

Table 2 Guide for Fuel Oil Grades Versus Firing Rate

Maximum Heat Input of Unit, kW	Volume Flow Rate, mL/s	Fuel Grade
Up to 1000	Up to 25	2
1000 to 2000	25 to 50	2, 4, 5
2000 to 4400	50 to 100	5, 6
Over 4400	Over 100	6

Boiler flue chimney connectors are equipped with special double-swing barometric draft regulators or, if required, sequential furnace draft control to operate an automatic flue damper.

Dual-fuel burners and their accessories should be installed by experienced contractors to ensure satisfactory operation.

3.4 EQUIPMENT SELECTION

Economic and practical factors (e.g., the degree of operating supervision required by the installation) generally dictate the selection of fuel oil based on the maximum heat input of the oil-burning appliance. For heating loads and where only one oil-burning appliance is operated at any given time, the relationship is as shown in Table 2 (which is only a guide). In many cases, a detailed analysis of operating parameters results in the burning of lighter grades of fuel oil at capacities far above those indicated.

Fuel Oil Storage Systems

All fuel-oil storage tanks should be constructed and installed in accordance with NFPA *Standard* 31 and with local ordinances.

Storage Capacity. Dependable and economical operation of oil-burning appliances requires ample and safe storage of fuel oil at the site. Design responsibility should include analysis of specific storage requirements as follows:

- Rate of oil consumption.
- Dependability of oil deliveries.
- Economical delivery lots. The cost of installing larger storage capacity should be balanced against the savings indicated by accommodating larger delivery lots. Truck lots and railcar lots vary with various suppliers, but the quantities are approximated as follows:

Small truck lots in metropolitan area	1900 to 7600 L
Normal truck lots	7600 to 19 000 L
Transport truck lots	19 000 to 34 000 L
Rail tanker lots	30 300 to 45 400 L

Tank Size and Location. Standard oil storage tanks range in size from 200 to 190 000 L and larger. Tanks are usually built of steel; concrete construction may be used only for heavy oil. Unenclosed tanks located in the lowest story, cellar, or basement should not exceed 2500 L capacity each, and the aggregate capacity of such tanks should not exceed 5000 L unless each 2500 L tank is insulated in an approved fireproof room having a fire resistance rating of at least 2 h.

If storage capacity at a given location exceeds about 3800 L, storage tanks should be underground and accessible for truck or rail delivery with gravity flow from the delivering carrier into storage. If the oil is to be burned in a central plant such as a boiler house, the storage tanks should be located, if possible, so that the oil burner pump (or pumps) can pump directly from storage to the burners. For year-round operation, except for storage or supply capacities below 7600 L, at least two tanks should be installed to facilitate tank inspection, cleaning, repairs, and clearing of plugged suction lines.

When the main oil storage tank is not close enough to the oil-burning appliances for the burner pumps to take suction from storage, a supply tank must be installed near the oil-burning appliances and oil must be pumped periodically from storage to the supply tank by a transport pump at the storage location. Supply tanks should be treated the same as storage tanks regarding location within buildings, tank design, etc. On large installations, it is recommended that standby pumps be installed as a protection against heat loss in case of pump failure.

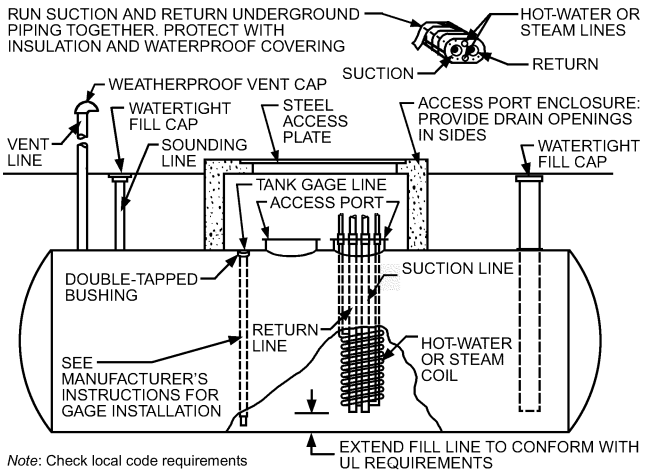

Fig. 12 Typical Oil Storage Tank (No. 6 Oil)

Because all piping connections to underground tanks must be at the top, such tanks should not be more than 3.2 m from top to bottom to avoid pump suction difficulties. (This dimension may have to be less for installations at high altitudes.) At sea level, the total suction pressure for the oil pump must not exceed 42 kPa.

Connections to Storage Tank. All piping connections for tanks over 1.0 m^3 capacity should be through the top of the tank. Figure 12 shows a typical arrangement for a cylindrical storage tank with a heating coil as required for No. 5 or 6 fuel oils. The heating coil and oil suction lines should be located near one end of the tank. The maximum allowable steam pressure in such a heating coil is 100 kPa. The heating coil is unnecessary for oils lighter than No. 5 unless a combination of high pour point and low outdoor temperature makes heating necessary.

A watertight access port with internal ladder provides access to the inside of the tank. If the tank is equipped with an internal heating coil, a second access port is required to permit withdrawal of the coil.

The fill line should be vertical and should discharge near the end of the tank away from the oil suction line. The inlet of the fill line must be outside the building and accessible to the oil delivery vehicle unless an oil transfer pump is used to fill the tank. When possible, the inlet of the fill line should be at or near grade where filling may be accomplished by gravity. For gravity filling, the fill line should be at least 50 mm in diameter for No. 2 oil and 150 mm in diameter for No. 4, 5, or 6 oils. Where filling is done by pump, the fill line for No. 4, 5, or 6 oils may be 100 mm in diameter.

An oil return line bringing recirculated oil from the burner line to the tank should discharge near the oil suction line inlet. Each storage tank should be equipped with a vent line sized and arranged in accordance with NFPA *Standard* 31.

Each storage tank must have a device for determining oil level. For tanks inside buildings, the gaging device should be designed and installed so that oil or vapor will not discharge into a building from the fuel supply system. No storage tank should be equipped with a glass gage or any gage that, if broken, would allow oil to escape from the tank. Gaging by a measuring stick is permissible for outdoor or underground tanks.

Fuel-Handling Systems

The fuel-handling system consists of the pumps, valves, and fittings for moving fuel oil from the delivery truck or car into the

storage tanks and from the storage tanks to the oil burners. Depending on the type and arrangement of the oil-burning appliances and the grade of fuel oil burned, fuel-handling systems vary from simple to quite complicated arrangements.

The simplest handling system would apply to a single burner and small storage tank for No. 2 fuel oil, similar to a residential heating installation. The storage tank is filled through a hose from the oil delivery truck, and the fuel-handling system consists of a supply pipe between the storage tank and the burner pump. Equipment should be installed on light-oil tanks to indicate visibly or audibly when the tank is full; on heavy-oil tanks, a remote-reading liquid-level gage should be installed.

Figure 13 shows a complex oil supply arrangement for two burners on one oil-burning appliance. For an appliance with a single burner, the change in piping is obvious. For a system with two or more appliances, the oil line downstream of the oil discharge strainer becomes a main supply header, and the branch supply line to each appliance includes a flowmeter, automatic control valve, etc. For light oils requiring no heating, all oil-heating equipment shown in Figure 13 would be omitted. Both a suction and a return line should be used, except for gravity flow in residential installations.

Oil pumps (steam or electrically driven) should deliver oil at the maximum rate required by the burners (this includes the maximum firing rate, the oil required for recirculating, plus a 10% margin).

The calculated suction pressure at the entrance of any burner pump should not exceed 35 kPa for installations at sea level. At higher elevations, the suction pressure should be reduced in direct proportion to the reduction in barometric pressure.

Oil temperature at the pump inlet should not exceed 50°C. Where oil burners with integral oil pumps (and oil heaters) are used and suction lift from the storage tank is within the capacity of the burner pump, each burner may take oil directly from the storage tank through an individual suction line unless No. 6 oil is used.

Where two or more tanks are used, the piping arrangement into the top of each tank should be the same as for a single tank so that any tank may be used at any time; any tank can be inspected, cleaned, or repaired while the system is in operation.

The length of suction line between storage tank and burner pumps should not exceed 30 m. If the main storage tank(s) are located more than 30 m from the pumps, a supply tank should be installed near the pumps, and a transfer pump should be installed at the storage tanks for delivery of oil to the supply tank.

Central oil distribution systems comprising a central storage facility, distribution pumps or provision for gravity delivery, distribution piping, and individual fuel meters are used for residential communities, notably mobile home parks. Provisions of NFPA *Standard* 31, Installation of Oil Burning Equipment, should be followed in installing a central oil distribution system.

Fuel Oil Preparation System

Fuel oil preparation systems consist of oil heater, oil temperature controls, strainers, and associated valves and piping required to maintain fuel oil at the temperatures necessary to control the oil viscosity, facilitate oil flow and burning, and remove suspended matter.

Preparation of fuel oil for handling and burning requires heating the oil if it is No. 5 or 6. This decreases its viscosity so it flows properly through the oil system piping and can be atomized by the oil burner. No. 4 oil occasionally requires heating to facilitate burning. No. 2 oil requires heating only under unusual conditions.

For handling residual oil from the delivering carrier into storage tanks, the viscosity should be about 156 mm^2/s. For satisfactory pumping, viscosity of oil surrounding the inlet of the suction pipe must be 444 mm^2/s or lower; for oil with a high pour point, the temperature of the entire oil content of the tank must be above the pour point.

Storage tank heaters are usually made of pipe coils or grids using steam or hot water at or less than 100 kPa as the heating medium. Electric heaters are sometimes used. For control of viscosity for pumping, the heated oil surrounds the oil suction line inlet. For heating oils with high pour points, the heater should extend the entire

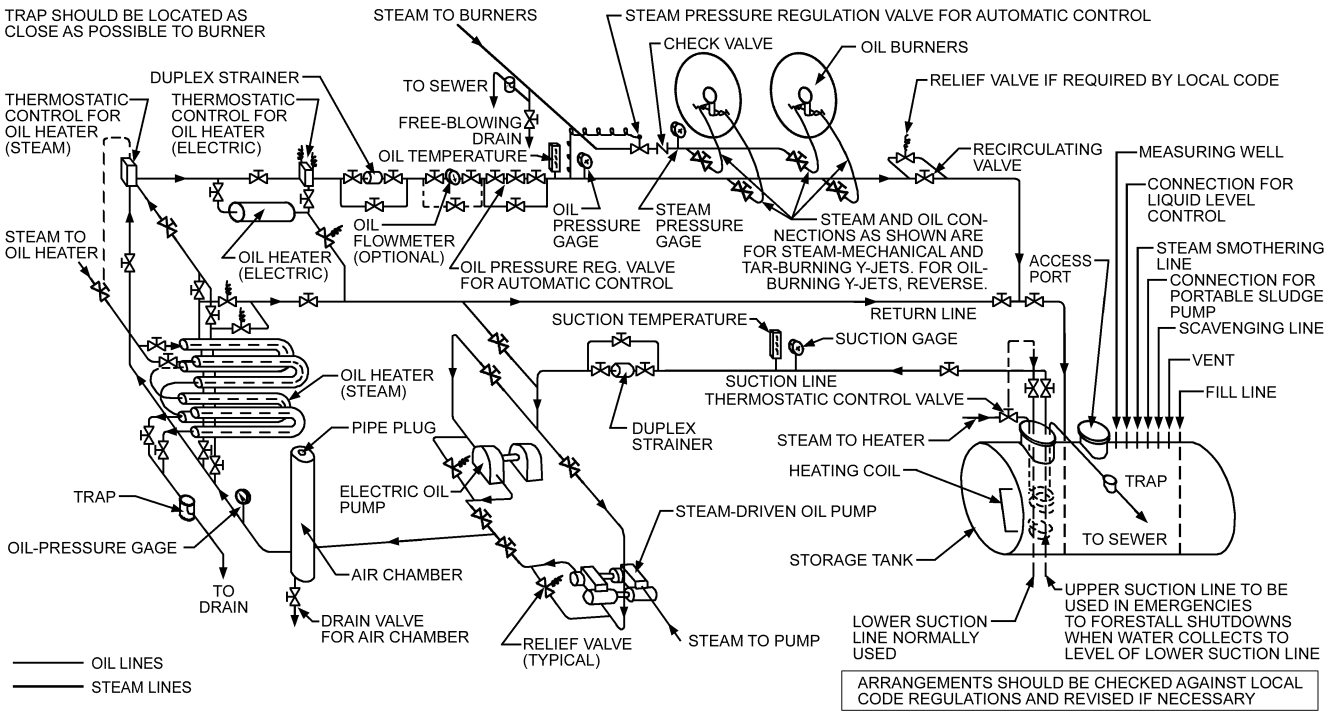

Fig. 13 Industrial Burner Auxiliary Equipment

length of the tank. All heaters have suitable thermostatic controls. In some cases, storage tanks may be heated satisfactorily by returning or recirculating some of the oil to the tank after it has passed through heaters located between the oil pump and oil burner.

Heaters to regulate viscosity at the burners are installed between the oil pumps and the burners. When required for small packaged burners, the heaters are either assembled integrally with the individual burners or mounted separately. The heat source may be electricity, steam, or hot water. For larger installations, the heater is mounted separately and is often arranged in combination with central oil pumps, forming a central oil pumping and heating set. The separate or central oil pumping and heating set is recommended for installations that burn heavy oils, have a periodic load demand, and require continuous circulation of hot oil during down periods.

Another system of oil heating to maintain pumping viscosity that is occasionally used for small- or medium-sized installations consists of an electrically heated section of oil piping. Low-voltage current is passed through the pipe section, which is isolated by nonconducting flanges.

The oil-heating capacity for any given installation should be approximately 10% greater than the maximum oil flow. Maximum oil flow is the maximum oil-burning rate plus the rate of oil recirculation.

Controls for oil heaters must be dependable to ensure proper oil atomization and avoid overheating of oil, which results in coke deposits inside the heaters. In steam or electric heating, include an interlock with a solenoid valve or switch to shut off the steam or electricity. When the oil pump is not operating, the oil in the heater can become overheated and deposit carbon. Overheating also can be a problem with oil heaters using high-temperature hot water. Provisions must be made to avoid overheating the oil when the oil pump is not operating.

Oil heaters with low- or medium-temperature hot water are not generally subject to coke deposits. Where steam or hot water is used in oil heaters located after the oil pumps, the pressure of the steam or water in the heaters is usually lower than the oil pressure. Consequently, heater leakage between oil and steam causes oil to flow into the water or condensing steam. To prevent oil from entering the boilers, discard the condensed steam or the water from such heaters from the system, or provide special equipment for oil removal.

Hot-water oil heaters of double-tube-and-shell construction with inert heat transfer oil and a sight glass between the tubes are available. With this type of heater, oil leaks through an oil-side tube appear in the sight glass, and repairs can be made to the oil-side tube before a water-side tube leaks.

This discussion of oil-burning equipment also applies to oil-fired boilers and furnaces (see Chapters 32 and 33).

4. SOLID-FUEL-BURNING APPLIANCES

A mechanical stoker is a device that feeds a solid fuel into a combustion chamber. It supplies air for burning the fuel under automatic control and, in some cases, incorporates automatic ash and refuse removal.

4.1 CAPACITY CLASSIFICATION OF STOKERS

Stokers are classified according to their coal-feeding rates. Although some residential applications still use stokers, their main application is in commercial and industrial areas. The U.S. Department of Commerce, in cooperation with the Stoker Manufacturers Association, use the following classification:

Class 1: Capacity less than 27 kg of coal per hour
Class 2: Capacity 27 to less than 45 kg of coal per hour
Class 3: Capacity 45 to less than 136 kg of coal per hour
Class 4: Capacity 136 to less than 544 kg of coal per hour
Class 5: Capacity 544 kg of coal per hour and over

Class 1 stokers are used primarily for residential heating and are designed for quiet, automatic operation. These stokers are usually underfeed types and are similar to those shown in Figure 14, except that they are usually screw-feed. Class 1 stokers feed coal to the furnace intermittently, in accordance with temperature or pressure demands. A special control is needed to ensure stoker operation to maintain a fire during periods when no heat is required.

Class 2 and 3 stokers are usually of the screw-feed type, without auxiliary plungers or other means of distributing the coal. They are used extensively for heating plants in apartment buildings, hotels, and industrial plants. They are of the underfeed type and are available in both the hopper and bin-feed type. These stokers are also built in a plunger-feed type with an electric motor, steam, or hydraulic cylinder coal-feed drive.

Class 2 and 3 stokers are available for burning all types of anthracite, bituminous, and lignite coals. The tuyere and retort design varies according to the fuel and load conditions. Stationary grates are used on bituminous models, and clinkers formed from the ash accumulate on the grates surrounding the retort.

Class 2 and 3 anthracite stokers are equipped with moving grates that discharge ash into a pit below the grate. This ash pit may be located on one side or both sides of the grate and, in some installations, is big enough to hold the ash for several weeks of operation.

Class 4 stokers vary in details of design, and several methods of feeding coal are practiced. Underfeed stokers are widely used, although overfeed types are used in the larger sizes. Bin-feed and hopper models are available in underfeed and overfeed types.

Class 5 stokers are spreader, underfeed, chain or traveling grate, and vibrating grate. Various subcategories reflect the type of grate and method of ash discharge.

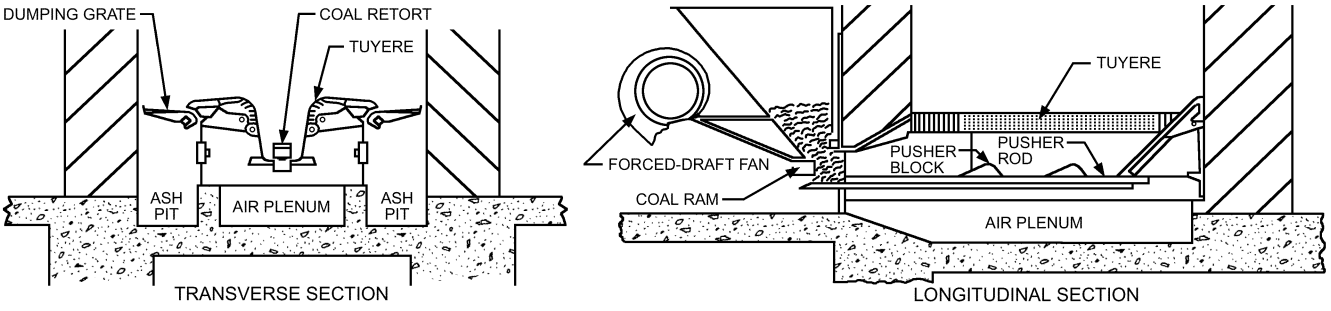

Fig. 14 Horizontal Underfeed Stoker with Single Retort

Table 3 Characteristics of Various Types of Stokers (Class 5)

Stoker Type and Subclass	Typical Capacity Range, kg/s	Maximum Burning Rate, kW/m²	Characteristics
Spreader			Capable of burning a wide range of coals; best to follow fluctuating loads; high fly ash carryover; low-load smoke
Stationary and dumping grate	2.5 to 10	1400	
Traveling grate	13 to 50	2400	
Vibrating grate	2.5 to 13	1300	
Underfeed	2.5 to 4	1300	Capable of burning caking coals and a wide range of coals (including anthracite); high maintenance; low fly ash carryover; suitable for continuous-load operation
Single- or double-retort			
Multiple-retort	4 to 63	1900	
Chain grate and *traveling grate*	2.5 to 13	1600	Low maintenance; low fly ash carryover; capable of burning a wide variety of weakly caking coals; smokeless operation over entire range
Vibrating grate	0.2 to 19	1300	Characteristics similar to chain and traveling grate stokers, except that these stokers have no difficulty in burning strongly caking coals

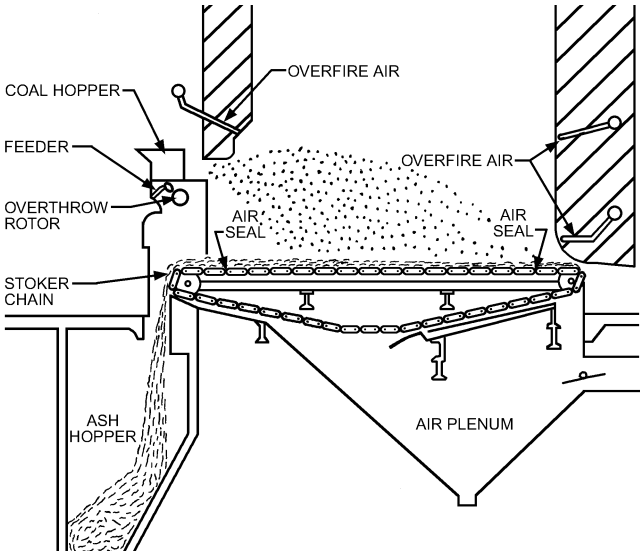

Fig. 15 Spreader Stoker, Traveling Grate Type

4.2 STOKER TYPES BY FUEL-FEED METHODS

Class 5 stokers are classified according to the method of feeding fuel to the furnace: (1) spreader, (2) underfeed, (3) chain or traveling grate, and (4) vibrating grate. The type of stoker used in a given installation depends on the general system design, capacity required, and type of fuel burned. In general, the spreader stoker is the most widely used in the capacity range of 9.5 to 50 kg/s because it responds quickly to load changes and can burn a wide variety of coals. Underfeed stokers are mainly used with small industrial boilers of less than 3.8 kg/s. In the intermediate range, the large underfeed stokers, as well as the chain and traveling grate stokers, are being displaced by spreader and vibrating grate stokers. Table 3 summarizes the major features of the different stokers.

Spreader Stokers

Spreader stokers use a combination of suspension burning and grate burning. As shown in Figure 15, coal is continually projected into the furnace above an ignited fuel bed. The coal fines are partially burned in suspension. Large particles fall to the grate and are burned in a thin, fast-burning fuel bed. Because this firing method provides extreme responsiveness to load fluctuations and because ignition is almost instantaneous on increased firing rate, the spreader stoker is favored over other stokers in many industrial applications.

The spreader stoker is designed to burn about 50% of the fuel in suspension. Thus, it generates much higher particulate loadings than other types of stokers and requires dust collectors to trap particulate material in the flue gas before discharge to the stack. To minimize carbon loss, fly carbon reinjection systems are sometimes used to return particles into the furnace for complete burnout. Because this process increases furnace dust emissions, it can be used only with highly efficient dust collectors.

Grates for spreader stokers may be of several types. All grates are designed with high airflow resistance to avoid formation of blowholes through the thin fuel bed. Early designs were simple stationary grates from which ash was removed manually. Later designs allowed intermittent dumping of the grate either manually or by a power cylinder. Both types of dumping grates are frequently used for small and medium-sized boilers (see Table 3). Also, both types are sectionalized, and there is a separate undergrate air chamber for each grate section and a grate section for each spreader stoker. Consequently, both the air supply and the fuel supply to one section can be temporarily discontinued for cleaning and maintenance without affecting operation of other sections of the stoker.

For high-efficiency operation, a continuous ash-discharging grate, such as the traveling grate, is necessary. Introduction of the spreader stoker with the traveling grate increased burning rates by about 70% over the stationary and dumping grate types. Although both reciprocating and vibrating continuous ash discharge grates have been developed, the traveling grate stoker is preferred because of its higher burning rates.

Fuels and Fuel Bed. All spreader stokers (particularly those with traveling grates) can use fuels with a wide range of burning characteristics, including caking tendencies, because the rapid surface heating of the coal in suspension destroys the caking tendency. High-moisture, free-burning bituminous and lignite coals are commonly burned; coke breeze can be burned in mixture with a high-volatile coal. However, anthracite, because of its low volatile content, is not a suitable fuel for spreader stoker firing. Ideally, the fuel bed of a coal-fired spreader stoker is 50 to 100 mm thick.

Burning Rates. The maximum heat release rates range from 1250 kW/m² (a coal consumption of approximately 5 g/s) on stationary, dumping, and vibrating grate designs to 2400 kW/m² on traveling grate spreader stokers. Higher heat release rates are practical with some waste fuels in which a greater portion of fuel can be burned in suspension than is possible with coal.

Underfeed Stokers

Underfeed stokers introduce raw coal into a retort beneath the burning fuel bed. They are classified as horizontal or gravity feed. In the horizontal type, coal travels within the furnace in a retort parallel with the floor; in the gravity-feed type, the retort is inclined by 25°. Most horizontal-feed stokers are designed with single or double

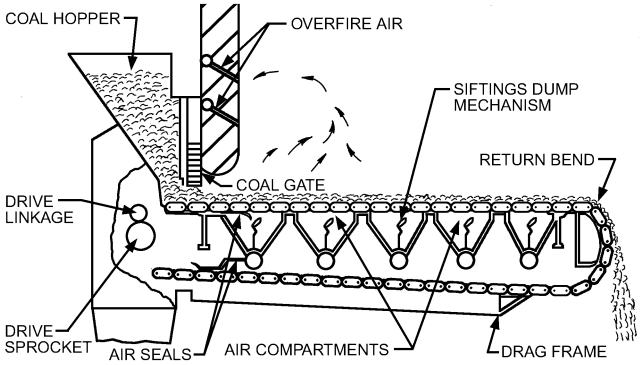

Fig. 16 Chain Grate Stoker

retorts (and, rarely, triple retorts), whereas gravity-feed stokers are designed with multiple retorts.

In the horizontal stoker (see Figure 14), coal is fed to the retort by a screw (for smaller stokers) or a ram (for larger stokers). Once the retort is filled, the coal is forced upward and spills over the retort to form and feed the fuel bed. Air is supplied through tuyeres at each side of the retort and through air ports in the side grates. Over-fire air provides additional combustion air to the flame zone directly above the bed to prevent smoking, especially at low loads.

Gravity-feed stokers are similar in operating principle. These stokers consist of sloping multiple retorts and have rear ash discharge. Coal is fed into each retort, where it is moved slowly to the rear while simultaneously being forced upward over the retorts.

Fuels and Fuel Bed. Either type of underfeed stoker can burn a wide range of coal, although the horizontal type is better suited for free-burning bituminous coal. These stokers can burn caking coal, if there is not an excess amount of fines. The ash-softening temperature is an important factor in selecting coals because the possibility of excessive clinkering increases at lower ash-softening temperatures. Because combustion occurs in the fuel bed, underfeed stokers respond slowly to load change. Fuel-bed thickness is extremely nonuniform, ranging from 200 to over 600 mm. The fuel bed often contains large fissures separating masses of coke.

Burning Rates. Single-retort or double-retort horizontal stokers are generally used to service boilers with capacities up to 3.8 kg/s. These stokers are designed for heat release rates of 1300 kW/m^2.

Chain and Traveling Grate Stokers

Figure 16 shows a typical chain or traveling grate stoker. These stokers are often used interchangeably because they are fundamentally the same, except for grate construction. The essential difference is that the links of chain grate stokers are assembled so that they move with a scissors-like action at the return bend of the stoker, whereas in most traveling grates there is no relative movement between adjacent grate sections. Accordingly, the chain grate is more suitable for handling coal with clinkering ash characteristics than is the traveling grate stoker.

Operation of the two types is similar. Coal, fed from a hopper onto the moving grate, enters the furnace after passing under an adjustable gate that regulates the thickness of the fuel bed. The layer of coal on the grate entering the furnace is heated by radiation from the furnace gases or from a hot refractory arch. As volatile matter is driven off by this rapid radiative heating, ignition occurs. The fuel continues to burn as it moves along the fuel bed, and the layer becomes progressively thinner. At the far end of the grate, where the coal completes combustion, ash is discharged into the pit as the grates pass downward over a return bend.

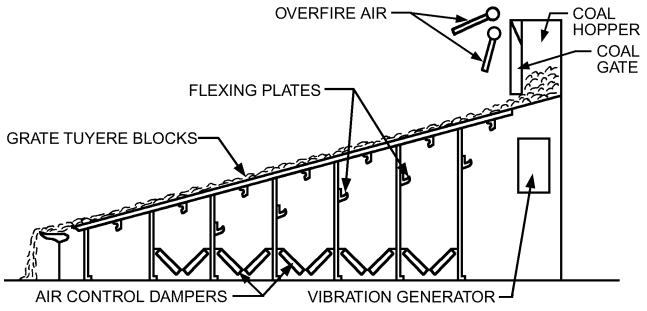

Fig. 17 Vibrating Grate Stoker

Often, furnace arches (front and/or rear) are included with these stokers to improve combustion by reflecting heat to the fuel bed. The front arch also serves as a bluff body, mixing rich streams of volatile gases with air to reduce unburned hydrocarbons. A chain grate stoker with overfire air jets eliminates the need for a front arch for burning volatiles. As shown in Figure 17, the stoker was zoned, or sectionalized, and equipped with individual zone dampers to control the pressure and quantity of air delivered to the various sections.

Fuels and Fuel Bed. The chain grate and traveling grate stokers can burn a variety of fuels (e.g., peat, lignite, subbituminous coal, free-burning bituminous coal, anthracite coal, coke), as long as the fuel is sized properly. However, strongly caking bituminous coals have a tendency to mat and prevent proper air distribution to the fuel bed. Also, a bed of strongly caking coal may not be responsive to rapidly changing loads. Fuel bed thickness varies with the type and size of the coal burned. For bituminous coal, a 125 to 180 mm bed is common; for small-sized anthracite, the fuel bed is reduced to 75 to 125 mm.

Burning Rates. Chain and traveling grate stokers are offered for a maximum continuous burning rate of 1100 to 1600 kW/m^2, depending on the type of fuel and its ash and moisture content.

Vibrating Grate Stokers

The vibrating grate stoker, as shown in Figure 17, is similar to the chain grate stoker in that both are overfeed, mass-burning, continuous ash discharge stokers. However, in the vibrating stoker, the sloping grate is supported on equally spaced vertical plates that oscillate back and forth in a rectilinear direction, causing the fuel to move from the hopper through an adjustable gate into the active combustion zone. Air is supplied to the stoker through laterally exposed areas beneath the stoker formed by the individual flexing of the grate support plates. Ash is automatically discharged into a shallow or basement ash pit. The grates are water cooled and are connected to the boiler circulating system.

The rates of coal feed and fuel bed movement are determined by the frequency and duration of the vibrating cycles and regulated by automatic combustion controls that proportion the air supply to optimize heat release rates. Typically, the grate is vibrated about every 90 s for durations of 2 to 3 s, but this depends on the type of coal and boiler operation. The vibrating grate stoker is increasingly popular because of its simplicity, inherently low fly ash carryover, low maintenance, wide turndown (10 to 1), and adaptability to multiple-fuel firing.

Fuels and Fuel Bed. The water-cooled vibrating grate stoker is suitable for burning a wide range of bituminous and lignite coals. The gentle agitation and compaction of the vibratory actions allow coal having a high free-swelling index to be burned and a uniform fuel bed without blowholes and thin spots to be maintained. The uniformity of air distribution and fuel bed conditions produce both good response to load swings and smokeless operation over the

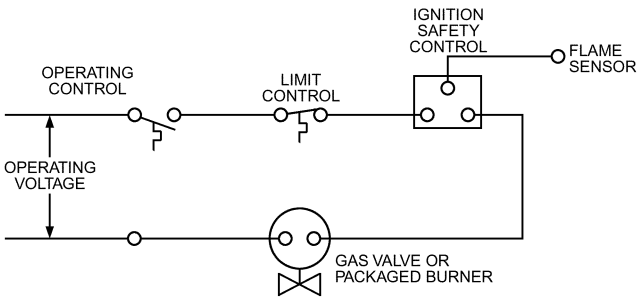

Fig. 18 Basic Control Circuit for Fuel-Burning Appliance

entire load range. Fly ash emission is probably greater than from the traveling grate because of the slight intermittent agitation of the fuel bed. The fuel bed is similar to that of a traveling grate stoker.

Burning Rates. Burning rates of vibrating grate stokers vary with the type of fuel used. In general, however, the maximum heat release rate should not exceed 1300 kW/m^2 (a coal use of approximately 5 g/s) to minimize fly ash carryover.

5. CONTROLS

This section covers controls required for automatic fuel-burning systems. Chapter 7 of the 2021 *ASHRAE Handbook—Fundamentals* addresses basic automatic control.

Automatic fuel-burning appliances require control systems that supervise combustion and take proper corrective action in the event of a failure in the appliance or related installation equipment. Requirements are similar for gas, oil, and solid fuel (stoker) burners.

Controls can be classified as safety or operating. **Safety controls** monitor potentially hazardous operating conditions such as ignition, combustion, temperature, and pressure, and function as required to ensure safe operation. **Operating controls** handle appliance operation at the required input rate when heat is required.

Figure 18 illustrates the basic elements of a control system for a fuel-fired appliance. In this diagram, the limit control and the ignition safety control, including its sensor, are safety controls.

5.1 SAFETY CONTROLS AND INTERLOCKS

Safety controls protect against hazards related to the combustion process. Personnel and material near the appliance must be protected against explosion, fire, or excessive temperature. Common safety control functions include the following:

- Ignition and flame monitoring
  - Ignition proving (e.g., gas pilot thermocouple, flame rectification)
  - Proof of flame
- Draft proof (e.g., sail switch, pressure switch)
- Limit controls
  - Excessive temperature of heated medium (e.g., air or water)
  - Excessive pressure of heated medium (e.g., steam or hot water)
  - Low water level in steam or hot-water boilers
  - Low fuel-oil pressure
  - Low or excessive fuel-oil temperature when burning heavy oils
  - Low atomizing air pressure or atomizing steam pressure
  - Low fuel-gas pressure (e.g., empty propane tank)
- Flue gas spillage switch
- Flame rollout detection
- Carbon monoxide sensors
- Similar devices to prevent hazards from abnormal conditions
- Safety-related mechanical malfunction controls (e.g., open furnace blower door, burner out of position or rotary cup burner motor failure)
- Field interlocks having safety function

Ignition and Flame Monitoring

Failure to ignite fuel or failure of an established flame can cause explosion, if unburned fuel is subsequently provided with an ignition source. Ignition and flame safeguard controls, properly applied and used, prevent these occurrences. Some ignition controls monitor existence of an ignition source such as a pilot burner, allowing introduction and continued flow of fuel only when the ignition source is proven. Others use devices that ignite the main flame directly, in conjunction with high-speed flame detection capabilities and rapid shutdown of the fuel supply, if ignition is not immediate or if the flame is lost. Ignition controls often include programming features that govern the entire sequence of operation when a burner is started, operated, and stopped.

In residential gas-fired appliances, burners are usually ignited by a small standing gas pilot flame, by an intermittent pilot system, or by a direct ignition system. Standing pilot systems prove existence of the ignition source by sensing its heat with a thermocouple. In intermittent pilot systems, a spark or hot surface igniter lights the pilot burner when there is a call for heat, thus saving pilot burner fuel when no heat is needed. Flame rectification (the ability of a flame to change an alternating current to direct current) is commonly used to prove the existence of the pilot flame (in intermittent pilot systems) or main burner flame (in direct-ignition systems). In direct-ignition systems, a spark or hot surface device ignites the main burner directly, eliminating the need for a pilot burner. If flame is not immediately established during ignition or if an established flame is lost, the gas supply system is quickly shut off. Flame rollout (flame escaping the appliance combustion chamber) protection detects flame in appliance combustion air inlet areas by sensing high temperatures and shuts off the fuel supply.

Most residential oil-burners use high-energy sparking for ignition. Sparking may be continuous (present for the entire duration of burner operation) or intermittent (present only long enough to establish presence of the flame). Most residential oil burners use an oil primary control that operates the burner motor and ignition spark transformer in conjunction with a flame detector. Flame proof is typically achieved by sensing visible or ultraviolet light emitted by the flame. A cadmium cell is used to detect visible light: its resistance changes when exposed to light from a burner flame, and that change is interpreted and acted upon by the primary control.

Commercial appliances with high fuel input rates normally use some form of a proven ignition source, often a standing or intermittent pilot burner, which itself may be quite large. North American safety standards do not allow use of direct-ignition systems for appliances with input greater than 117 kW. Standing pilots or a proved igniter system must be used. The latter may closely resemble the direct-ignition system, except that the existence of the ignition source must be proven before fuel gas is allowed to flow to the main burner. As in the direct-ignition system, main burner gas flow is shut down if flame is not established quickly or if it goes out after ignition. Flame proving in large appliances is typically by flame rectification or ultraviolet light sensing.

Draft Proving

Fuel-burning appliances often include forced- or induced-draft blowers to move combustion air and combustion products through the appliance and venting systems. Sometimes blowers are applied outside the appliance in the venting system. Draft-proving controls supervise proper operation of these components to allow gas flow, ignition, and combustion only if appliance draft is adequate, typically using pressure and/or flow sensors to verify sufficient draft.

Limit Controls

In a warm-air furnace or space heater, excessive air temperature must be prevented. In a hot-water boiler, water temperature and pressure must not exceed the ratings of external piping and terminal equipment. Steam pressure must not exceed ratings of pressure vessels and steam system equipment. Fuel oil must be provided at pressures and temperatures that allow proper operation of oil burners. These requirements and restrictions are the focus of limit controls required by installation codes and appliance standards, and applied by appliance manufacturers and field installers. Design and principle of operation vary greatly, but in all cases limit controls must provide reliable detection of a fault and shut down the fuel-burning appliance.

Other Safety Controls

Requirements for safety devices are a function of the particular appliance and installation circumstances, and must be considered in that context. Appliances listed or design-certified as complying with recognized safety standards generally have appropriate safety devices as required by those standards. Building codes typically require appliances to be listed or design-certified by recognized testing laboratories, and that appliances not listed or design-certified comply with requirements within the code. Field circumstances may impose a need for control interlocks that relate to safety. Mechanical-draft venting systems, for example, must be proven to be in operation before an appliance ignition attempt and during burner operation. An appropriate field-installed interlock to prove mechanical-draft venting system operation before an ignition attempt would be considered a safety control.

Prescriptive Requirements for Safety Controls

Industrial safety codes and insurers often require that fuel-fired appliances be provided with specific components and construction features related to safety. Codes and requirements such as ASME *Standard* CSD-1 for boilers or those of insurance organizations may apply. Prescriptive governmental requirements may also apply to some types of installations. Often, requirements are based on the type of appliance, its capacity or size, or the intended use, such as type of building occupancy.

Reliability of Safety Controls

Devices suitable for use as safety controls must meet special quality and reliability requirements. Electrical contacts, for example, must be able to switch the intended load through high cycle counts under extreme environmental conditions. Products designed for safety control application are invariably listed, or design-certified as complying with recognized standards that impose a wide range of construction and testing requirements. The degree of reliability of safety controls must be extremely high, and normally far exceeds that required of operating controls to meet appliance safety standards.

5.2 OPERATING CONTROLS

Operating controls start and stop burner operation in response to demands of the application load, and often incorporate capabilities for load matching and other application-related features. In contrast to safety controls, their purpose is to satisfy the application's fundamental purpose (e.g., warm air, hot water, steam pressure). Related functions may involve operating ancillary components of the appliance or system, such as blowers or pumps, which must operate at the appropriate speed.

Load matching is the most significant differentiating feature of operating controls. The major categories are on/off, staged, and modulated control. Fuel input rate varies for the latter two modes, but combustion airflow rate may also be controlled.

An **on/off control** starts and stops the flow of fuel to the burner to satisfy heat demand. An appliance with on/off control can operate only at its rated input regardless of the rate at which combustion heat may be needed. In a typical system, demand is sensed by a temperature or pressure sensor. When the temperature or pressure falls to an *on* set point, the control initiates combustion, which proceeds until the temperature or pressure increases to an *off* set point. The difference between the *off* and *on* values is called the **differential**. On/off control is satisfactory for systems with high thermal inertia (i.e., those in which heat input does not rapidly change the controlled temperature or pressure).

A **staged control** operates an appliance at multiple fixed input rates in response to heat demand. The input rates are determined by burner system hardware and settings. A residential gas-fired appliance, for example, may include a gas pressure regulator capable of providing high and low gas pressures to the gas orifice(s). Applying electrical power to a solenoid associated with the pressure regulator enables a second orifice pressure and thus a second gas input rate. In large appliances such as commercial boilers, staging is often accomplished with multiple burner assemblies, operated singly or together as necessary to match the load. As in on/off control, combustion initiation and changes between high and low input rates are in response to demand, as determined by the sensor and control logic.

Staged control logic is sometimes provided within an appliance control to enhance load response of the appliance. For example, a heating appliance control can provide staged burner operation without a staged room thermostat by beginning burner operation on burner stage 1 when a single-stage thermostat calls for heat. If burner stage 1 does not satisfy the thermostat within a specified time period, the appliance control turns on burner stage 2 until the thermostat is satisfied, at which time the burner is completely shut off until the thermostat's next call for heat.

Figure 19 illustrates the characteristics of a three-stage control system that provides heat in response to a temperature sensor and is required to maintain temperature at a set point t_S. If the controlled temperature is above t_S, no heat is provided. When the temperature drops to t_{1On}, the first-stage burner is operated; if the temperature then rises back to t_S, the burner is turned off. If the first stage is inadequate, the temperature continues to fall; when it reaches t_{2On}, the second stage is operated. A third stage is available if the second stage is not adequate, operating when the temperature falls to its *on* temperature t_{3On}. Successful handling of the load results in raising of the controlled temperature and stepped sequential reduction of the heat input as the

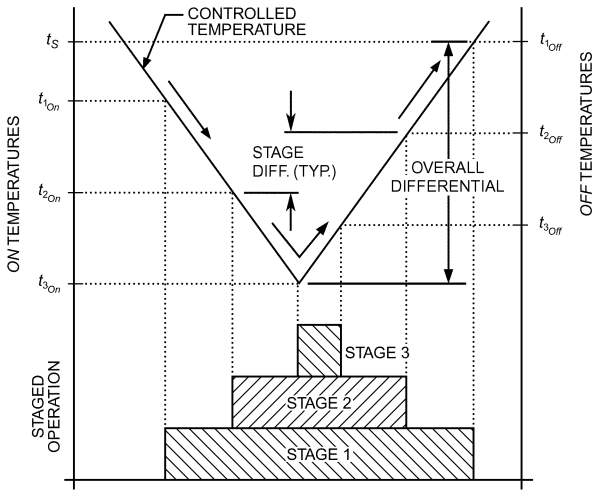

Fig. 19 Control Characteristics of Three-Stage System

off temperatures t_{3Off}, t_{2Off}, and t_{1Off} (= t_S) are reached. The individual stages operate subject to a **stage differential**, which is the difference between the temperature at which a stage is shut off and the (lower) temperature at which it is again turned on. Interstage differential and overall differential, as shown in Figure 19, are analogous. The *on* and *off* temperatures may or may not overlap, depending on the relative size of the stage differentials. In sophisticated electronic controls, the differential settings are adjustable to meet the particular requirements of the application.

Staged control logic often includes features that enhance load response or appliance operation. As shown in Figure 19, load matching might be best if the control initiates the lowest input rate on a call for heat and proceeds to higher inputs only if the demand cannot be met at lower rates. Appliance or application characteristics may dictate other approaches. For example, if appliance ignition is most reliable at high input rate, a staged control might require that ignition begin at a high input rate with an immediate reduction to a lower input rate to meet the actual heat demand.

Combustion airflow may or may not be staged. If not, operation at lower input rates, particularly in appliances with fan-assisted combustion, results in lean operation (a high percentage of excess air). There may be little effect, but in general, heat transfer efficiency suffers if the combustion air-to-fuel ratio (A/F) is not maintained at an optimum level on each stage.

A **modulating control** regulates input rate to follow load demands more closely than on/off or staged controls. Fuel input rate may be varied by throttling (mechanical restriction of flow by a valve) or by pressure regulation to control injector (orifice) pressure. Demand is often indicated by a temperature or pressure sensor, and the input rate increases as the temperature or pressure falls from set point values. In large fuel-oil appliances, a fuel oil control valve and burner damper respond over a range of positions within the operating range of the burner.

Air/fuel proportioning controls are a variation of modulating controls in which the proper ratio of air to fuel is maintained throughout the burner's fuel input range. In response to the need for heat, both fuel input rate and combustion airflow rate are modulated, maintaining an optimal air/fuel ratio to maximize efficiency. The controls may change blower speed or (particularly in large commercial appliances) link air dampers to fuel input rate control.

Tracking controls are proportioning controls that maintain the proper air/fuel ratio by applying basic Bernoulli-equation fluid flow behavior. Gas-fired appliances are especially suitable for this approach. As combustion air or gas flow rate changes, such as through metering orifices or venturis, pressure changes in proportion to the square of the air or gas velocity. The pressure differential created by forcing air through a venturi, for example, can be used to regulate gas flow through an orifice. When the relationship is established, a change of airflow rate results in a pressure differential change that causes a proportional (tracking) change in gas flow rate. In one approach, airflow rate is varied according to heating demand by changing blower speed or adjusting a damper position, and gas flow rate tracks the change. Variations may use intermediate ratio controllers. Other systems control gas input rate, and combustion air rate tracks. In the ideal case, the air-to-fuel ratio remains constant at all input rates, and efficiency increases substantially when firing rate is reduced.

Combustion quality is monitored and controlled in some large installations to ensure efficient operation or satisfactory emission characteristics. Air or fuel can be controlled in response to devices that sense concentrations of various combustion product constituents. Butcher (1990) used the measured intensity of light emitted from flames of fixed-input oil burners to judge basic flame quality. Flame steady-state intensity is compared to a predetermined flame intensity set point. Deviation of flame intensity beyond an optimum intensity range indicates poor flame quality.

Operating controls often provide functions not directly related to combustion. These **appliance controls** include things such as operating air-circulating blowers or pumps according to the fuel combustion system's needs. A blower or pump can be operated in response to a temperature or pressure sensor or according to a time protocol imposed with electronic or digital capabilities. Additional algorithms in the appliance control can further enhance appliance operation.

Integrated and Programmed Controls

Integrated Controls. Many appliance controls combine safety and operating functions into electronic microprocessors with various sensors and electromechanical devices to handle most of the control functions necessary to operate fuel-burning appliances. Figure 20 illustrates an integrated control approach typical of residential forced-air furnaces or boilers with fan-assisted combustion and a limit control. Other safety devices, such as a flame roll-out switch, typically are present. For a forced-air furnace, the remote thermostat would be a wall thermostat. For a hot-water boiler, the operating control might be a wall thermostat, possibly with a second sensor to control boiler water temperature. Ignition and flame safety algorithms are provided in the microprocessor-based control. The ignition device and flame sensor are connected to the control. Note that the control operates both the circulating blower or pump and a combustion blower. Both are controlled in accordance with an appropriate sequence of operation. A draft-proving device is connected to the control to confirm operation of the combustion blower prior to igniter operation and opening of the gas valve, and during subsequent burner operation. Typically, light-emitting diodes (LEDs) are provided on the control to indicate operating status and to facilitate diagnosis of operating problems.

Programmed controls for ignition and flame safeguard have been used in large fuel-fired appliances for many years. More recently, programming has been applied in integrated controls for smaller appliances. These controls handle not only the ignition sequence, but also operating functions, and provide status and diagnostic information. Accomplishing those functions with separate components would be difficult and clumsy.

When power is supplied, an integrated control conducts a self-check to ensure that the appliance and control system are in safe working order, and then typically indicates readiness by flashing one or more LEDs. The self-check may include verifying that the flame-proving device does not indicate flame before the ignition sequence has started and the draft-proving device does not indicate draft before the combustion blower has started. Self-checking for safe conditions may continue during burner operation and during

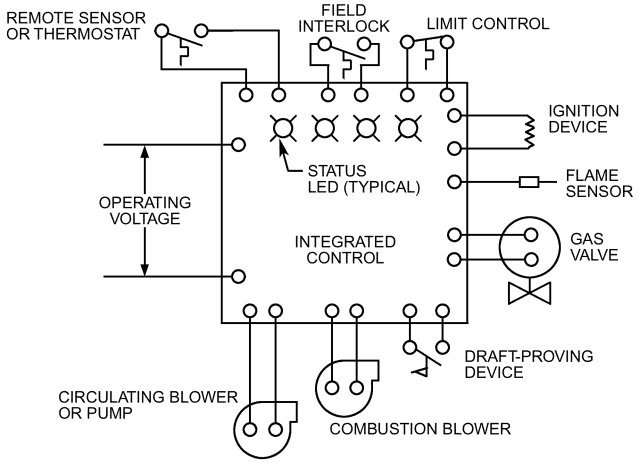

Fig. 20 Integrated Control System for Gas-Fired Appliance

standby after the thermostat is satisfied. If unacceptable operation is detected, the control will take corrective action or attempt safe shutoff of the appliance. On a call for heat, an operating sequence typically proceeds as follows:

1. The call for heat is indicated by an assigned LED flashing sequence.
2. The combustion blower starts and its operation is verified by the draft-proving device.
3. When the combustion blower has run long enough to purge the combustion chamber of residual fuel and combustion products (i.e., flush it with four air changes), the ignition device energizes.
4. The control allows enough time for the ignition device to become operative. In some applications, operation is verified electronically.
5. The gas valve opens.
6. Flame detection checks for main burner ignition. If flame presence is not proven within a very short predetermined time, or if continuous proof of flame fails at any time while the gas valve is open, the gas valve closes. Programming typically requires rapid detection of flame failure, and gas shutoff in accordance with safety standards.
7. If flame presence is detected, the air circulating blower or hot-water pump is started. Depending on the application, blower or pump operation could start with burner operation or after a time delay.
8. When the call for heat is satisfied, the gas valve closes to extinguish the burner flame.
9. The combustion blower operates for a short period to flush the combustion chamber with air (post purge).
10. The circulating blower or pump stops, usually after an application-specific delay.
11. The status LED(s) return to the standby mode.

This sequence can be varied as necessary to accommodate the requirements of specific appliances and applications. For example, staged or modulated operation may be included.

Status LEDs are turned on and off in particular patterns to display coded diagnostic information for many different normal and abnormal conditions (e.g., failure to prove draft, failure to detect flame, overtemperature). Appliance standards and installation codes require that appliance controls lock out operation of the burner system in response to certain failure conditions, when manual intervention by a qualified service agency is necessary.

Burner Types 32.7
Boiler Controls 32.7
Flame Safeguard Controls 32.8

BOILERS are pressure vessels designed to transfer heat (produced by combustion) to a fluid. The definition has been expanded to include transfer of heat from electrical resistance elements to the fluid or by direct action of electrodes on the fluid. In most boilers, the fluid is usually water in the form of liquid or steam. If the fluid being heated is air, the heat exchange device is called a furnace, not a boiler. The firebox, or combustion chamber, of some boilers is also called a furnace.

Excluding special and unusual fluids, materials, and methods, a boiler is a cast-iron, carbon or stainless steel, aluminum, or copper pressure vessel heat exchanger designed to (1) burn fossil fuels (or use electric current) and (2) transfer the released heat to water (in water boilers) or to water and steam (in steam boilers). Boiler heating surface is the area of fluid-backed surface exposed to the products of combustion, or the fire-side surface. Various manufacturers define allowable heat transfer rates in terms of heating surface based on their specific boiler design and material limitations. Boiler designs provide for connections to a piping system, which delivers heated fluid to the point of use and returns the cooled fluid to the boiler.

Chapters 6, 11, 12, 13, and 15 cover applications of heating boilers. Chapter 7 discusses cogeneration, which may require boilers.

1. CLASSIFICATIONS

Boilers may be grouped into classes based on working pressure and temperature, fuel used, material of construction, type of draft (natural or mechanical), and whether they are condensing or noncondensing. They may also be classified according to shape and size, application (e.g., heating, process), and state of output medium (steam or water). Boiler classifications are important to the specifying engineer because they affect performance, first cost, and space requirements. Excluding designed-to-order boilers, significant class descriptions are given in boiler catalogs or are available from the boiler manufacturer. The following basic classifications may be helpful.

Working Pressure and Temperature

With few exceptions, boilers are constructed to meet ASME *Boiler and Pressure Vessel Code*, Section IV (SCIV), Rules for Construction of Heating Boilers (low-pressure boilers), or Section I (SCI), Rules for Construction of Power Boilers (high-pressure boilers).

Low-pressure boilers are constructed for maximum working pressures of 103 kPa (gage) steam and up to 1100 kPa (gage) hot water. Hot-water boilers are limited to 120°C operating temperature. Operating and safety controls and relief valves, which limit temperature and pressure, are ancillary devices required to protect the boiler and prevent operation beyond design limits.

High-pressure boilers are designed to operate above 103 kPa (gage) steam, or above 1100 kPa (gage) and/or 120°C for water boilers. Similarly, operating and safety controls and relief valves are required.

Steam boilers are generally available in standard sizes from 17 kW to 30 MW, many of which are used for space heating applications in both new and existing systems. On larger installations, they may also provide steam for auxiliary uses, such as hot water heat exchangers, absorption cooling, laundry, and sterilizers. In addition, many steam boilers provide steam at various temperatures and pressures for a wide variety of industrial processes.

Water boilers are generally available in standard sizes from 10 kW to over 30 MW, many of which are in the low-pressure class and are used primarily for space heating applications in both new and existing systems. Some water boilers may be equipped with either internal or external heat exchangers for domestic water service.

Every steam or water boiler is rated for a maximum working pressure that is determined by the applicable boiler code under which it is constructed and tested. When installed, it also must be equipped at a minimum with operation and safety controls and pressure/temperature-relief devices mandated by such codes.

Fuel Used

Boilers may be designed to burn coal, wood, various grades of fuel oil, waste oil, or various types of fuel gas, or to operate as electric boilers. A boiler designed for one specific fuel type may not be convertible to another type of fuel. Some boilers can be adapted to burn coal, oil, or gas. Several designs accommodate firing oil or gas, and other designs allow firing dual-fuel-burning equipment. Accommodating various fuel-burning equipment is a fundamental concern of boiler manufacturers, who can furnish details to a specifying engineer. The manufacturer is responsible for performance and rating according to the code or standard for the fuel used (see section on Performance Codes and Standards).

Construction Materials

Most noncondensing boilers are made with cast iron sections or steel. Some small boilers are made of copper or copper-clad steel. Condensing boilers are typically made of stainless steel or aluminum because copper, cast iron, and carbon steel will corrode because of acidic condensate.

Cast-iron sectional boilers generally are designed according to ASME Section IV requirements and range in size from 10 kW to 4.1 MW gross output. They are constructed of individually cast sections, assembled into blocks (assemblies) of sections. Push or screw nipples, gaskets, and/or an external header join the sections pressure-tight and provide passages for the water, steam, and products of combustion. The number of sections assembled determines the boiler size and energy rating. Sections may be vertical or horizontal, the vertical design being more common (Figures 1A and 1C).

The boiler may be **dry-base** (the combustion chamber is beneath the fluid-backed sections), as in Figure 1B; **wet-base** (the combus-

The preparation of this chapter is assigned to TC 6.1, Hydronic and Steam Equipment and Systems.

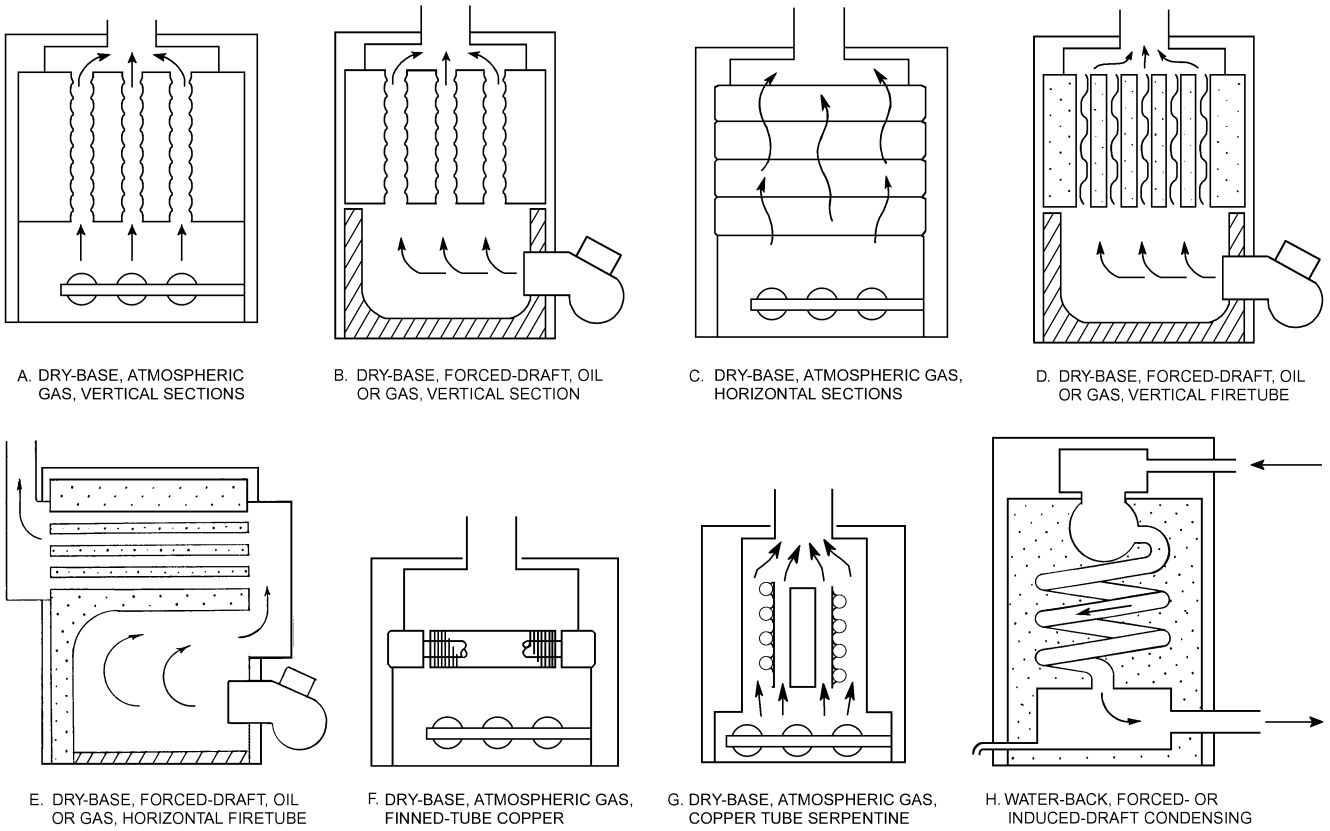

Fig. 1 Residential Boilers

tion chamber is surrounded by fluid-backed sections, except for necessary openings), as in Figure 2A; or **wet-leg** (the combustion chamber top and sides are enclosed by fluid-backed sections), as in Figure 2B.

The three types of boilers can be designed to be equally efficient. Testing and rating standards apply equally to all three types. The wet-base design is easiest to adapt for combustible floor installations. Applicable codes usually demand a floor temperature under the boiler no higher than 50 K above room temperature. A steam boiler at 102°C or a water boiler at 116°C may not meet this requirement without appropriate floor insulation. Large cast-iron boilers are also made as water-tube units with external headers (Figure 2C).

Steel boilers generally range in size from 15 kW to the largest boilers made. Designs are constructed to either ASME SCI or SCIV (or other applicable code) requirements. They are fabricated into one assembly of a given size and rating, usually by welding. The heat exchange surface past the combustion chamber is usually an assembly of vertical, horizontal, or slanted tubes. Boilers of the fire-tube design contain flue gases in tubes completely submerged in fluid (Figures 1D and 1E show residential units, and Figures 3A to 3D and Figure 4A show commercial units). Water-tube boilers contain fluid inside tubes with tube pattern arrangement providing for the combustion chamber (Figures 4C and 4D). The internal configuration may accommodate one or more flue gas passes. As with cast-iron sectional boilers, dry-base, wet-leg, or wet-base designs may be used. Most small steel boilers are of the dry-base, vertical fire-tube type (Figure 1D).

Larger boilers usually incorporate horizontal or slanted tubes; both fire-tube and water-tube designs are used. A popular horizontal fire-tube design for medium and large steel boilers is the **scotch marine**, which is characterized by a central fluid-backed cylindrical combustion chamber, surrounded by fire-tubes accommodating two

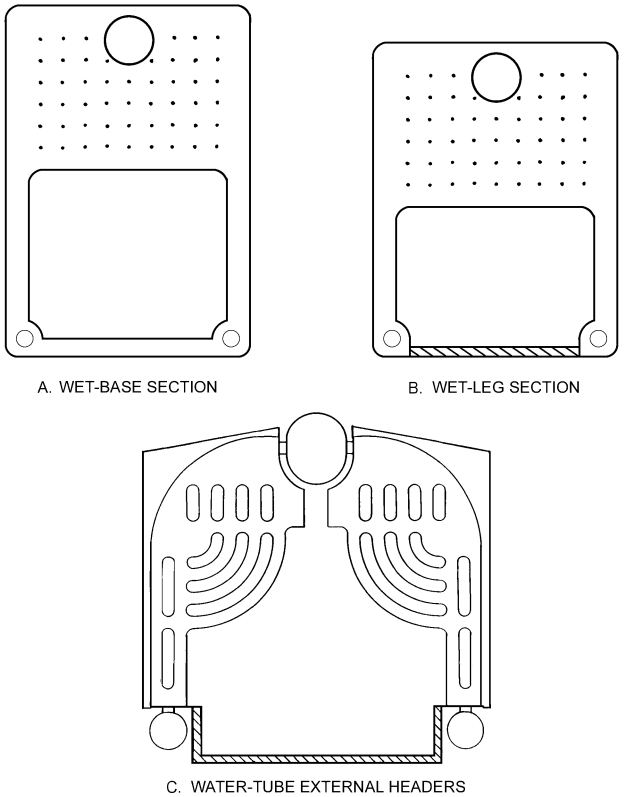

Fig. 2 Cast-Iron Commercial Boilers

or more flue gas passes, all within an outer shell (Figures 3A to 3D). In another horizontal fire-tube design, the combustion chamber has a similar central fluid-backed combustion chamber surrounded by fire tubes accommodating two or more flue gas passes, all within an outer shell. However, this design uses a dry base and wet leg (or mud leg) (Figure 4A).

Copper boilers are usually some variation of the water-tube boiler. Parallel finned copper tube coils with headers, and serpentine copper tube units are most common (Figures 1F and 1G). Some are offered as wall-hung residential boilers. The commercial bent water-tube design is shown in Figure 4B. Natural gas is the usual fuel for copper boilers.

Stainless steel boilers usually are designed to operate with condensing flue gases. Most are single-pass, fire-tube design and are generally resistant to thermal shock. ASME limits operating temperatures to 99°C and 1103 kPa (gage) working pressure.

Aluminum boilers are also usually designed to operate with condensing flue gases. Typical designs incorporate either cast aluminum boiler sections or integrally finned aluminum tubing. ASME limits operating temperatures to 93°C and working pressure to 345 kPa (gage).

Type of Draft

Draft is the pressure difference that causes air and/or fuel to flow through a boiler or chimney. A **natural draft boiler** is designed to operate with a negative pressure in the combustion chamber and in the flue connection. The pressure difference is created by the tendency of hot gases to rise up a chimney or by the height of the boiler up to the draft control device. In a **mechanical draft boiler**, a fan or blower or other machinery creates the required pressure difference. These boilers may be either forced draft or induced draft. In a **forced-draft boiler**, air is forced into the combustion chamber to maintain a positive pressure in the combustion chamber and/or the space between the tubing and the jacket (breaching). In an **induced-draft boiler**, air is drawn into the combustion chamber to maintain a negative pressure in the combustion chamber (see Chapter 35 for a more detailed discussion on draft).

Condensing or Noncondensing

Traditionally designed boilers must operate without condensing the flue gas in the boiler. This precaution was necessary to prevent corrosion of cast-iron, steel, or copper parts. Hot-water units were operated at 60°C minimum water temperature to prevent this corrosion and to reduce the likelihood of thermal shock.

Because a higher boiler efficiency can be achieved with a lower water temperature, the condensing boiler allows the flue gas water vapor to condense and drain. Full condensing boilers are now available from a large number of manufacturers. These boilers are specifically designed for operation with the low return water temperatures found in hot-water reset, water-source heat pump, two-pipe fan-coil, and reheat systems. Two types of commercial condensing boilers are shown in Figure 5. Figure 6 shows a typical relationship of overall condensing boiler efficiency to return water temperature. The dew point of 55°C shown in the figure varies with the percentage of hydrogen in the fuel and oxygen/carbon dioxide ratio, or excess air, in the flue gases. A condensing boiler is shown in Figure 1H. Condensing boilers can be of the fire-tube, water-tube, cast-iron, and cast-aluminum sectional design.

Condensing boilers are generally provided with high-turndown modulating burners and are more efficient than noncondensing boilers at any return water temperature (RWT), including noncondensing-temperature applications. Efficiencies of noncondensing boilers must be limited to avoid potential condensing and corrosion. Further efficiencies can be gained by using lower RWT or higher Δt as recommended by ASHRAE. For example, a natural gas condensing boiler operating with 15°C RWT in a water-source heat

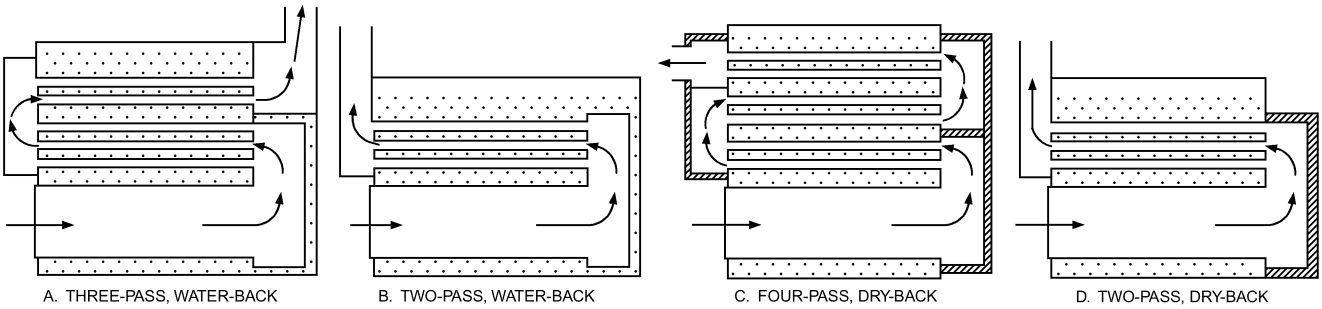

Fig. 3 Scotch Marine Commercial Boilers

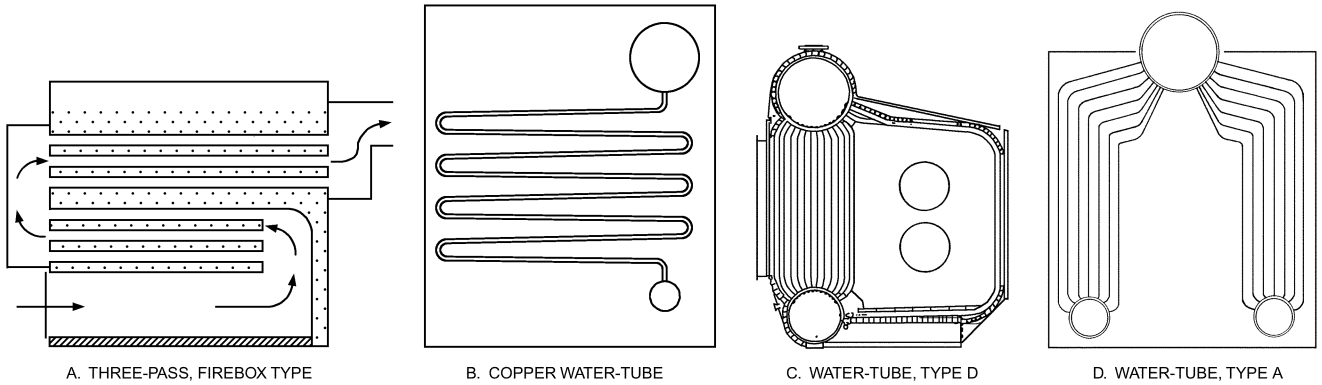

Fig. 4 Commercial Fire-Tube and Water-Tube Boilers

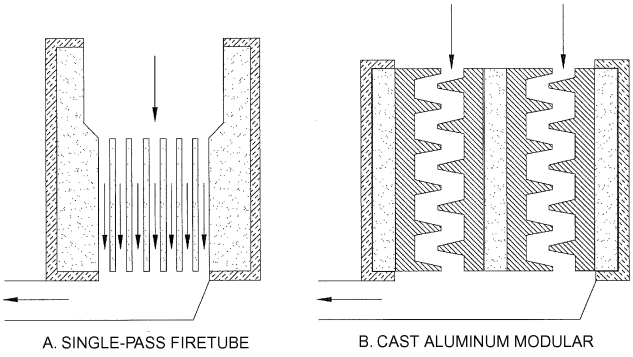

Fig. 5 Commercial Condensing Boilers

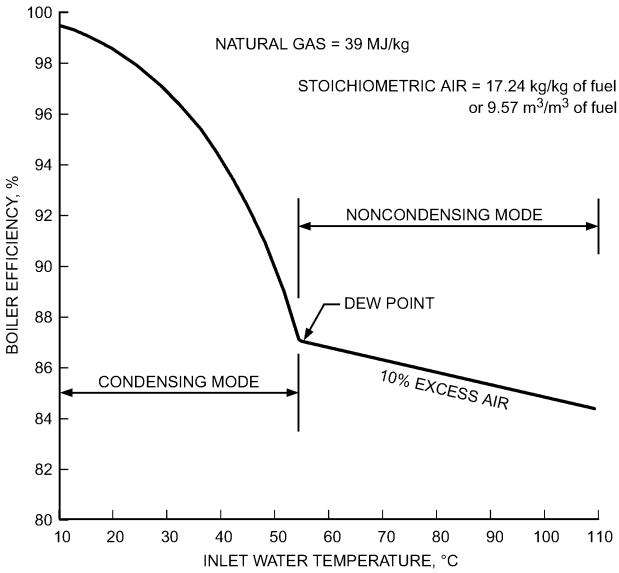

Fig. 6 Effect of Inlet Water Temperature on Efficiency of Condensing Boilers

pump application has potential boiler efficiency in excess of 98% (Figure 6).

For maximum reliability and durability over extended product life, condensing boilers should be constructed for corrosion resistance throughout the fireside combustion chamber and heat exchanger.

Noncondensing heat plant efficiency may in some cases be improved with the use of external flue gas-to-water economizers. The condensing medium may include domestic hot-water (DHW) preheat, steam condensate or hot-water return, fresh-water makeup, or other fluid sources in the 20 to 55°C range. The medium can also be used as a source of heat recovery in the HVAC system. Be sure to protect the noncondensing boiler from the low-temperature water return in the event of economizer service or control failure.

Figure 7 shows how dew point varies with a change in the percentages of oxygen/carbon dioxide for natural gas. Boilers that operate with a combustion efficiency and oxygen and carbon dioxide concentrations in the flue gas such that the flue gas temperature falls between the dew point and the dew point plus 80 K should be avoided, unless the venting is designed for condensation. This temperature typically occurs with boilers operating between 83 and 87% efficiency, and the flue gas has an oxygen concentration of 7 to 10% and the carbon dioxide is 6 to 8%. Chapter 35 gives further details on chimneys.

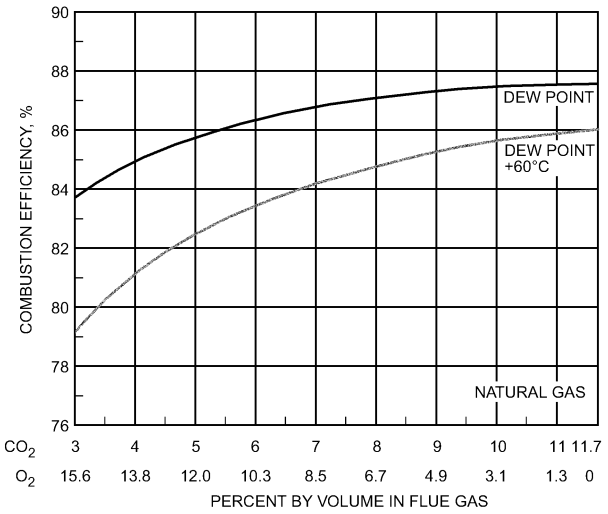

Fig. 7 Relationship of Dew Point, Carbon Dioxide, and Combustion Efficiency for Natural Gas

The condensing portion of these boilers may require special material or operating techniques to resist the corrosive effects of the condensing flue gases. In the past, typical cast iron, carbon steel, and copper were not suitable materials for the condensing section of a boiler. Certain stainless steels and aluminum alloys were suitable. However, advances in design, controls, and manufacturing have allowed materials such as cast iron to be used where they previously could not be; as with all products, consult the manufacturer for proper application. Commercial boiler installations can be adapted to condensing operation by adding a condensing heat exchanger in the flue gas vent.

Heat exchangers in the flue gas venting require a condensing medium such as (1) low pressure steam condensate or hot water return, (2) domestic water service, (3) fresh water makeup, or (4) other fluid sources in the 20 to 55°C range. The medium can also be a source of heat recovery in HVAC systems.

Wall-Hung Boilers

Wall-hung boilers are a type of small residential gas-fired boiler developed to conserve space in buildings such as apartments and condominiums. These boilers are popular in Europe. The most common designs are mounted on outer walls. Combustion air enters through a pipe from the outdoors, and flue products are vented directly through another pipe to the outdoors. In some cases, the air intake pipe and vent pipe are concentric. Other designs mount adjacent to a chimney for venting and use indoor air for combustion. These units may be condensing or noncondensing. Because these boilers are typically installed in the living space, provisions for proper venting and combustion air supply are very important.

Integrated (Combination) Boilers

Integrated boilers are relatively small, residential boilers that combine space heating and water heating in one appliance. They are usually wall mounted, but may also be floor standing. They operate primarily on natural gas and are practical to install and operate. The most common designs have an additional heat exchanger and a storage tank to provide domestic hot water. Some designs (particularly European) do not have a storage tank. Instead, they use a larger heat exchanger and the appropriate burner input to provide instantaneous domestic hot water.

Electric Boilers

Electric boilers are a separate class of boiler. Because no combustion occurs, a boiler heating surface and flue gas venting are unnecessary. The heating surface is the surface of the electric elements or electrodes immersed in the boiler water. The design of electric boilers is largely determined by the shape and heat release rate of the electric elements used. Electric boiler manufacturers' literature describes available size, shapes, voltages, ratings, and methods of control.

Heat Pump Boilers

Heat pump boiler, different from electric boilers, use refrigeration cycles to either absorb heat from the air or ground around the unit. The main components of a heat pump include an evaporative heat exchanger, a compressor, a condensing heat exchanger. Other components exist depending on the application and complexity as designed by the manufacturer. Like an electric boiler, no combustion occurs, and flue gas venting is unnecessary, but boiler surface area is still important. The heating surface is the surface of a heat exchanger that passes refrigerant on one side of the equipment, and boiler water on the other. Depending on the source of the heat, either water or air, one will have an additional heat exchanger designed for that medium, to complement heating surface area. The design of a heat pump boiler revolves around the operating temperature range of the equipment and the size of the heat exchanger attached to the appliance. Heat pump manufacturers' literature describes available size, shapes, voltages, ratings, and methods of control. This technology is currently under development, where refrigerants, compressor, and exchanger design may vary depending on the application of the three main components.

2. SELECTION PARAMETERS

Boiler selection depends on many variables of the individual application, including operating characteristics of actual loads; load distribution; total heating demand on the boiler plant; number of boilers in the plant; operational characteristics of individual boilers; and the whole boiler, burner, and control package.

The load's operational characteristics drive boiler selection. The purpose of boilers is not to make steam or hot water, but rather to supply heating as required by the process. Space heating can be accomplished with water or low-pressure steam. It is often possible to use lower water temperatures and a very efficient condensing boiler. An extremely wide range of products exist for this market. In industrial or institutional buildings, a process may require high-temperature hot water or high-pressure steam; this is a more specialized market and process loads require careful review. Often, the initial warm-up of a process load is very large and the loads are intermittent. Where a space-heating load is (after start-up) relatively constant, process loads can cause sudden increases and decreases in heating demand.

High-pressure steam or high-temperature hot water allow for economical distribution on large systems. A substantial part of the first cost of a new system is often distribution piping; there also are consequences on the operational cost to distribute the load. It may be appropriate to use a system with a high energy density for larger systems. Trade-offs of this approach include additional equipment to support a high-temperature and -pressure system, as well as lower system efficiency.

The boiler plant should be sized for the maximum system load. This is not merely the sum of connected loads, but should also take in to account piping loss, warm-up loads, possible diversity, etc. The plant also must operate at the minimum load, so the boiler should have sufficient turndown so that the boiler does not cycle excessively. It also must be able to increase or decrease its output with the load. If the load has a short burst of high instantaneous demand, a boiler with a high thermal capacity may be appropriate. If the load increases steadily and then remains for a long period, then a boiler with lower thermal mass but a quick response may be preferred. The designer should not only calculate the maximum but also the low load, and estimate the average load.

It is sometimes advantageous to split the load among multiple boilers. Splitting the load allows the plant to meet a seasonal high maximum and improves plant turndown in the shoulder season, and can increase efficiency for loads that tend to vary over the course of the year. Another factor to consider when selecting the number of boilers to be installed is redundancy. Redundant boilers allow for a more flexible maintenance schedule and possible future expansion. Also, consider plant layout and physical restrictions on the plant. An important issue is that, once a boiler reaches a certain size or pressure/temperature, many jurisdictions require an operating engineer to be always on site.

Once the system characteristics are established, the maximum load and general architectural of the plant can be selected. Important performance characteristics for base boiler selection include efficiency, part-load efficiency, and available fuels.

The physical boiler should be selected with burner and controls package. None of these elements operate independently of the others; they must operate as a whole. Each component of the boiler system affects

- Emissions
- Energy efficiency
- Indoor air quality (IAQ)
- System turndown
- System sensitivity

For IAQ purposes, it may be advantageous to have two boiler systems: a low-temperature hot-water heating system on outdoor reset control (60 to 32°C), and a clean-steam boiler for sterilizers and humidifiers.

The codes and standards outlined in the section on Performance Codes and Standards include requirements for minimum efficiency, maximum temperature, burner operating characteristics, and safety control. Test agency certification and labeling, which are published in boiler manufacturers' catalogs and shown on boiler rating plates, are generally sufficient for determining boiler steady-state operating characteristics. However, for noncondensing commercial and industrial boilers, these ratings typically do not consider part-load or seasonal efficiency, which is less than steady-state efficiency. Condensing boilers, generally provided with modulating burners, provide higher part- and full-load efficiency. Some boilers are not tested and rated by a recognized agency, and therefore do not bear the label of an agency. Nonrated boilers (rated and warranted only by the manufacturer) are used when jurisdictional codes or standards do not require a rating agency label. As previously indicated, almost without exception, both rated and nonrated boilers are of ASME code construction and are marked accordingly.

Boiler selection should be based on a competent review of the following parameters:

All Boilers

- Application of terminal unit selection
- Applicable code under which the boiler is constructed and tested
- Gross boiler heat output
- Part- versus full-load efficiency (life-cycle cost)
- Total heat transfer surface area
- Water content mass or volume
- Auxiliary power requirement
- Cleaning and service access provisions for fireside and waterside heat transfer surfaces
- Space requirement and piping arrangement
- Water treatment requirement

- Operating personnel capabilities and maintenance/operation requirements
- Regulatory requirements for emissions, fuel usage/storage

Fuel-Fired Boilers

- Combustion chamber (furnace volume)
- Internal flow pattern of combustion products
- Combustion air and venting requirements
- Fuel availability/capability

Steam Boilers

- Steam quality
- Condensate recovery system design

3. EFFICIENCY: INPUT AND OUTPUT RATINGS

The efficiency of fuel-burning boilers is defined in the following ways: combustion, overall, and seasonal. However, manufacturers are not required to test or publish efficiencies that coincide with these industry definitions. Further explanation of boiler test requirements is found in the section on Performance Codes and Standards.

Combustion efficiency is input minus stack (flue gas outlet) loss, divided by input, and generally ranges from 75 to 86% for most noncondensing boilers. Condensing boilers generally rated in the range of 88 to 99% combustion efficiency.

Overall (or **thermal**) **efficiency** is gross energy output divided by energy input. Gross output is measured in the steam or water leaving the boiler and depends on the characteristics of the individual installation. Overall efficiency of electric boilers is generally 92 to 96%. Overall efficiency is lower than combustion efficiency by the percentage of heat lost from the outer surface of the boiler (radiation loss or jacket loss) and by off-cycle energy losses (for applications where the boiler cycles on and off). Overall efficiency can be precisely determined only under controlled laboratory test conditions, directly measuring the fuel input and the heat absorbed by the water or steam of the boiler. Precise efficiency measurements are generally not performed under field conditions because of the inability to control the required parameters and the high cost involved in performing such an analysis. An approximate combustion efficiency for noncondensing boilers can be determined under any operating condition by measuring flue gas temperature and percentage of CO_2 or O_2 in the flue gas and by consulting a chart or table for the fuel being used. The approximate combustion efficiency of a condensing boiler must include the energy transferred by condensation in the flue gas.

Seasonal efficiency is the actual operating efficiency that the boiler will achieve during the heating season at various loads. Because most heating boilers operate at part load, the part-load efficiency, including heat losses when the boiler is off, has a great effect on the seasonal efficiency. The difference in seasonal efficiency between a boiler with an on/off firing rate and one with modulating firing rate can be appreciable if the airflow through the boiler is modulated along with the fuel input. Figure 8 shows how efficiency increases at part load for a typical boiler equipped with a burner that can fire at reduced inputs while modulating both fuel and air. This increase in efficiency comes from the increase in the ratio of heat exchanger surface area to heat input as the firing rate is reduced.

4. PERFORMANCE CODES AND STANDARDS

Commercial heating boilers (i.e., boilers with inputs of 90 kW and larger) at present are only tested for full-load steady-state efficiency according to standards developed by either (1) the Air-Conditioning, Heating, and Refrigeration Institute (AHRI), (2) the American Gas Association (AGA), or (3) Underwriters Laboratories (UL).

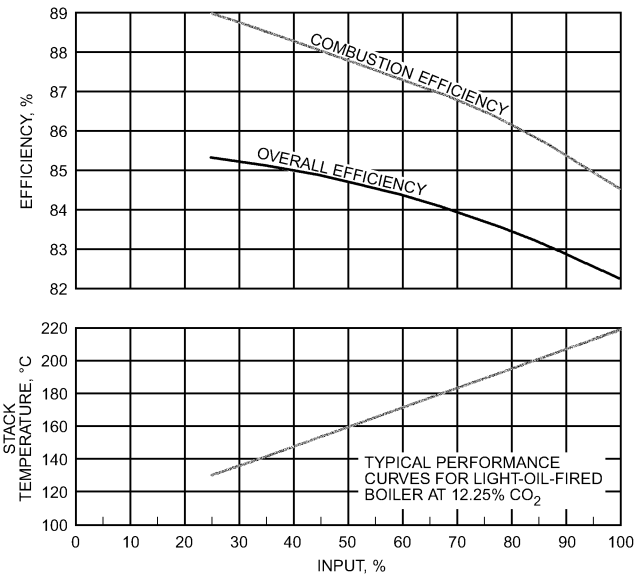

Fig. 8 Boiler Efficiency as Function of Fuel and Air Input

AHRI *Standard* 1500 for rating cast-iron sectional, steel, and copper boilers bases performance on controlled test conditions for fuel inputs of 117 kW and larger. The gross output obtained by the test is limited by such factors as flue gas temperature, draft, CO_2 in the flue gas, and minimum overall efficiency. This standard applies primarily to oil-fired and natural gas equipment; however, it is also applied to all forced-draft gas-fired or dual-fueled units.

Gas boilers are generally design-certified by an accredited testing laboratory based on tests conducted in accordance with ANSI/CSA *Standard* Z21.13 or UL *Standard* 795. Note that the Z21.13 test procedure may be applied to both condensing and noncondensing boilers. This test uses 27°C return water temperature, 56 K temperature differential, steady-state, full-load operation, and allows the presence of condensate to be ignored. Efficiencies published under this test procedure are generally not achieved in actual operation.

Instead of the HI-GAMA, AGA, and UL standards, test procedures for commercial-industrial and packaged fire-tube boilers are often performed based on ASME *Performance Test Code* 4 (2023). Units are tested for performance under controlled test conditions with minimum required levels of efficiency. Further, the American Boiler Manufacturers Association (ABMA) publishes several guidelines for the care and operation of commercial and industrial boilers and for control parameters.

Residential heating boilers (i.e., all gas- and oil-fired boilers with inputs less than 90 kW in the United States) are rated according to standards developed by the U.S. Department of Energy (DOE). The procedure determines both on- and off-cycle losses based on a laboratory test. The test results are applied to a computer program, which simulates an installation and predicts an annual fuel utilization efficiency (AFUE). The steady-state efficiency developed during the test is similar to combustion efficiency and is the basis for determining DOE **heating capacity**, a term similar to gross output. The AFUE represents the part-load efficiency at the average outdoor temperature and load for a typical boiler installed in the United States. Although this value is useful for comparing different boiler models, it is not meant to represent actual efficiency for a specific installation.

5. SIZING

Boiler sizing is the selection of boiler output capacity to meet connected load. The boiler gross output is the rate of heat delivered

by the boiler to the system under continuous firing at rated input. Net rating (I-B-R rating) is gross output minus a fixed percentage (called the piping and pickup factor) to allow for an estimated average piping heat loss, plus an added load for initially heating up the water in a system (sometimes called **pickup**). This I-B-R piping and pickup factor is 1.15 for water boilers and ranges from 1.27 to 1.33 for steam boilers, with the smaller number applying as the boilers get larger. The net rating is calculated by dividing the gross output by the appropriate piping and pickup factor.

Piping loss is variable. If all piping is in the space defined as load, loss is zero. If piping runs through unheated spaces, heat loss from the piping may be much higher than accounted for by the fixed net rating factor. Pickup is also variable. When the actual connected load is less than design load, the pickup factor may be unnecessary.

On the coldest day, extra output (boiler and radiation) is needed to pick up the load from a shutdown or low night setback. If night setback is not used, or if no extended shutdown occurs, no pickup load exists. Standby capacity for pickup, if needed, can be in the form of excess capacity in baseload boilers or in a standby boiler.

If piping and pickup losses are negligible, the boiler gross output can be considered the design load. If piping loss and pickup load are large or variable, those loads should be calculated and equivalent gross boiler capacity added. Boiler capacity must be matched to the terminal unit and system delivery capacity. That is, if the boiler output is greater than the terminal output, the water temperature rises and the boiler cycles on the high-limit control, delivering an average input that is much lower than the boiler gross output. Significant oversizing of the boiler may result in a much lower overall boiler efficiency.

6. BURNER TYPES

Burners for installation on boilers are grouped generally by fuel used and pressure type. Fuel groupings include fuel oil, natural gas, propane, wood, or coal. A **dual-fuel burner** may use two or more fuels (e.g., No. 2 fuel oil and natural gas). The pressure type refers to whether the burner is atmospheric or a fan is used for pressurization. In **atmospheric burners**, firing generally natural gas or propane, the fuel is introduced across a drilled orifice manifold where it contacts combustion air and is ignited. The chimney or flue produces a natural draft to remove the products of combustion. In **power burners**, a fan pushes combustion air into a burner or combustion chamber under positive pressure where it mixes with the fuel and is ignited. The products of combustion are pushed through the combustion chamber and boiler by the fan, then flow through the chimney by natural draft, or induced draft caused by a chimney fan.

Burners may also be classified by method of fuel atomization. In **pressure atomization**, fuel oil at 550 to 2070 kPa (gage) is pumped through a nozzle orifice to create a fine mist. The fuel-rich mist is mixed with combustion air provided by a fan and is ignited at the burner. In **steam atomization**, generally used on heavy grades of fuel oil, high-pressure steam is mixed with pressurized fuel oil through a nozzle orifice to heat the oil and reduce the oil's viscosity to create a fine mist. The mist is mixed with combustion air provided by a fan and is ignited at the burner.

7. BOILER CONTROLS

Boiler controls provide automatic regulation of burner and boiler performance to ensure safe and efficient operation. Operating and combustion controls regulate the rate of fuel input in response to a signal representing load change (demand), so that the average boiler output equals the load within some accepted tolerance. Water level and flame safety controls cut off fuel flow when unsafe conditions develop. The National Fire Protection Association (NFPA) *Code* 85, Boiler and Combustion Systems Hazard Code, is generally accepted as the governing code for boiler control systems. Other requirements from insurance companies or local governing agencies may also be applicable. Often, the governing agency having jurisdiction may specify specific requirements that the heating system designer or specifying engineer must comply with in the design. It is essential that the designer or engineer determine the applicable codes, and specify the controls and skills needed to complete the control system.

Operating Controls

Steam boilers are operated by boiler-mounted, pressure-actuated controls, which vary fuel input to the boiler. Traditional examples of burner controls were on/off, high/low/off, and modulating. Modulating controls infinitely vary fuel input from 100% down to a selected minimum set point. The ratio of maximum to minimum is the turndown ratio. The minimum input is usually between 5 and 33% (i.e., 20 to 1 down to 3 to 1 ratios); input depends on the size and type of fuel-burning equipment and system. High turndown ratios in noncondensing boilers must be considered carefully to prevent condensation at lower firing rates.

Hot-water boilers are operated by temperature-actuated controls that are usually mounted on the boiler. Traditionally, burner controls were the same as for steam boilers (i.e., on/off, high/low/off, and modulating). Modulating controls typically offer more precise water temperature control and higher efficiency than on/off or high/low controls, if airflow through the boiler is modulated along with fuel input.

Boiler reset controls can enhance the efficiency of hot-water boilers. These controls may operate with any of the burner controls mentioned previously. They automatically change the high-limit set point of the boiler to match the variable building load demands caused by changing outdoor temperatures. By keeping boiler water temperature as low as possible, efficiency is enhanced and standby losses are reduced.

Microprocessor-Based Control Systems. The introduction of microprocessor-based control systems has changed traditional operating controls on boilers. In the past, smaller boilers were equipped with on/off or high/low/off electromagnetic-relay-based burner operating controls with mercury switches, with larger boilers provided with modulating controls. The low cost and greater efficiency of microprocessor-based control systems has resulted in the availability of such controls on small factory-packaged boilers, and nearly all medium and larger boiler installations. The recent introduction of integrated combustion and burner safeguard microprocessor controllers has accelerated this availability.

Traditionally, most burner installations used a single actuator to drive the combustion air damper and fuel ratio valves through common linkages. Such installations were called **single-jackshaft** controls. The fuel ratio valves often used set screw cams to produce efficient combustion throughout the firing range of the burner. Tuning the burner involved positioning the set screws to adjust the cam, which in turn regulated the fuel ratio at various firing rates. Tuning was often cumbersome, and easily lost when set screws loosened. Single-jackshaft control also invariably meant compromises were made in tuning, generally resulting in inefficient combustion with high excess air ratios at low firing rates. Current technology eliminates the single-jackshaft, using "linkless" burners with individual actuators controlling the combustion air damper and each fuel valve. With the high-speed processing ability of the microprocessors, individual actuators can quickly and accurately respond to changes in load, ensuring efficient combustion throughout the full firing range. When oxygen analyzers are installed to measure the oxygen content of the flue gas, microprocessor combustion controllers can modulate the combustion air damper and fuel valve actuators to ensure optimal combustion efficiency.

Water Level Controls

Maintaining proper water level in a boiler is of paramount concern. Should water level drop below a preset limit, damage may occur from overheating of boiler surfaces, resulting in cracking of cast-iron sections, or plastic deformation of steel tubes and tubesheets. Such a condition is known as **dry-firing** of the boiler. Installation of a low-water cutoff switch to stop fuel flow to the burner is necessary to prevent damage from dry firing.

To maintain proper water levels, different methods may be used. Smaller boilers generally use a boiler feedwater controller to cause a feedwater pump to pump water directly to the boiler to maintain proper water level. In larger installations, a feedwater piping loop may serve several boilers in parallel. In such an installation, each boiler has a feedwater valve controlled by a feedwater controller mounted on the boiler. The controller modulates the feedwater valve to maintain proper water level in the boiler. Simple feedwater control systems use water level as the control parameter to modulate the feedwater valve. Such systems are considered **single-element** feedwater systems. In larger boiler installations where steam is generated, the steam flow rate or rate of change of steam pressure may also be monitored with a signal sent to the feedwater controller. If the controller is programmed to modulate the feedwater valve based on both water level and steam flow rate or rate of change of pressure, the feedwater control system is referred to a **two-element** system. A **three-element** system uses water level, steam flow rate, and rate of pressure change to modulate the feedwater valve.

8. FLAME SAFEGUARD CONTROLS

Flame safeguard controls monitor flame condition and shut fuel flow to the burner in the event of an unsafe condition. The safety circuit of a flame safeguard control system typically includes switch contacts for low-water cutoff, high limits, air proving switches, redundant safety and operating controls, and flame monitors. Flame monitors typically use either infrared or ultraviolet scanners to monitor flame condition and deactivate the burner in the event of nonignition or other unsafe flame condition. Flame safeguard controllers usually use preprogrammed algorithms to operate a burner and cycle it through stages of operation. The first stage is a purge cycle wherein the boiler's combustion chamber is flushed with combustion air to remove any unspent fuel and products of combustion that remain from the previous cycle. After purging, the pilot flame is ignited and the main fuel introduced into the burner and ignited. In the absence of a pilot fuel, such as with direct electronic spark ignition, the main fuel is introduced and ignited. In either case, the flame monitor determines whether ignition has occurred and whether the resulting flame is proper. If ignition has failed, or flame is not indicated, the flame monitor cuts off fuel flow, causing a postpurge cycle to rid the combustion chamber of unspent fuel and products of combustion. On restart, the burner again starts with a purge cycle and repeats the steps to ignition. When proper flame is established, the flame safeguard control system allows the operating control or combustion control system to control or modulate the burner firing rate.

Traditionally, flame safeguard systems were separate controllers from operating or combustion control systems. With the advent of microprocessor-based control systems, separate microprocessors control the individual functions of flame safeguard and combustion control. Recently introduced burner controllers provide an integrated control with algorithms for both flame safeguard and combustion control.

Equipment Selection 33.6
Calculations 33.8
Technical Data 33.8
Installation 33.9
Agency Listings 33.10

FURNACES are self-enclosed, permanently installed major appliances that provide heated air through ductwork to the space being heated. In addition, a furnace may provide the indoor fan necessary for circulating heated or cooled air from a split or single-package air conditioner or heat pump (see Chapter 10). Furnaces may be used in either residential or commercial applications, and may be grouped according to the following characteristics:

- Heat source: electricity, natural gas/propane (fan assisted, condensing or noncondensing), or oil (forced draft with power atomizing burner)
- Installation location: within conditioned space (indoors), or outside conditioned space (either outdoors, or inside the structure but not within the conditioned space)
- Combustion air source: direct vent (outdoor air) or indoor air
- Mounting arrangement and airflow: horizontal, vertical upflow, vertical downflow, or multiposition

Furnaces that use electricity as a heat source include one or more resistance-type heating elements that heats the circulating air either directly or through a metal sheath that encloses the resistance element. In gas- or oil-fired furnaces, combustion occurs in the heat exchanger sections or in a combustion chamber. Circulating air passes over the outer surfaces of a heat exchanger so that it does not contact the fuel or the products of combustion, which are passed to the outdoor atmosphere through a vent.

In North America, natural gas is the most common fuel supplied for residential heating, and the central-system forced-air furnace (Figure 1) is the most common way of heating with natural gas. This type of furnace is equipped with a blower to circulate air through the furnace enclosure, over the heat exchanger, and through the ductwork distribution system. A furnace such as that in Figure 1 is categorized as follows:

- Heat source: natural gas
- Mounting arrangement and airflow: vertical upflow
- Installation location: varies; usually inside the structure but not necessarily within the conditioned space
- Combustion air source: varies; high-efficiency furnaces usually are direct vent

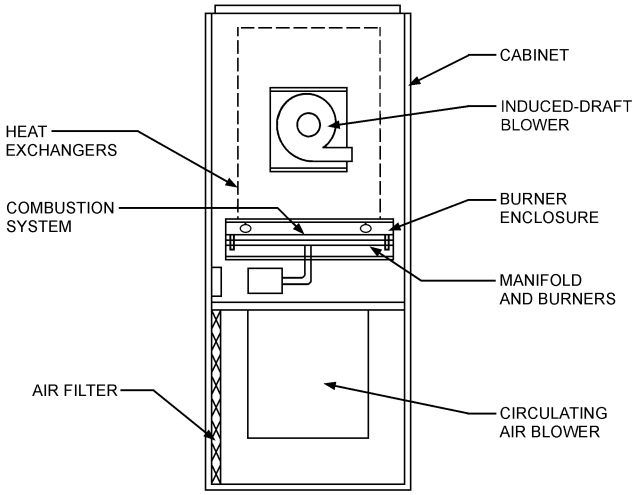

Fig. 1 Induced-Draft Gas Furnace

1. COMPONENTS

A typical furnace consists of the following basic components: (1) a cabinet or casing; (2) heat exchangers; (3) heat sources, including burners and controls; (4) venting components, such as an induced-draft blower; (5) a circulating air blower and motor; and (6) an air filter and other accessories such as a humidifier, electronic air cleaner, air-conditioning coil, or a combination of these elements.

Casing or Cabinet

The furnace casing is most commonly formed from painted cold-rolled steel. Access panels on the furnace allow access to those sections requiring service. The inside of the casing adjacent to the heat exchanger or electric heat elements is lined with a foil-faced blanket insulation and/or a metal radiation shield to reduce heat losses through the casing and to limit the outer surface temperature of the furnace. On some furnaces, the inside of the blower compartment is lined with insulation to acoustically dampen the blower noise. Commercial furnace cabinets may also include the indoor and outdoor air-conditioning or heat pump components.

New scrutiny of the airtightness of system ductwork has drawn attention to the furnace casing as a common source of leakage. ASHRAE *Standard* 193-2010 provides a method of test to determine the airtightness of forced-air HVAC equipment before field installation. The standard is cited in the U.S. Department of Energy (DOE) *ENERGY STAR*® Program Requirements Product Specification for Furnaces, Version 4.0 (DOE 2013).

Heat Exchangers

Furnaces with gas-fired burners have heat exchangers that are typically made either of left/right sets of formed parts that are joined together to form a clamshell, finless tubes bent into a compact form, or finned-tube (condensing) heat exchangers. Standard indoor furnace heat exchangers are generally made of alloy steel. Common corrosion-resistant materials include aluminized steel and stainless steel. Furnaces certified for use downstream of a cooling coil must have corrosion-resistant heat exchangers.

Some problems of heat exchanger corrosion and failure have been encountered because of exposure to halogen ions in flue gas. These problems were caused by combustion air contaminated by substances such as laundry bleach, cleaning solvents, and halogenated hydrocarbon refrigerants.

Heat exchangers of oil-fired furnaces are normally heavy-gage steel formed into a welded assembly. Hot flue products flow through the inside of the heat exchanger into the chimney, and conditioned

The preparation of this chapter is assigned to TC 6.3, Central Forced Air Heating and Cooling Systems.

air flows over the outside of the heat exchanger and into the air supply plenum.

Heat Sources

Electric Heat Elements. Elements for electric furnaces are generally either open wire, open ribbon, or wire enclosed in a tube. Current is applied to the element and heats it through resistance of the material.

Burners and Internal Controls. Gas burners are most frequently made of stamped sheet metal, although cast iron is also used. Fabricated sheet metal burners may be made from cold-rolled steel coated with high-temperature paint or from a corrosion-resistant material such as stainless or aluminized steel. Burner material must meet the corrosion protection requirements of the specific application. Gas furnace burners may be of either the monoport or multiport type; the type used with a particular furnace depends on compatibility with the heat exchanger.

Gas furnace controls include an ignition device, gas valve, fan control, limit switch, and other components specified by the manufacturer. These controls allow gas to flow to the burners when heat is required. The most common ignition systems are (1) direct spark, and (2) hot-surface ignition. The section on Technical Data has further details on the function and performance of individual control components.

Oil furnaces are generally equipped with pressure-atomizing burners. The pump pressure and size of the injection nozzle orifice regulate the firing rate of the furnace. Electric ignition lights the burners. Other furnace controls, such as the blower switch and the limit switch, are similar to those used on gas furnaces.

Combustion Venting Components

Fan-assisted combustion furnaces use a small blower to induce flue products through the furnace. Induced-draft furnaces may or may not have a relief air opening, but they meet the same safety requirements regardless. Residential furnaces built since 1987 are equipped with a blocked-vent shutoff switch to shut down the furnace in case the vent becomes blocked.

Research into common venting of natural-draft appliances (water heaters) and fan-assisted combustion furnaces shows that nonpositive vent pressure systems may operate on a common vent. Refer to manufacturers' instructions for specific information.

Direct-vent furnaces use outdoor air for combustion. Outdoor air is supplied to the furnace combustion chamber by direct connections between the furnace and the outdoor air. If the vent or the combustion air supply becomes blocked, the furnace control system will shut down the furnace.

ANSI *Standard* Z21.47/CSA 2.3 classifies venting systems. Central furnaces are categorized by temperature and pressure attained in the vent and by the steady-state efficiency attained by the furnace. Although ANSI *Standard* Z21.47/CSA 2.3 uses 83% as the steady-state efficiency dividing central furnace categories, a general rule of thumb is as follows:

Category I: nonpositive vent pressure and flue loss of 17% or more

Category II: nonpositive vent pressure and flue loss less than 17%

Category III: positive vent pressure and flue loss of 17% or more

Category IV: positive vent pressure and flue loss less than 17%

Furnaces rated in accordance with ANSI *Standard* Z21.47/CSA 2.3 that are not direct vent are marked to show that they are in one of these four venting categories.

Ducted-system, oil-fired, forced-air furnaces are usually forced draft.

Circulating Blowers and Motors

Centrifugal blowers with forward-curved blades of the double-inlet type are used in most forced-air furnaces. These blowers overcome the resistance of furnace air passageways, filters, and ductwork. They are usually sized to provide the additional air requirement for cooling and the static pressure required for the cooling coil. The blower may be a direct-drive type, with the blower wheel attached directly to the motor shaft, or it may be a belt-drive type, with a pulley and V-belt used to drive the blower wheel.

Electric motors used to drive furnace blowers are usually custom designed for each furnace model or model series. Direct-drive motors may be shaded-pole, permanent split-capacitor (PSC), or brushless permanent magnet. Speed may be varied by taps connected to extra windings in the motor. Belt-drive blower motors are normally split-phase or capacitor-start. The speed of belt-drive blowers is controlled by adjusting a variable-pitch drive pulley.

Electronically controlled, variable-speed motors using a brushless permanent magnet design are inherently more efficient than shaded-pole or PSC motors. The motor is controlled electronically by a microprocessor and electronic controls, which provides the ability to increase or decrease motor speed and maintain efficiency across a wide range of operating speeds.

In the United States, the DOE regulates energy efficiency of residential furnace fans. DOE has initiated a rulemaking to consider new energy conservation or use standards for furnace fans. For the current status of DOE regulations, visit www.energy.gov/eere/buildings/appliance-and-equipment-standards-program.

Filters and Other Accessories

Air Filters. An air filter in a forced-air furnace removes dust from the air that could reduce the effectiveness of the blower and heat exchanger(s), and may also help provide cleaner air for the indoor environment (see ASHRAE *Standard* 52.2). Filters installed in a forced-air furnace are often disposable. Permanent filters that may be washed or vacuum-cleaned and reinstalled are also used. The filter is always located in the circulating airstream ahead of the blower and heat exchanger. Because the air filter keeps airflow components of the furnace clean, it should be cleaned or replaced regularly to extend the life of the furnace components. See Chapters 10 and 29 for further information on air filters.

Humidifiers. These are not included as a standard part of the furnace package. However, one advantage of a forced-air heating system is that it offers the opportunity to control the relative humidity of the heated space at a comfortable level. Chapter 22 addresses various types of humidifiers used with forced-air furnaces.

Electronic Air Cleaners. These air cleaners may be much more effective than the air filter provided with the furnace, and they filter out much finer particles, including smoke and pollen. Electronic air cleaners create an electric field of high-voltage direct current in which dust particles are given a charge and collected on a plate having the opposite charge. The collected material is then cleaned periodically from the collector plate by the homeowner. Electronic air cleaners are mounted in the airstream entering the furnace. Chapter 29 has detailed information on filters.

Airflow Variations

The components of a forced-air furnace can be arranged in a variety of configurations to suit a residential heating system. The relative positions of the components in the different types of furnaces are as follows:

- **Upflow furnace.** In an upflow furnace (Figure 2), the blower is located beneath the heat exchanger and discharges vertically upward. Air enters through the bottom or the side of the blower compartment and leaves at the top. This furnace may be used in closets and utility rooms on the first floor or in basements, with

the return air ducted down to the blower compartment entrance.

Downflow furnace. In a downflow furnace (Figure 3), the blower is located above the heat exchanger and discharges downward. Air enters at the top and is discharged vertically at the bottom. This furnace is normally used with a perimeter heating system in a house without a basement. It is also used in upstairs furnace closets and utility rooms supplying conditioned air to both levels of a two-story house.

- **Horizontal furnace.** In a horizontal furnace, the blower is located beside the heat exchanger (Figure 4). Air enters at one end, travels horizontally through the blower and over the heat exchanger, and is discharged at the opposite end. This furnace is used for locations with limited head room such as attics and crawlspaces, or is suspended under a roof or floor or placed above a suspended ceiling. These units are often designed so that the components may be rearranged to allow installation with airflow from left to right or from right to left.
- **Multiposition (multipoise) furnace.** This furnace can be installed in more than one airflow configuration (e.g., upflow or horizontal; downflow or horizontal; or upflow, downflow, or horizontal). In some models, field conversion is necessary to accommodate an alternative installation.
- **Basement furnace.** The basement furnace (Figure 5) is a variation of the upflow furnace and requires less head room. The blower is located beside the heat exchanger at the bottom. Air enters the top of the cabinet, is drawn down through the blower, is discharged over the heat exchanger, and leaves vertically at the top. This type of furnace has become less popular because of the advent of short upflow furnaces.
- **Gravity furnace.** These furnaces are no longer available, and they are not common. This furnace has larger air passages through the casing and over the heat exchanger so that the buoyancy force created by the air being warmed circulates the air through the ducts. Wall furnaces that rely on natural convection (gravity) are discussed in Chapter 34.

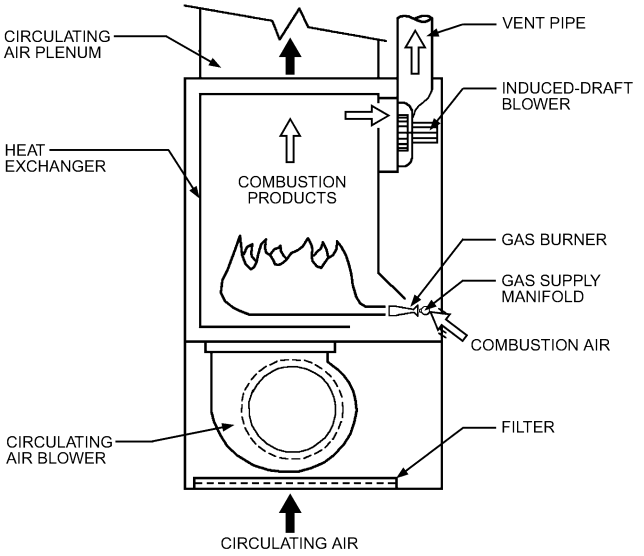

Fig. 2 Upflow Category I Furnace with Induced-Draft Blower

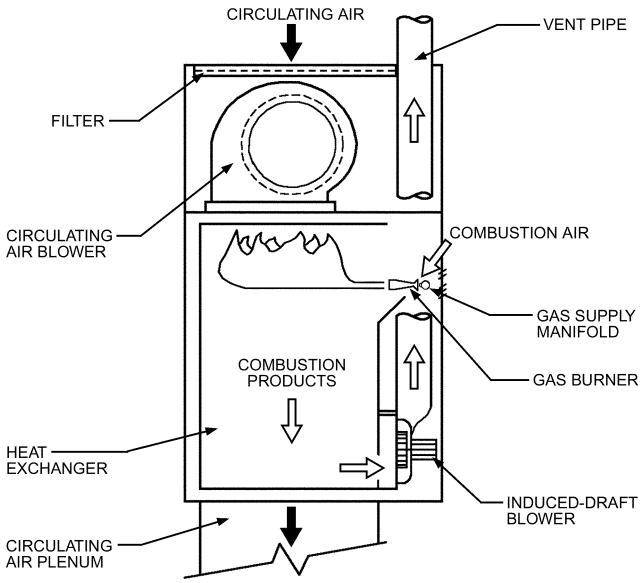

Fig. 3 Downflow (Counterflow) Category I Furnace with Induced-Draft Blower

Combustion System Variations

Gas-fired furnaces use a fan-assisted combustion system. Fan-assisted combustion furnaces have a combustion blower, which may be located either upstream or downstream from the heat exchangers (Figure 6). If the blower is located upstream, blowing the combustion air into the heat exchangers, the system is known as a forced-draft system. If the blower is downstream, the arrangement is known as an induced-draft system.

Direct-vent furnaces obtain combustion air from outside the structure. Mobile home furnaces must be of the direct-vent type.

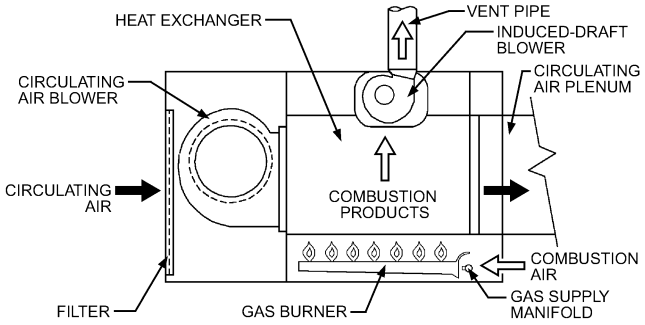

Fig. 4 Horizontal Category I Furnace with Induced-Draft Blower

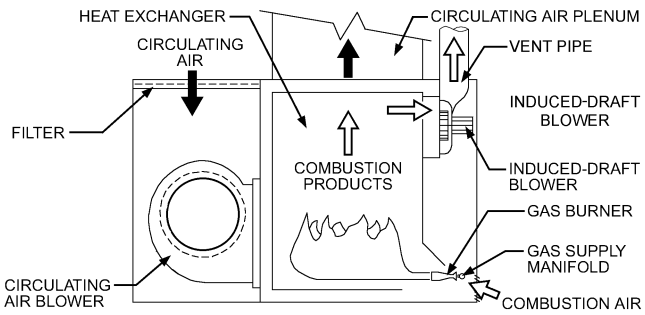

Fig. 5 Basement (Lowboy) Category I Furnace with Induced-Draft Blower

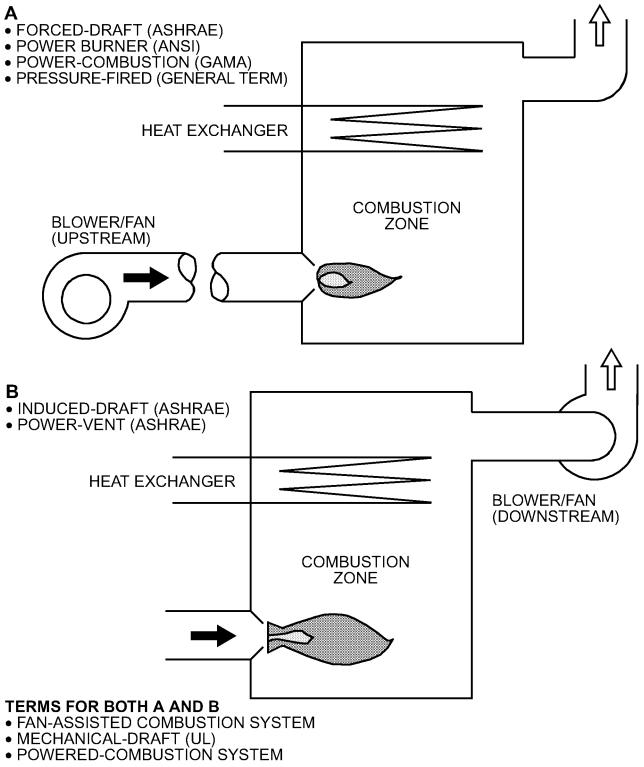

Fig. 6 Terminology Used to Describe Fan-Assisted Combustion

Indoor/Outdoor Furnace Variations

Central system residential furnaces are designed and certified for either indoor or outdoor use. Outdoor furnaces are normally horizontal flow and convertible to downflow.

The heating-only outdoor furnace is similar to the more common indoor horizontal furnace. The primary difference is that the outdoor furnace is weatherized; the motors and controls are sealed, and the exposed components are made of corrosion-resistant materials such as galvanized or aluminized steel.

A common style of outdoor furnace is the combination package unit. This unit is a combination of an air conditioner and a gas or electric furnace built into a single casing. The design varies, but the most common combination consists of an electric air conditioner coupled with a horizontal gas or electric furnace. The advantage is that much of the interconnecting piping and wiring is included in the unit.

2. HEAT SOURCE TYPES

Natural Gas and Propane Furnaces

Most manufacturers have their furnaces certified for both natural gas and propane. The major difference between natural gas and propane furnaces is the pressure at which the gas is injected from the manifold into the burners. For natural gas, the manifold pressure is usually controlled at 750 to 1000 Pa; for propane, the pressure is usually 2500 to 2700 Pa.

Because of the higher injection pressure and the greater heat content per volume of propane, there are certain physical differences between a natural gas furnace and a propane furnace. One difference is that the burner orifices must be smaller for propane furnaces. The gas valve regulator spring is also different. Sometimes it is necessary to change burners, but this is not normally required. Manufacturers sell conversion kits containing both the required parts and instructions to convert furnace operation from one gas to the other.

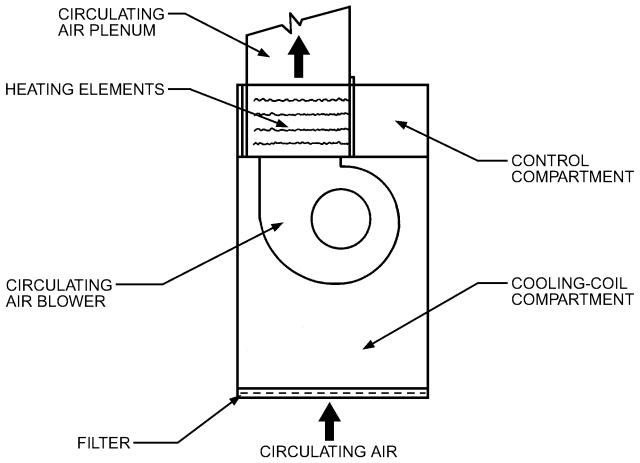

Fig. 7 Electric Forced-Air Furnace

Oil Furnaces

Indoor oil furnaces come in the same configurations as gas furnaces. They are available in upflow, downflow, horizontal, and lowboy configurations for ducted systems. Oil-fired outdoor furnaces and combination units are not common.

The major differences between oil and gas furnaces are in the combustion system, heat exchanger, and barometric draft regulator.

Electric Furnaces

Electric-powered furnaces come in a variety of configurations and have some similarities to gas- and oil-fired furnaces. However, when a furnace is used with an air conditioner, the cooling coil may be upstream from the blower and heaters. On gas- and oil-fired furnaces, the cooling coil is normally mounted downstream from the blower and heat exchangers so cold air leaving the cooling coil does not contact the heat exchangers, which could cause premature corrosion from condensation. If the cooling coil is upstream of the heat exchangers on a gas- or oil-fired product, the heat exchanger may require a mechanism to remove the condensed moisture.

Figure 7 shows a typical arrangement for an electric forced-air furnace. Air enters the bottom of the furnace and passes through the filter, then flows up through the cooling coil section into the blower. The electric heating elements are immediately above the blower so that the high-velocity air discharging from the blower passes directly through the heating elements.

The furnace casing, air filter, and blower are similar to equivalent gas furnace components. The heating elements are made in modular form, with 5 kW capacity being typical for each module. Electric furnace controls include electric overload protection, contactor, limit switches, and a fan control switch. The overload protection may be either fuses or circuit breakers. The contactor brings the electric heat modules on. The fan control switch and limit switch functions are similar to those of the gas furnace, but one limit switch is usually used for each heating element.

Frequently, electric furnaces are made from modular sections; for example, the coil box, blower section, and electric heat section are made separately and then assembled in the field. Regardless of whether the furnace is made from a single-piece casing or a modular casing, it is generally a multiposition unit. Thus, the same unit may be used for upflow, downflow, or horizontal installations.

When an electric heating appliance is sold without a cooling coil, it is known as an electric furnace. The same appliance is called a fan-coil air handler when it has an air-conditioning coil already installed. When the unit is used as the indoor section of a split heat

pump, it is called a heat pump fan-coil air handler. For detailed information on heat pumps, see Chapters 9 and 48.

Electric forced-air furnaces are also used with packaged heat pumps and packaged air conditioners.

3. COMMERCIAL EQUIPMENT

The basic differences between residential and commercial furnaces are available options such as economizers, outdoor air dampers, and the type of electrical service required (three-phase).

Commercial heating equipment comes in almost as many flow arrangements and design variations as residential equipment. Some are identical to residential equipment, whereas others are unique to commercial applications. Some commercial units function as a part of a ducted system, and others operate as unducted space heaters.

Ducted Equipment

Upflow Gas-Fired Commercial Furnaces. These furnaces are normally incorporated into a system in conjunction with a commercial split-system air-conditioning unit and are available in either propane or natural gas. Oil-fired units may be available on a limited basis.

Horizontal Gas-Fired Duct Furnaces. Available for built-up light commercial systems, this type of furnace is not equipped with its own blower but is designed for uniform airflow across the entire furnace. Duct furnaces are normally certified for operation either upstream or downstream of an air conditioner cooling coil. If a combination blower and duct furnace is desired, a package called a blower unit heater is available. Duct furnaces and blower unit heaters are available in natural gas, propane, oil, and electric models.

Electric Duct Furnaces. These furnaces are available in a large range of sizes and are suitable for operation in upflow, downflow, or horizontal positions. These units are also used to supply auxiliary heat with the indoor section of a split heat pump.

Package Units. The most common commercial furnace is the package unit, sometimes known as a **rooftop unit (RTU)**. These are available as air-conditioning units with propane and natural gas furnaces, electric resistance heaters, or heat pumps. Combination oil-heat/electric-cool units are not commonly available.

Package units of 50 kW and under are available as single-zone units. The entire unit must be in either heating mode or cooling mode. All air delivered by the unit is at the same temperature. Frequently, the heating function is staged so that the system operates at reduced heat output when the load is small.

Large package units in the 50 to 175 kW range are available as single-zone units, as are small units; however, they are also available as multizone units. A multizone unit supplies conditioned air to several different zones of a building in response to individual thermostats controlling those zones. These units can supply heating to one or more zones at the same time that cooling is supplied to other zones.

Large package units are normally available only in a curbed configuration (i.e., units are mounted on a rooftop over a curbed opening in the roof). Supply and return air enters through the bottom of the unit. Smaller units may be available for either curbed or uncurbed mounting. In either case, the unit is usually connected to ductwork in the building to distribute the conditioned air.

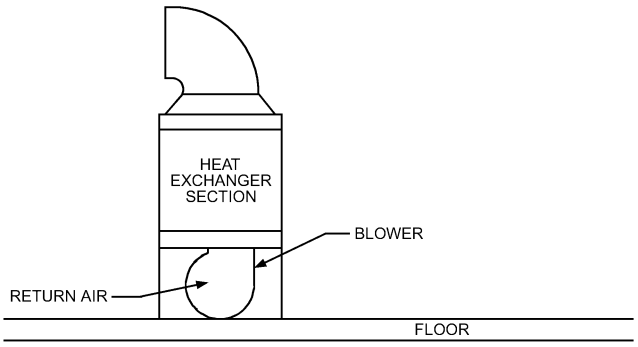

Fig. 8 Standing Floor Furnace

Unducted Heaters

Ductless furnaces, floor furnaces (Figure 8), and wall furnaces are discussed in Chapter 34. Infrared heating equipment is covered in Chapter 16.

4. CONTROLS AND OPERATING CHARACTERISTICS

External to Furnace

Externally, the furnace is controlled by a low-voltage room thermostat. Chapter 7 of the 2021 *ASHRAE Handbook—Fundamentals* discusses thermostats in detail.

In North America, a furnace that is not part of a package unit is commonly installed with a split-system air conditioner. The furnace control receives input from the room thermostat, which determines the mode of operation. The furnace blower is used to circulate air through the ducts in the heating, cooling, and circulating modes of operation.

Internal to Furnace

Several types of gas valves perform various functions within the furnace. The type of valve available relates closely to the type of ignition device used. **Two-stage valves**, available on some furnaces, operate at full gas input or at a reduced rate, and are controlled by either a two-stage thermostat or a software algorithm programmed in the furnace control system. They provide less heat at the reduced input and, therefore, may produce less space temperature variation and greater comfort during mild weather conditions when full heat output is not required. Two-stage control is used frequently for zoning applications. Fuel savings with two-stage firing rate systems may not be realized unless both the fuel and the combustion air are controlled.

The **fan control switch** controls the circulating air blower. This switch may be temperature-sensitive and exposed to the circulating airstream in the furnace cabinet, or it may be an electronically operated relay. Blower start-up is typically delayed about 1 min after burner start-up. This delay gives the heat exchangers time to warm up and reduces the flow of cold air when the blower comes on. Blower shutdown is also delayed several minutes after burner shutdown to remove residual heat from the heat exchangers and to improve the annual efficiency of the furnace. Constant blower operation throughout the heating season is sometimes used to improve air circulation; however, this increases fan motor energy consumption, duct conductive losses, and air distribution system air leakage losses. Electronic motors that provide continuous but variable airflow use less energy. Both strategies may be considered when air filtering performance is important.

The **limit switch** prevents overheating in the event of severe reduction in circulating airflow. This temperature-sensitive switch is exposed to the circulating airstream and shuts off the heat source (e.g., gas valve or electric element) if the temperature of air leaving the furnace is excessive. The fan control and limit switches are sometimes incorporated in the same housing and may be operated by the same thermostatic element. In the United States, the **blocked-vent shutoff switch** and **flame rollout switch** have been required on residential furnaces produced since November 1989; they shut off the gas valve if the vent is blocked or when insufficient combustion air is present.

Furnaces using fan-assisted combustion feature a **pressure switch** to verify the flow of combustion air before opening the gas valve.

Electronic control systems are available in furnaces to provide sequencing of the inducer prepurge, ignition, circulating air blower operation, and inducer postpurge functions according to an algorithm provided by the manufacturer.

5. EQUIPMENT SELECTION

Many options are available to consumers, and careful planning is needed when selecting equipment. Some decisions can be very basic, whereas others may require research into the various kinds of equipment and features that are available. Several selection considerations are presented here.

Distribution System

A fundamental question in the selection process is whether the space to be heated uses a circulating forced-air system or a hydronic system. These two types of systems are vastly different with respect to equipment selection. For hydronic systems, refer to Chapter 36.

Forced-air systems vary widely. A forced-air distribution system typically has a central air duct, with branches feeding air to numerous supply registers. The duct branches are designed to proportion the air to the different spaces in the building, so that temperatures are best managed by a central thermostat location. Some systems are zoned, with different thermostat sensors; in these systems, dampers with electrical motors are placed at strategic branches of the distribution system and are opened or closed according to each zone's demand for heat. Choosing a zoned system affects the type of equipment selected. Chapter 10 discusses the overall design configuration and efficiency of forced-air systems.

Equipment Location

Furnaces can be installed inside or outside a building. For ideal air distribution, locate the unit in the center of the structure being heated. Furnaces are typically located in a closet, mechanical room, basement, attic, crawlspace, garage, or outdoors. As minimum efficiency levels have increased for residential air-conditioning systems, evaporator coils have increased in height to accommodate additional coil surface area. Compact furnaces have been introduced that allow the evaporator coil and furnace system combination to be installed as a replacement without structural modification in some cases. For installations that cannot be accommodated by the more compact furnace designs, the furnace and evaporator coil are more often located in attic or garage spaces.

Installation locations are characterized as either indoors, outdoors (weatherized), or isolated combustion systems (ICS). **Indoor** furnaces are installed in the heated structure, such as in a basement that is connected to the internal living space, in a utility room, or in a closet. In these locations, air that directly surrounds the furnace is in communication with the air of the heated space. Heat that is lost from the cabinet and adjacent ducts by conduction or air leakage is largely recaptured, helping to preserve furnace efficiency. Some furnaces use combustion air from inside the building. In these applications, room air is used for combustion and exhausted to the outdoors. Additionally, dilution air is also drawn from the room. Combustion/dilution makeup air is provided to the combustion appliance zone by infiltration or by a duct designed specifically to provide makeup air, as required by installation codes.

Furnaces located **outside** the conditioned space (e.g., crawlspace, attic, garage, outdoors) regain little or none of the conductive or air leakage energy losses. Outdoor installations require furnaces to be qualified as weatherized. Outdoor installation locations are on rooftops, platforms, or on a pad adjacent to the heated structure. Ducts for supply and return air connections may also be exposed to the elements and should be weatherized appropriately or moved inside to the conditioned space.

Isolated combustion systems (ICS) are within the structure being heated, but the air that directly surrounds the furnace does not communicate with the heated space. Air needed for combustion and ventilation is admitted through grille openings or ducts (NFPA *Standard* 54). Heat given off from the casing is not considered usable heat, and is subtracted from the furnace efficiency. Typical ICS locations include garages, attics, crawlspaces, and closets that are directly ventilated to the outdoors. These furnaces are protected from the elements (but not temperature) by the surrounding structure.

Forced-Air System Primary Use

Forced-air systems have many benefits, the most significant of which is that they can be used for both heating and cooling without needing separate duct systems and separate air-handling units. A primary function of the furnace is to circulate air through the forced-air distribution system.

Heating the air is an inherent function of a furnace. Cooling is typically a modular add-on, although some furnaces are included as a part of a packaged furnace-and-air-conditioner combination appliance. Forced-air systems also make it possible to add humidifiers and air filters or purifiers. In some cases, forced-air systems can also be connected to an additional appliance to bring clean air from the outdoors through air-to-air energy recovery heat exchangers. Proposed central-fan-integrated ventilation systems would use the furnace blower to pull in and distribute a controlled amount of outdoor air.

Air distribution system design must take into account all the system's intended functions. The air-handling capacity must be designed to meet the demand of the highest airflow and static pressure needs. Typically, the airflow needed for heating is less than that needed for cooling. Manufacturers provide information on furnace performance capabilities, including how much airflow it can deliver at different static pressures. Furnace specification data typically describe the gas input for heating and the airflow (or cooling capacity) for which the unit is designed.

Fuel Selection

The type of fuel selected for heating is based on relative fuel cost, number of heating degree-days, and availability of utilities in the area. The most common fuel is natural gas because of its clean burning characteristics, and because of the continuous supply of this fuel through underground distribution networks to most urban settings. Propane and oil fuels are also commonly used. These fuels require on-site storage and periodic fuel deliveries. Electric heat is also continuously available through electrical power grids and is common especially where natural gas is not provided, or where the heating demand is small relative to the cooling demand.

Furnaces are clearly marked for the type of fuel to be used. In some cases, a manufacturer-approved conversion kit may be necessary to convert a furnace from one fuel type to another. If the fuel type is changed after the original installation, the conversion must be done by a qualified service person per the manufacturer's instructions and using the manufacturer's specified conversion kit. After conversion, the unit must be properly inspected by the local code authority.

Combustion Air and Venting

All fuel-burning furnaces must be properly vented to the outdoors. Metal vents, masonry chimneys, and plastic vents are commonly used for furnaces. Manufacturers provide installation instructions for venting their furnaces, and Chapter 35 has a detailed discussion on venting.

Air for combustion enters the combustion zone through louvers or pipes. Outdoor air usually has lower levels of pollutants than are

typically found in air from indoors, garages, utility rooms, and basements. If the furnace is not exposed to pollutants, the heat exchanger material will have a long life.

Equipment Sizing

The furnace's heating capacity (i.e., the maximum heating rate the furnace can provide) is provided on the appliance rating plate; it is also available through the Air-Conditioning, Heating, and Refrigeration Institute directories (AHRI 2016) and manufacturers' product literature. The heating load for the intended space must be determined; variables that must be considered when calculating space load include heat gains or losses through walls, floors, and ceiling; infiltration; fenestration; ventilation; internal loads; and humidification. Chapters 17 to 19 in the 2021 *ASHRAE Handbook—Fundamentals* provide the information necessary to determine residential and nonresidential heating loads.

Other factors should be considered when determining furnace capacity. Thermostat setback recovery may require additional heating capacity. On the other hand, supplemental heat sources or off-peak storage devices may offset some of the peak demand capacity. Increasing furnace capacity may increase space temperature swing, and thus reduce comfort. Two-stage or step-modulating equipment could help by using the unit's maximum capacity to meet the setback recovery needs, and providing a lower stage of heating capacity at other times.

If cooling is included, the cooling load must be considered, especially in climates that have substantial cooling loads but minimal heating loads. When a large cooling load necessitates a large airflow rate, heating capacity may be greater than necessary. Two-stage or modulating heating may be a suitable alternative to reduce the potentially large temperature swings that can occur with excessively oversized furnaces.

Types of Furnaces

Fuel-burning furnaces are typically subdivided into two primary categories: noncondensing and condensing. **Condensing** furnaces typically have high efficiencies, ranging from 89 to 98%, because they have a specially designed secondary heat exchanger that extracts the heat of vaporization of water vapor in the exhaust. Such heat exchangers may collect soot in small passages if the burners are not set up properly for the heating value of the gas used. The dew-point temperatures of flue gases of condensing furnaces are significantly above the vent temperature, so plastic or other corrosion-resistant venting material is required. Condensing furnaces must be plumbed for condensate disposal. Provisions must be taken to prevent the condensate trap and drain line from freezing if installed in a location that is likely to be below freezing at some point in the year.

Noncondensing furnaces have generally less than 82% steady-state efficiency. This type of furnace has higher flue gas temperatures and requires either metal, masonry, or a combination of the two for venting materials. Because there is no water management, noncondensing furnaces do not need freeze protection.

Consumer Considerations

Safety and Reliability. Gas furnaces sold in North America are tested and certified to ANSI *Standard* Z21.47/CSA 2.3 requirements. Oil furnaces are tested in accordance with UL *Standard* 727, and oil burners in accordance with UL *Standard* 296. These standards are intended to ensure that consumer safety and product reliability are maintained in appliance design. Because of open-flame combustion, the following safety items need to be considered: (1) the surrounding atmosphere should be free of dust or chemical concentrations; (2) a path for combustion air must be provided for both sealed and open combustion chambers; and (3) the gas piping and vent pipes must be installed according to the NFPA/AGA *National Fuel Gas Code* (NFPA *Standard* 54), local codes, and the manufacturer's instructions. For electric furnaces, safety primarily concerns proper wiring techniques. Wiring should comply with the *National Electrical Code*® (NEC) (NFPA *Standard* 70) and applicable local codes.

Efficiency, Operating, and Life-Cycle Costs. Annual operating costs of furnaces must take into account both the cost of the heating fuel as well as the electrical efficiency of the blower motor. Life-cycle cost determination includes initial cost, maintenance, energy consumption, design life, and price escalation of the fuel. Annual fuel utilization efficiency (AFUE) and energy consumption data to help calculate the annual cost for heating a building are available in the AHRI (2016) directory. AFUE and fuel cost are primary drivers in the operating cost. Electric furnaces are listed as nearly 100% AFUE (site-based) because all of the electrical energy is converted into heat, and the only inefficiency is from cabinet conduction and air leakage losses.

Cabinet leakage can affect energy consumption and indoor air quality when furnaces are installed outside the conditioned living space, especially when the home and distribution system are otherwise of tight construction. Air leakage should be taken into account during system design and location. Care should also be taken to install equipment according to the manufacturer's instructions, and that gaps are not overlooked by the installer where service entries or attachments are made to the cabinet. The *ENERGY STAR*® qualification specifications for furnaces require that cabinet leakage be less than or equal to 2% of the maximum airflow, measured according to ANSI/ASHRAE *Standard* 193-2010.

Design Life. Typically, heat exchangers made of aluminized steel have a design life of approximately 15 years. Some furnaces now have a 20 year warranty, or even a "lifetime" warranty on the heat exchanger.

The design life of electric furnaces depends on the durability of the contactors and heating elements. The typical design life is approximately 15 years.

Comfort. Consumer opinions of comfort vary quite a bit. Thermal comfort is affected by supply air temperature, air velocity leaving the supply registers, and proximity of the supply airflow stream to occupants. Complaints of draftiness are common when delivered supply air temperatures are low and register velocities are high. A common solution is to reduce the blower speed to get more temperature rise, while staying within the rated temperature rise range listed on the rating plate. However, reducing blower speed can lead to distribution problems. System design, including register selection and placement, should take these issues into account to avoid comfort problems.

Large temperature swings may also cause discomfort. Factors that affect temperature swing include oversizing, thermostat cycling characteristics related to the number of cycles per hour, and thermostatic control. Two-stage or step-modulated heating can improve comfort by reducing the wide, variable temperature swings. These control schemes reduce furnace capacity through gas and blower modulation, which reduces the amount of oversizing for the current demand.

Comfort can also be affected by the indoor air quality. Adding air filters with high minimum efficiency reporting value (MERV; see ASHRAE *Standard* 52.2) ratings reduces airborne particulate matter and allergens. Winter months typically cause drier indoor air conditions, which can be offset by adding duct-integrated humidifiers. Both filters and humidifiers affect duct resistance, which in turn affects electrical energy consumption, and therefore must be considered in system design.

Sound level can be classified as a comfort consideration. Chapter 49 of the 2023 *ASHRAE Handbook—HVAC Applications* outlines procedures for determining acceptable noise levels.

Many options are available to increase comfort or economy. To manage comfort and cost of operation, a fuel-burning furnace can be combined with a heat pump; this takes advantage of the heat pump's relatively high efficiency during mild weather, and switches to fuel heating when outdoor temperatures drop and it becomes more difficult for heat pumps to meet the demand. To reduce peak demand for energy, off-peak storage devices may be used to decrease the required capacity of the furnace. The storage device can supply the additional capacity required during the morning recovery of a night setback cycle or reduce the daily peak loads to help in load shedding. Detailed calculations can determine the contribution of storage devices.

Selecting Furnaces for Commercial Buildings

The procedure for design and selection of a commercial furnace is similar to that for a residential furnace. First, the design capacity of the heating system must be determined, considering heat loss from the structure, recovery load, internal heat sources, humidification, off-peak storage, waste heat recovery, and back-up capacity. Because most commercial buildings use setback during weekends, evenings, or other long periods of inactivity, the recovery load is important, as are internal loads and waste heat recovery. The furnace should be sized according to the load per ACCA (2004).

Efficiency of commercial units is about the same as for noncondensing residential units. Two-stage gas valves are frequently used with commercial furnaces, but the efficiency of a two-stage system may be lower than for a single-stage system. At a reduced firing rate, excess combustion airflow through the burners increases, decreasing the steady-state operating efficiency of the furnace. Multistage furnaces with multistage thermostats and controls may be used to more appropriately match load conditions.

The design life of commercial heating and cooling equipment is about 20 years. Most gas furnace heat exchangers are either coated steel or stainless steel. Because most commercial furnaces are made for outdoor application, the cabinets are made from corrosion-resistant coated steel (e.g., galvanized or aluminized). Blowers can be direct- or belt-driven and can deliver air at higher static pressure.

The noise level of commercial heating equipment is important in some applications, such as schools, office buildings, churches, and theaters. Unit heaters, for example, are used primarily in industrial applications where noise is less important. Duct design can greatly affect noise levels.

In many jurisdictions, safety requirements are the same for light commercial systems and residential systems. Above 117 kW gas input, ANSI *Standard* Z21.47/CSA 2.3 requirements for gas controls are more stringent.

6. CALCULATIONS

Performance Criteria. Residential furnaces and boilers manufactured and distributed in commerce, as defined by 42 U.S.C. 6291 (16), must meet the energy conservation standards specified in the *Code of Federal Regulations*, 10 CFR 430.32(e)(1)(i) and (e)(2)(i). This information is also available in the Electronic Code of Federal Regulations, and is published in the AHRI (2016) directories. To calculate the furnace's rated heating capacity, the steady-state efficiency must be determined. In the United States, manufacturers may publish only the AFUE as an efficiency measure. The unit capacity is proportional to the steady-state efficiency when compared to the fuel input rate.

U.S. federal law requires manufacturers of furnaces to use AFUE as determined using the isolated combustion system method to rate efficiency. Since January 1, 1992, all furnaces produced have a minimum AFUE (ICS) level of 78%. Table 1 gives efficiency values for different furnaces.

Table 1 Historical and Typical Values of Efficiency

	AFUE, %	
Type of Gas Furnace	**Indoor**	**ICS[a]**
1. Natural-draft with standing pilot	64.5	63.9[b]
2. Natural-draft with intermittent ignition	69.0	68.5[b]
3. Natural-draft with intermittent ignition and auto vent damper	78.0	68.5[b]
4. Fan-assisted combustion with standing pilot or intermittent ignition	80.0	78.0
5. Same as 4, except with improved heat transfer	82.0	80.0
6. Direct vent, natural-draft with standing pilot, preheat	66.0	64.5[b]
7. Direct vent, fan-assisted combustion, and intermittent ignition	80.0	78.0
8. Fan-assisted combustion (induced-draft)	80.0	78.0
9. Condensing	90.0	88.0
Type of Oil Furnace	**Indoor**	**ICS[a]**
1. Standard: pre-1992	71.0	69.0[b]
2. Standard: post-1992	80.0	78.0
3. Same as 2, with improved heat transfer	81.0	79.0
4. Same as 3, with automatic vent damper	82.0	80.0
5. Condensing	91.0	89.0

[a]Isolated combustion system (estimate).
[b]Pre-1992 design (pilot lights and natural draft systems are now obsolete).

7. TECHNICAL DATA

Detailed technical data on furnaces are available from manufacturers, wholesalers, and dealers. The data are generally tabulated in product specification bulletins printed by the manufacturer for each furnace line. These bulletins usually include performance information, electrical data, blower and air delivery data, control system information, optional equipment information, and dimensions.

Natural Gas Furnaces

Capacity Ratings. ANSI *Standard* Z21.47/CSA 2.3 requires that the heating capacity be marked on the rating plates of commercial furnaces in the United States. The heating capacity of residential furnaces, less than 65 kW input, is required by the Federal Trade Commission and can be found in furnace directories provided by AHRI at www.ahridirectory.org. Capacity is calculated by multiplying the input by the steady-state efficiency.

Residential gas furnaces with heating capacities ranging from 10 to 50 kW are readily available. Some smaller furnaces are manufactured for special-purpose installations such as mobile homes. Smaller-capacity furnaces are becoming common because new homes are better insulated and have lower heat loads than older homes. Larger furnaces are also available, but these are generally considered for commercial use.

Because of the overwhelming popularity of the upflow furnace, or multiposition including upflow, it is available in the greatest number of models and sizes. Downflow furnaces, dedicated horizontal furnaces, and various combinations are also available but are generally limited in model type and size.

Residential gas furnaces can be installed as heating-only systems or as part of a heat/cool system. The difference is that, in the heat/cool system, the furnace operates as the air-handling section of a split-system air conditioner. Heating-only systems typically operate with enough airflow to yield a 22 to 40 K air temperature rise through the furnace. Condensing furnaces may be designed for a lower temperature rise (as low as 20 K).

Furnaces have blowers capable of multiple speeds. When the furnace is used as the air handler for a cooling system, the blower is typically capable of delivering about 55 L/s per kilowatt of air conditioning. Furnaces are generally available to accommodate 5 to 18 kW air conditioners. The blower speed for each mode of opera-

tion should be selected to provide the required airflow for both heating and cooling operation. Controls of furnaces used in a heat/cool system can be installed to operated the multispeed blower motor at the most appropriate speed for either heating or cooling when airflow requirements vary for each mode.

Efficiency Ratings. Currently, gas furnaces have steady-state efficiencies that vary from about 78 to 98%. Natural-draft and fan-assisted combustion furnaces typically range from 78 to 80% efficiency, whereas condensing furnaces have over 90% steady-state efficiency.

Propane Furnaces

Most residential natural gas furnaces are also available in a propane version with identical ratings. The technical data for these two furnaces are identical, except for gas control and burner and pilot orifice sizes. Orifice sizes on propane furnaces are much smaller because propane has a higher density and may be supplied at a higher manifold pressure. The heating value and relative density of typical gases are listed as follows:

Gas Type	Heating Value, MJ/m^3	Relative Density (Air = 1.0)
Natural	38.4	0.60
Propane	93.1	1.53
Butane	118.3	2.00

As in natural gas furnaces, the ignition systems have a required pilot gas shutoff feature in case the pilot ignition fails. Pilot gas leakage is more critical with propane or butane gas because both are heavier than air and can accumulate to create an explosive mixture in the furnace or furnace enclosure.

Besides natural and propane, a furnace may be certified for manufactured gas, mixed gas, or propane/air mixtures; however, furnaces with these certifications are not commonly available. Mobile home furnaces are certified as convertible from natural gas to propane.

Oil Furnaces

Oil furnaces are similar to gas furnaces in size, shape, and function, but the heat exchanger, burner, and combustion control are significantly different.

Input ratings are based on oil flow rate (L/s), and heating capacity is calculated by the same method as that for gas furnaces. The typical heating value of oil is 39 MJ/L. Fewer models and sizes are available for oil than are available for gas, but residential furnaces in the range of 19 to 44 kW heating capacity are common. Air delivery ratings are similar to gas furnaces.

The efficiency of an oil furnace can drop during normal operation if the burner is not maintained and kept clean. In this case, the oil does not atomize sufficiently to allow complete combustion, and energy is lost up the chimney in the form of unburned hydrocarbons. Because most oil furnaces use power burners and electric ignition, the annual efficiency is relatively high.

Oil furnaces are available in upflow, downflow, and horizontal models. The thermostat, fan control switch, and limit switch are similar to those of a gas furnace. Oil flow is controlled by a pump and burner nozzle, which sprays the oil/air mixture into a single-chamber drum-type heat exchanger. The heat exchangers are normally heavy-gage cold-rolled steel. Humidifiers, electronic air cleaners, and night setback thermostats are available as accessories.

Electric Furnaces

Residential electric resistance furnaces are available in heating capacities of 5 to 35 kW. Electric resistance furnaces are typically part of a heat/cool system and provide the appropriate airflow for both heating and cooling modes.

The only losses associated with an electric resistance furnace are the conductive and air leakage losses in the cabinet. If the furnace is located fully within the heated space, then the seasonal efficiency would be 100%.

Although the efficiency of an electric furnace is high, electricity is generally a relatively expensive form of energy. The operating cost may be reduced substantially by using an electric heat pump in place of a straight electric resistance furnace. Heat pump systems are discussed in Chapter 9.

Electric furnaces are available in upflow, downflow, or horizontal models. Internal controls include overload fuses or circuit breakers, overheat limit switches, a fan control switch, and contactors to bring on the heating elements at timed intervals.

Commercial Furnaces

Furnaces with capacities above 44 kW are classified as commercial furnaces. The 1992 U.S. Energy Policy and Conservation Act (EPCA) prescribes minimum efficiency requirements for commercial furnaces based on ASHRAE *Standard* 90.1. Some efficiency improvement components, such as intermittent ignition devices, are common in commercial furnaces.

8. INSTALLATION

Installation requirements call for a forced-air heating system to meet three basic criteria: (1) the system must be safe, (2) it must provide comfort for the occupants of the conditioned space, and (3) it must be energy efficient. Location of equipment and ducts, materials selected for the distribution system, and installation practices all affect the total system efficiency. Conduction and air leakage losses can result in substantial energy and system performance degradation and deserve special attention. For maximum safety, comfort, and efficiency, proper treatment of distribution system air leakage is necessary. A few significant considerations for installing furnaces are discussed here; for additional issues, see Chapter 10.

Generally, the following three categories of installation guidelines must be followed to ensure the safe operation of a heating system: (1) the equipment manufacturer's installation instructions, (2) local installation code requirements, and (3) national installation code requirements. Local code requirements may or may not be available, but the other two are always available. Depending on the type of fuel being used, one of the following national code requirements apply in the United States:

- NFPA 54 (also AGA Z223.1) — *National Fuel Gas Code*
- NFPA 70 — *National Electrical Code®*
- NFPA 31 — *Standard for the Installation of Oil-Burning Equipment*

Comparable Canadian standards are

- CAN/CSA-B149.1 — *Natural Gas and Propane Installation Code*
- CSA C22.1 — *Canadian Electrical Code*
- CAN/CSA B139 — *Installation Code for Oil Burning Equipment*

An additional source is the *International Fuel Gas Code®* (IFGC®) (ICC 2015). These regulations provide complete information about construction materials, gas line sizes, flue pipe sizes, wiring sizes, and so forth.

Proper design of the air distribution system is necessary for both comfort and safety. Chapter 21 of the 2021 *ASHRAE Handbook—Fundamentals*, Chapter 1 of the 2023 *ASHRAE Handbook—HVAC Applications*, and Chapter 10 of this volume provide information on the design of ductwork for forced-air heating systems. Forced-air furnaces provide design airflow at a static pressure as low as 30 Pa for a residential unit to above 250 Pa for a commercial unit. The air distribution system must handle the required volumetric flow rate within the pressure limits of the equipment. If the system is a combined heating/cooling installation, the air distribution system

must meet the cooling requirement because more air is required for cooling than for heating. It is also important to include the pressure drop of the cooling coil. The Air-Conditioning, Heating, and Refrigeration Institute (AHRI) maximum allowable pressure drop for residential cooling coils is 75 Pa.

Condensing furnaces generate a large amount of relatively low-temperature water. It is important that the exhaust vent be sloped so that water runs back into the furnace. All furnace condensate should go into a drain and not be discharged where it might freeze. If there is not a gravity path to a drain, an adequate-capacity condensate pump is required.

9. AGENCY LISTINGS

Construction and performance of furnaces are regulated by several agencies.

AHRI, in cooperation with its industry members, sponsors a certification program relating to gas- and oil-fired residential furnaces and boilers. This program uses an independent laboratory to verify commercial and residential furnace and boiler manufacturers' certified AFUEs and heating capacities, as determined by testing in accordance with the U.S. DOE's *Uniform Test Method for Measuring the Energy Consumption of Furnaces and Boilers* (Title II, 10 CFR 430, Subpart B, Appendix N). Gas and oil furnaces with input ratings less than 66 kW and gas and oil boilers with input ratings less than 88 kW are currently included in the program.

Also included in the program are the online consumers' directories, which identify certified products and list the input rating, certified heating capacity, and AFUE for each furnace. Participating manufacturers are entitled to use the AHRI certification symbol.

ANSI *Standard* Z21.47/CSA 2.3 (CSA America is secretariat) gives minimum construction, safety, and performance requirements for gas furnaces. The CSA maintains laboratories to certify furnaces and operates a factory inspection service. Furnaces tested and found to be in compliance are listed in the CSA directory and carry the seals of certification. Underwriters Laboratories (UL) and other approved laboratories can also test and certify equipment in accordance with ANSI *Standard* Z21.47/CSA 2.3.

Gas furnaces may be certified for standard, alcove, closet, or outdoor installation. Standard installation requires clearance between the furnace and combustible material of at least 150 mm. Furnaces certified for alcove or closet installation can be installed with reduced clearance, as listed. Furnaces certified for either sidewall venting or outdoor installation must operate properly in a 50 km/h wind. Construction materials must be able to withstand natural elements without degradation of performance and structure. Horizontal furnaces are normally certified for installation on combustible floors and for attic installation and are so marked, in which case they may be installed with point or line contact between the jacket and combustible constructions. Upflow and downflow furnaces are normally certified for alcove or closet installation. Gas furnaces may be listed to burn natural gas, mixed gas, manufactured gas, propane, or propane/air mixtures. A furnace must be equipped and certified for the specific gas to be used because different burners and controls, as well as orifice changes, may be required.

Sometimes oil burners and control packages are sold separately; however, they are normally sold as part of the furnace package. Pressure-type or rotary burners should bear the Underwriters Laboratory label showing compliance with ANSI/UL *Standard* 296. In addition, the complete furnace should bear markings indicating compliance with UL *Standard* 727. Vaporizing burner furnaces should also be listed under UL *Standard* 727.

UL *Standard* 1995 gives requirements for the listing and labeling of electric furnaces and heat pumps.

The following list summarizes important standards issued by Underwriters Laboratories, the Canadian Gas Association, and the Canadian Standards Association that apply to space-heating equipment:

ANSI/ASHRAE 103	Method of Testing for Annual Fuel Utilization Efficiency of Residential Central Furnaces and Boilers
ANSI Z21.66/CGA 6.14	Automatic Vent Damper Devices for Use with Gas-Fired Appliances
ANSI Z83.4/CSA 3.7	Non-Recirculating Direct Gas-Fired Industrial Air Heaters

Stoves 34.5
GENERAL INSTALLATION PRACTICES 34.6

IN-SPACE heating equipment differs from central heating in that fuel is converted to heat in the space to be heated. In-space heaters may be either permanently installed or portable and may transfer heat by a combination of radiation, natural convection, and forced convection. The energy source may be liquid, solid, gaseous, or electric.

1. GAS IN-SPACE HEATERS

Room Heaters

A **vented circulator room heater** is a self-contained, freestanding, nonrecessed gas-burning appliance that furnishes warm air directly to the space in which it is installed, without ducting (Figure 1). It converts the energy in the fuel gas to convected and radiant heat without mixing flue gases and circulating heated air by transferring heat from flue gases to a heat exchanger surface.

A **vented radiant circulator** is equipped with high-temperature glass panels and radiating surfaces to increase radiant heat transfer. Separation of flue gases from circulating air must be maintained. Vented radiant circulators range from 3 to 22 kW.

Gravity-vented radiant circulators may also have a circulating air fan, but they perform satisfactorily with or without the fan. Fan-type vented radiant circulators are equipped with an integral circulating air fan, which is necessary for satisfactory performance.

Vented room heaters are connected to a vent, chimney, or single-wall metal pipe venting system engineered and constructed to develop a positive flow to the outdoor atmosphere. Room heaters should not be used in a room that has limited air exchange with adjacent spaces because combustion air is drawn from the space.

Unvented radiant or **convection heaters** range in size from 3 to 12 kW and can be freestanding units or wall-mounted, nonrecessed units of either the radiant or closed-front type. Unvented room heaters require an outdoor air intake. The size of the fresh air opening required is marked on the heater. To ensure adequate fresh air supply, unvented gas-heating equipment must, according to voluntary standards, include a device that shuts the heater off if the oxygen in the room becomes inadequate. Unvented room heaters may not be installed in hotels, motels, or rooms of institutions such as hospitals or nursing homes.

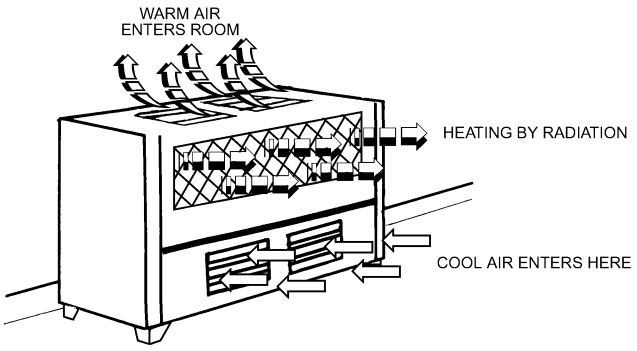

Fig. 1 Room Heater

Catalytic room heaters are fitted with fibrous material impregnated with a catalytic substance that accelerates the oxidation of a gaseous fuel to produce heat without flames. The design distributes the fuel throughout the fibrous material so that oxidation occurs on the surface area in the presence of a catalyst and room air. Catalytic heaters transfer heat by low-temperature radiation and by convection. The surface temperature is below a red heat and is generally below 650°C at the maximum fuel input rate. The flameless combustion of catalytic heaters is an inherent safety feature not offered by conventional flame-type gas-fueled burners. Catalytic heaters have also been used in agriculture and for industrial applications in combustible atmospheres.

Unvented household catalytic heaters are used in Europe. Most of these are portable and mounted on casters in a casing that includes a cylinder of liquefied petroleum gas (LPG) so that they may be rolled from one room to another. LPG cylinders holding more than 0.9 kg of fuel are not permitted for indoor use in the United States. As a result, catalytic room heaters sold in the United States are generally permanently installed and fixed as wall-mounted units. Local codes and the *National Fuel Gas Code* (NFPA 54/ANSI Z223.1) should be reviewed for accepted combustion air requirements.

Wall Furnaces

A wall furnace is a self-contained vented appliance with grilles that are designed to be a permanent part of the structure of a building (Figure 2). It furnishes heated air that is circulated by natural or forced convection. A wall furnace can have boots, which may not extend more than 250 mm beyond the horizontal limits of the casing through walls of normal thickness, to provide heat to adjacent rooms. Wall furnaces range from 3 to 26 kW. Wall furnaces are classified as conventional or direct vent.

Conventional vent units require approved B-1 vent pipes and are installed to comply with the *National Fuel Gas Code*. Some wall furnaces are counterflow units that use fans to reverse the natural flow of air across the heat exchanger. Air enters at the top of the furnace and discharges at or near the floor. Counterflow systems reduce heat stratification in a room. As with any vented unit, a minimum of inlet air for proper combustion must be supplied.

Vented-recessed wall furnaces are recessed into the wall, with only the decorative grillwork extending into the room. This leaves more usable area in the room being heated. Dual-wall furnaces are two units that fit between the studs of adjacent rooms, thereby using a common vent.

Both vented-recessed and dual-wall furnaces are usually natural convection units. Cool room air enters at the bottom and is warmed

The preparation of this chapter is assigned to TC 6.5, Radiant Heating and Cooling.

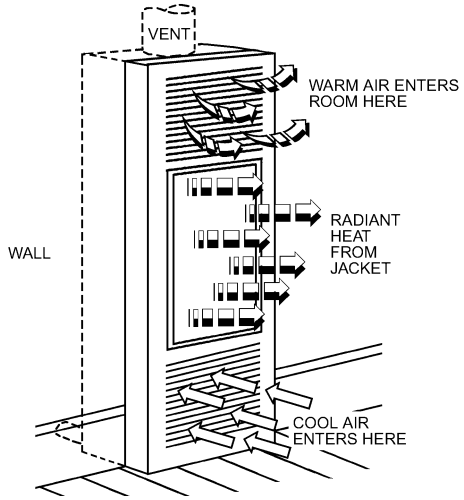

Fig. 2 Wall Furnace

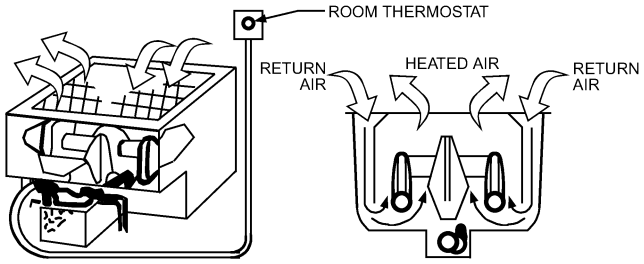

Fig. 3 Floor Furnace

as it passes over the heat exchanger, entering the room through the grillwork at the top of the heater. This process continues as long as the thermostat calls for the burners to be on. Accessory fans assist in the movement of air across the heat exchanger and help minimize air stratification.

Direct-vent wall furnaces are constructed so that combustion air comes from the outdoors, and all flue gases discharge into the outdoor atmosphere. These appliances include grilles or the equivalent and are designed to be attached to the structure permanently. Direct-vent wall heaters are normally mounted on walls with outdoor exposure.

Direct-vent wall furnaces can be used in extremely tight (well-insulated) rooms because combustion air is drawn from outside the room. There are no infiltration losses for dilution or combustion air. Most direct-vent heaters are designed for natural convection, although some may be equipped with fans. Direct-vent furnaces are available with inputs of 2 to 19 kW.

Floor Furnaces

Floor furnaces are self-contained units suspended from the floor of the heated space (Figure 3). Combustion air is taken from the outdoors, and flue gases are also vented outdoors. Cold air returns at the periphery of the floor register, and warm air comes up to the room through the center of the register.

U.S. Minimum Efficiency Requirements

The National Appliance Energy Conservation Act (NAECA) of 1987 mandates that the U.S. Department of Energy establish minimum annual fuel utilization efficiency (AFUE) requirements for gas-fired direct heating equipment. The first minimums were established on January 1, 1990, and were most recently updated on April 16, 2013 (Table 1).The AFUE is measured using the U.S. Department of Energy test method (DOE 2015) and must be met by manufacturers of direct heating equipment (i.e., gas-fired room heaters, wall furnaces, and floor furnaces).

Table 1 Efficiency Requirements in the United States for Gas-Fired Direct Heating Equipment

Input, kW	Minimum AFUE, %	Input, kW	Minimum AFUE, %
Wall Furnace (with fan)		*Floor Furnace*	
≤12.3	75	≤10.8	57
>12.3	76	>10.8	58
Wall Furnace (gravity type)			
≤7.9	65	*Room Heaters*	
>7.9 to 13.5	66	≤5.9	61
>13.5	67	>5.9 to 7.9	66
		>7.9 to 13	67
		>13.5	68

1.1 CONTROLS

Valves

Gas in-space heaters are controlled by four types of valves:

The full on/off, **single-stage valve** is controlled by a wall thermostat. Models are available that are powered by a 24 V supply or from energy supplied by the heat of the pilot light on the thermocouple (self-generating).

The **two-stage control valve** (with hydraulic thermostat) fires either at full input (100% of rating) or at some reduced step, which can be as low as 20% of the heating rate. The amount of time at the reduced firing rate depends on the heating load and the relative oversizing of the heater.

The **step-modulating control valve** (with a hydraulic thermostat) steps on to a low fire and then either cycles off and on at the low fire (if the heating load is light) or gradually increases its heat output to meet any higher heating load that cannot be met with the low firing rate. This control allows an infinite number of fuel firing rates between low and high fire.

The **manual control valve** is controlled by the user rather than by a thermostat. The user adjusts the fuel flow and thus the level of fire to suit heating requirements.

Thermostats

Temperature controls for gas in-space heaters are of the following two types.

- **Wall thermostats** are available in 24 V and millivolt systems. The 24 V unit requires an external power source and a 24 V transformer. Wall thermostats respond to temperature changes and turn the automatic valve to either full-on or full-off. The millivolt unit requires no external power because the power is generated by multiple thermocouples and may be either 250 or 750 mV, depending on the distance to the thermostat. This thermostat also turns the automatic valve to either full-on or full-off.
- **Built-in hydraulic thermostats** are available in two types: (1) a snap-action unit with a liquid-filled capillary tube that responds to changes in temperature and turns the valve to either full-on or full-off; and (2) a modulating thermostat, which is similar to the snap-action unit, except that the valve comes on and shuts off at a preset minimum input. Temperature alters the input anywhere from full-on to the minimum input. When the heating requirements are satisfied, the unit shuts off.

Table 2 Gas Input Required for In-Space Supplemental Heaters

Heater Type	Average AFUE, %	Steady State Efficiency, %	Gas Consumption per Unit House Volume, W/m³					
			Outdoor Air Temperature, °C					
			Older Bungalow[a]			Energy-Efficient House[b]		
			–15	0	10	–15	0	10
Vented	54.6	73.1	67.1	36.9	16.8	28.6	15.7	7.1
Unvented	90.5	90.5	61.7	33.9	15.4	26.3	14.4	6.6
Direct vent	76.0	78.2	60.7	33.4	15.2	21.1	11.6	5.3

[a]Tested bungalow total heated volume = 193.3 m³ and $U \approx 1.7$ to 2.8 W/(m²·K).
[b]Tested energy-efficient house total heated volume = 333.7 m³ and $U \approx 1.1$ to 1.7 W/(m²·K).

1.2 VENT CONNECTORS

Any vented gas-fired appliance must be installed correctly to vent combustion products. A detailed description of proper venting techniques is found in the *National Fuel Gas Code* and Chapter 35.

1.3 SIZING UNITS

The size of the unit selected depends on the size of the room, the number and direction of exposures, the amount of insulation in the ceilings and walls, and the geographical location. Heat loss requirements can be calculated from procedures described in Chapter 17 of the 2021 *ASHRAE Handbook—Fundamentals*.

DeWerth and Loria (1989) studied the use of gas-fired, in-space supplemental heaters in two test houses. They proposed a heater sizing guide, which is summarized in Table 2. The energy consumption in Table 2 is for unvented, vented, and direct vent heaters installed in (1) a bungalow built in the 1950s with average insulation, and (2) a townhouse built in 1984 with above-average insulation and tightness.

2. OIL AND KEROSENE IN-SPACE HEATERS

Vaporizing Oil Pot Heaters

These heaters have an oil-vaporizing bowl (or other receptacle) that admits liquid fuel and air in controllable quantities; the fuel is vaporized by the heat of combustion and mixed with the air in appropriate proportions. Combustion air may be induced by natural draft or forced into the vaporizing bowl by a fan. Indoor air is generally used for combustion and draft dilution. Window-installed units have the burner section outdoors. Both natural- and forced-convection heating units are available. A small blower is sold as an option on some models. The heat exchanger, usually cylindrical, is made of steel (Figure 4). These heaters are available as room units (both radiant and circulation), floor furnaces, and recessed wall heaters. They may also be installed in a window, depending on the cabinet construction. The heater is always vented to the outdoors. An 11 to 19 L fuel tank may be attached to the heater, or a larger outdoor tank can be used.

Vaporizing pot burners are equipped with a single constant-level and metering valve. Fuel flows by gravity to the burner through the adjustable metering valve. Control can be manual, with an off pilot and variable settings up to maximum, or it can be thermostatically controlled, with the burner operating at a selected firing rate between pilot and high.

Powered Atomizing Heaters

Wall furnaces, floor furnaces, and freestanding room heaters are also available with a powered gun-type burner using No. 1 or No. 2 fuel oil. For more information, refer to Chapter 31.

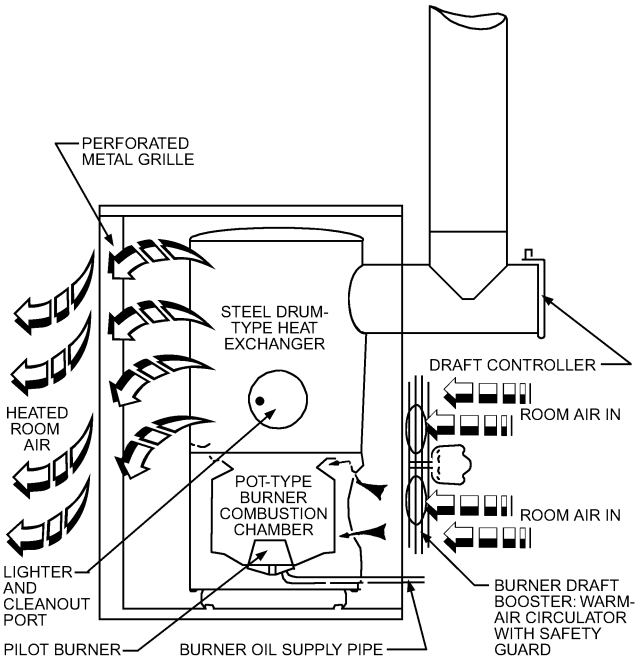

Fig. 4 Oil-Fueled Heater with Vaporizing Pot-Type Burner

Portable Kerosene Heaters

Because kerosene heaters are not normally vented, precautions must be taken to provide sufficient ventilation. Kerosene heaters are of four basic types: radiant, natural-convection, direct-fired, forced-convection, and catalytic.

The radiant kerosene heater has a reflector, while the natural convection heater is cylindrical in shape. Fuel vaporizes from the surface of a wick, which is immersed in an integral fuel tank of up to 7.6 L capacity similar to that of a kerosene lamp. Fuel-burning rates range from about 1.5 to 6.5 kW. Radiant heaters usually have a removable fuel tank to facilitate refueling.

The direct-fired, forced-convection portable kerosene heater has a vaporizing burner and a heat-circulating fan. These heaters are available with thermostatic control and variable heat output.

The catalytic type uses a metal catalyst to oxidize the fuel. It is started by lighting kerosene at the surface; however, after a few moments, the catalyst surface heats to the point that flameless oxidation of the fuel begins.

3. ELECTRIC IN-SPACE HEATERS

Wall, Floor, Toe Space, and Ceiling Heaters

Heaters for recessed or surface wall mounting are made with open wire or enclosed, metal-sheathed elements. An inner liner or reflector is usually placed between the elements and the casing to promote circulation and minimize the rear casing temperature. Heat is distributed by both convection and radiation; the proportion of each depends on unit construction.

Ratings are usually 1000 to 5000 W at 120, 208, 240, or 277 V. Models with air circulation fans are available. Other types can be recessed into the floor. Electric convectors should be placed so that air moves freely across the elements.

Baseboard Heaters

These heaters consist of a metal cabinet containing one or more horizontal, enclosed, metal-sheathed elements. The cabinet is less than 150 mm in overall depth and can be installed 460 mm above the

floor; the ratio of the overall length to the overall height is more than two to one.

Units are available from 610 to 3700 mm in length, with ratings from 300 to 1300 W/m, and they fit together to make up any desired continuous length or rating. Electric hydronic baseboard heaters containing immersion heating elements and an antifreeze solution are made with ratings of 300 to 2000 W. The placement of any type of electric baseboard heater follows the same principles that apply to baseboard installations (see Chapter 36) because baseboard heating is primarily perimeter heating.

3.1 RADIANT HEATING SYSTEMS

Heating Panels and Heating Panel Sets

These systems have electric resistance wire or etched or graphite elements embedded between two layers of insulation. High-density thermal insulation behind the element minimizes heat loss, and the outer shell is formed steel with baked enamel finish. Heating panels provide supplementary heating by convection and radiation. They can be recessed into or surface mounted on hard surfaces or fit in standard T-bar suspended ceilings.

Units are usually rated between 250 and 1000 W in sizes varying from 610 by 610 mm to 610 by 2440 mm in standard voltages of 120, 208, 240, and 277 V.

Embedded Cable and Storage Heating Systems

Ceiling and floor electric radiant heating systems that incorporate embedded cables are covered in Chapter 6. Electric storage systems, including room storage heaters and floor slab systems, are covered in Chapter 50.

Cord-Connected Portable Heaters

Portable electric heaters are often used in areas that are not accessible to central heat. They are also used to maintain an occupied room at a comfortable level independent of the rest of the residence.

Portable electric heaters for connection to 120 V, 15 A outlets are available with outputs of 600 to 1500 W, the most common being 1320 and 1500 W. Many heaters are available with a selector switch for three wattages (e.g., 1100-1250-1500 W). Heavy-duty heaters are usually connected to 240 V, 20 A outlets with outputs up to 4000 W, whereas those for connection to 240 V, 30 A outlets have outputs up to 5600 W. All electric heaters of the same wattage produce the same amount of heat.

Portable electric heaters transfer heat by one of two predominant methods: radiation and convection. Radiant heaters provide heat for people or objects. An element in front of a reflector radiates heat outward in a direct line. Conventional radiant heaters have ribbon or wire elements. Quartz radiant heaters have coil wire elements encased in quartz tubes. The temperature of a radiant wire element usually ranges between 650 and 870°C.

Convection heaters warm the air in rooms or zones. Air flows directly over the hot elements and mixes with room air. Convection heaters are available with or without fans. The temperature of a convection element is usually less than 500°C.

An adjustable, built-in bimetal thermostat usually controls the power to portable electric heaters. Fan-forced heaters usually provide better temperature control because the fan, in addition to cooling the case, forces room air past the thermostat. One built-in control uses a thermistor to signal a solid logic circuit that adjusts wattage and fan speed. Most quartz heaters use an adjustable control that operates the heater for a percentage of total cycle time from 0 (off) to 100% (full-on).

Controls

Low-voltage and line-voltage thermostats with on-off operation are used to control in-space electric heaters. Low-voltage thermostats, operating at 30 V or less, control relays or contactors that carry the rated voltage and current load of the heaters. Because the control current load is small (usually less than 1 A), the small switch can be controlled by a highly responsive sensing element.

Line-voltage thermostats carry the full load of the heaters at rated voltage directly through their switch contacts. Most switches carry a listing by Underwriters Laboratories (UL) at 22 A (resistive), 277 V rating. Most electric in-space heating systems are controlled by remote wall-mounted thermostats, but many are available with integral or built-in line-voltage thermostats.

Most low-voltage and line-voltage thermostats use small internal heaters, either fixed or adjustable in heat output, that provide heat anticipation by energizing when the thermostat contacts close. The cycling rate of the thermostat is increased by the use of anticipation heaters, resulting in more accurate control of the space temperature.

Droop is an apparent shift or lowering of the control point and is associated with line-voltage thermostats. In these thermostats, switch heating caused by large currents can add materially to the amount of droop. Most line-voltage thermostats in residential use control room heaters of 3 kW (12.5 A at 240 V) or less. At this moderate load and with properly sized anticipation heaters, the droop experienced is acceptable. Cycling rates and droop characteristics have a significant effect on thermostat performance.

4. SOLID-FUEL IN-SPACE HEATERS

Most wood-burning and coal-burning devices, except central wood-burning furnaces and boilers, are classified as solid-fuel in-space heaters (see Table 3). An in-space heater can be either a fireplace or a stove.

Table 3 Solid-Fuel In-Space Heaters

Type*	Approximate Efficiency,* %	Features	Advantages	Disadvantages
Simple fireplaces, masonry or prefabricated	–10 to +10	Open front. Radiates heat in one direction only.	Aesthetic.	Low efficiency. Heats only small areas.
High-efficiency fireplaces	25 to 45	Freestanding or built-in with glass doors, grates, ducts, and blowers.	Aesthetic. More efficient. Heats larger areas. Long service life. Maximum safety.	Medium efficiency.
Box stoves	20 to 40	Radiates heat in all directions.	Low initial cost. Heats large areas.	Fire hard to control. Short life. Wastes fuel.
Airtight stoves	40 to 55	Radiates heat in all directions. Sealed seams, effective draft control.	Good efficiency. Long burn times, high heat output. Longer service life.	Can create creosote problems.
High-efficiency catalytic wood heaters	65 to 75	Radiates heat in all directions. Sealed seams, effective draft control.	Highest efficiency. Long burn times, high heat output. Long life.	Creosote problems. High purchase price.

*Product categories are general; product efficiencies are approximate.

4.1 FIREPLACES

Simple Fireplaces

Simple fireplaces, especially all-masonry and noncirculating metal built-in fireplaces, produce little useful heat. They lend atmosphere and a sense of coziness to a room. Freestanding fireplaces are slightly better heat producers. Simple fireplaces have an average efficiency of about 10%. In extreme cases, the chimney draws more heated air than the fire produces.

The addition of glass doors to the front of a fireplace has both a positive and a negative effect. The glass doors restrict the free flow of indoor heated air up the chimney, but at the same time they restrict the radiation of the heat from the fire into the room.

Factory-Built Fireplaces

A factory-built fireplace consists of a fire chamber, chimney, roof assembly, and other parts that are factory made and intended to be installed as a unit in the field. These fireplaces have fireboxes of refractory-lined metal rather than masonry. Factory-built fireplaces come in both radiant and heat-circulating designs. Typical configurations are open-front designs, but corner-opening, three-sided units with openings either on the front or side; four-sided units; and see-through fireplaces are also available.

Radiant Design. The radiant system transmits heat energy from the firebox opening by direct radiation to the space in front of it. These fireplaces may also incorporate such features as an outdoor air supply and glass doors. Radiant-design factory-built fireplaces are primarily used for aesthetic wood burning and typically have efficiencies similar to those of masonry fireplaces (0 to 10%).

Heat-Circulating Design. This unit transfers heat by circulating air around the fire chamber and releasing to the space to be heated. The air intake is generally below the firebox or low on the sides adjacent to the opening, and the heated air exits through grilles or louvers located above the firebox or high on the sides adjacent to it. In some designs, ducts direct heated air to spaces other than the area near the front of the fireplace. Some circulating units rely on natural convection, while others have electric fans or blowers to move air. These energy-saving features typically boosts efficiency 25 to 60%.

Freestanding Fireplaces

Freestanding fireplaces are open-combustion wood-burning appliances that are not built into a wall or chase. One type of freestanding fireplace is a fire pit in which the fire is open all around; smoke rises into a hood and then into a chimney. Another type is a prefabricated metal unit that has an opening on one side. Because they radiate heat to all sides, freestanding fireplaces are typically more efficient than radiant fireplaces.

4.2 STOVES

Conventional Wood Stoves

Wood stoves are chimney-connected, solid-fuel-burning room heaters designed to be operated with the fire chamber closed. They deliver heat directly to the space in which they are located. They are not designed to accept ducts and/or pipes for heat distribution to other spaces. Wood stoves are controlled-combustion appliances. Combustion air enters the firebox through a controllable air inlet; the air supply and thus the combustion rate are controlled by the user. Conventional controlled-combustion wood stoves manufactured before the mid-1980s typically have overall efficiencies ranging from 40 to 55%.

Most **controlled-combustion** appliances are constructed of steel, cast iron, or a combination of the two metals; others are constructed of soapstone or masonry. Soapstone and masonry have lower thermal conductivities but greater specific heats (the amount of heat that can be stored in a given mass). Other materials such as special refractories and ceramics are used in low-emission appliances. Wood stoves are classified as either radiant or convection (sometimes called circulating) heaters, depending on the way they heat interior spaces.

Radiant wood stoves are generally constructed with single exterior walls, which absorb radiant heat from the fire. This appliance heats primarily by infrared radiation; it heats room air only to the extent that air passes over the hot surface of the appliance.

Convection wood stoves have double vertical walls with an air space between the walls. The double walls are open at the top and bottom of the appliance to permit room air to circulate through the air space. The more buoyant hot air rises and draws in cooler room air at the bottom of the appliance. This air is then heated as it passes over the surface of the inner radiant wall. Some radiant heat from the inner wall is absorbed by the outer wall, but the constant introduction of room temperature air at the bottom of the appliance keeps the outer wall moderately cool. This characteristic generally allows convection wood stoves to be placed closer to combustible materials than radiant wood stoves. Fans in some wood stoves augment the movement of heated air. Convection wood stoves generally provide more even heat distribution than do radiant types.

Advanced-Design Wood Stoves

Strict air pollution standards have prompted the development of new stove designs. These clean-burning wood stoves use either catalytic or noncatalytic technology to achieve very high combustion efficiency and to reduce creosote and particulate and carbon monoxide emission levels.

Catalytic combustors are currently available as an integral part of many new wood-burning appliances and are also available as add-on or retrofit units for most existing appliances. The catalyst may be platinum, palladium, rhodium, or a combination of these elements. It is bonded to a ceramic or stainless steel substrate. A catalytic combustor's function in a wood-burning appliance is to substantially lower the ignition temperatures of unburned gases, solids, and/or liquid droplets (from approximately 540°C to 260°C). As these unburned combustibles leave the main combustion chamber and pass through the catalytic combustor, they ignite and burn rather than enter the atmosphere.

For the combustor to efficiently burn the gases, the proper amount of oxygen and a sufficient temperature to maintain ignition are required; further, the gases must have sufficient residence time in the combustor. A properly operating catalytic combustor has a temperature in the range of 540 to 930°C. Catalyst-equipped wood stoves have a default efficiency, as determined by the U.S. Environmental Protection Agency (EPA), of 72%, although many stoves are considerably more efficient. This EPA default efficiency is the value one standard deviation below the mean of the efficiencies from a database of stoves.

Another approach to increasing combustion efficiency and meeting emissions requirements is the use of technologically advanced internal appliance designs and materials. Generally, noncatalytic, low-emission wood-burning appliances incorporate high-temperature refractory materials and have smaller fireboxes than conventional appliances. The fire chamber is designed to increase temperature, turbulence, and residence time in the primary combustion zone. Secondary air is introduced to promote continued burning of the gases, solids, and liquid vapors in a secondary combustion zone. Many stoves add a third and fourth burn area within the firebox. The location and design of the air inlets is critical because proper air circulation patterns are the key to approaching complete combustion. Noncatalytic wood stoves have an EPA default efficiency of 63%; however, many models approach 80%.

Fireplace Inserts

Fireplace inserts are closed-combustion wood-burning room heaters that are designed to be installed in an existing masonry fireplace. They combine elements of both radiant and convection wood stove designs. They have large radiant surfaces that face the room and circulating jackets on the sides that capture heat that would otherwise go up the chimney. Inserts may use either catalytic or noncatalytic technology to achieve clean burning.

Pellet-Burning Stoves

Pellet-burning stoves burn small pellets made from wood byproducts rather than burning logs. An electric auger feeds the pellets from a hopper into the fire chamber, where air is blown through, creating very high temperatures in the firebox. The fire burns at such a high temperature that the smoke is literally burned up, resulting in a very clean burn, and no chimney is needed. Instead, the waste gases are exhausted to the outdoors through a vent. An air intake is operated by an electric motor; another small electric fan blows the heated air from the area around the fire chamber into the room. A microprocessor controls the operation, allowing the pellet-burning stove to be controlled by a thermostat. Pellet-burning stoves typically have the lowest emissions of all wood-burning appliances and have an EPA default efficiency of 78%. Because of the high air/fuel ratios used by pellet-burning stoves, these stoves are excluded from EPA wood stove emissions regulations.

5. GENERAL INSTALLATION PRACTICES

The criteria to ensure safe operation are normally covered by local codes and ordinances or, in rare instances, by state and federal requirements. Most codes, ordinances, or regulations refer to the following building codes and standards for in-space heating:

Building Codes	
BOCA/National Building Code	BOCA
CABO One- and Two-Family Dwelling Code	CABO
International Building Code	ICC
National Building Code of Canada	NBCC
Standard Building Code	SBCCI
Uniform Building Code	ICBO
Mechanical Codes	
National Mechanical Code	BOCA
Uniform Mechanical Code	IAPMO
International Mechanical Code	ICC
Standard Mechanical Code	SBCCI
Electrical Codes	
National Electrical Code	NFPA 70
Canadian Electrical Code	CSA C22.1
Chimneys	
Chimneys, Fireplaces, Vents and Solid Fuel-Burning Appliances	NFPA 211
Chimneys, Factory-Built Residential Type and Building Heating Appliance	UL 103
Solid-Fuel Appliances	
Factory-Built Fireplaces	UL 127
Room Heaters, Solid-Fuel Type	UL 1482

Chapter 51 has further information, including the names and addresses of these agencies. Safety and performance criteria are furnished by these agencies.

Table 4 Chimney Connector Wall Thickness*

Diameter	Gage	Minimum Thickness, mm
Less than 152 mm	26	0.48
152 mm to 254 mm	24	0.58
254 mm to 406 mm	22	0.74
406 mm or greater	16	1.42

*Do not use thinner connector pipe. Replace connectors as necessary. Leave at least 460 mm clearance between the connector and a wall or ceiling, unless the connector is listed for a smaller clearance or an approved clearance reduction system is used.

Safety with Solid Fuels

The evacuation of combustion gases is a prime concern in the installation of solid-fuel-burning equipment. NFPA *Standard* 211, Chimneys, Fireplaces, Vents and Solid Fuel-Burning Appliances, lists requirements that should be followed. Because safety requirements for connector pipes (stovepipes) are not always readily available, these requirements are summarized as follows:

- Connector pipe is usually black (or blue) steel single-wall pipe; thicknesses are shown in Table 4. Stainless steel is a corrosion-resistant alternative that does not have to meet the thicknesses listed in Table 4.
- Connectors should be installed with the crimped (male) end of the pipe toward the stove, so that creosote and water drip back into the stove.
- The pipe should be as short as is practical, with a minimum of turns and horizontal runs. Horizontal runs should be pitched 20 mm per metre up toward the chimney.
- Chimney connectors should not pass through ceilings, closets, alcoves, or concealed spaces.
- When passing through a combustible interior or exterior wall, connectors must be routed through a listed wall pass-through that has been installed in accordance with the conditions of the listing, or they must follow one of the home-constructed systems recognized in NFPA *Standard* 211 or local building codes. Adequate clearance and protection of combustible materials is extremely important. In general, listed devices are easier to install and less expensive than home-constructed systems.

Creosote forms in all wood-burning systems. The rate of formation is a function of the quantity and type of fuel burned, the appliance in which it is burned, and the manner in which the appliance is operated. Thin deposits in the connector pipe and chimney do not interfere with operation, but thick deposits (greater than 6 mm) may ignite. Inspection and cleaning of chimneys connected to wood-burning appliances should be performed on a regular basis (at least annually).

Only the solid fuel that is listed for the appliance should be burned. Coal should be burned only in fireplaces or stoves designed specifically for coal burning. The chimney used in coal-fired applications must also be designed and approved for coal and wood.

Solid-fuel appliances should be installed in strict conformance with the clearance requirements established as part of their safety listing. When clearance reduction systems are used, stoves must remain at least 300 mm and connector pipe at least 150 mm from combustibles, unless smaller clearances are established as part of the listing.

Utility-Furnished Energy

Those systems that rely on energy furnished by a utility are usually required to comply with local utility service rules and regulations. The utility usually provides information on the installation and operation of the equipment using their energy. Bottled gas (LPG) equipment is generally listed and tested under the same standards as natural gas. LPG equipment may be identical to natural gas equipment, but it always has a different orifice and sometimes has a different burner and controls. The listings and examinations are usually the same for natural, mixed, manufactured, and liquid petroleum gas.

Products of Combustion

The combustion chamber of equipment that generates products of combustion must be connected by closed piping to the outdoors. Gas-fired equipment may be vented through masonry stacks, chimneys, specifically designed venting, or, in some cases, venting incorporating forced- or induced-draft fans. Chapter 35 covers chimneys, gas vents, and fireplace systems in more detail.

Agency Testing

The standards of several agencies contain guidelines for the construction and performance of in-space heaters. The following list summarizes the standards that apply to residential in-space heating; they are coordinated or sponsored by ASHRAE, the American National Standards Institute (ANSI), Underwriters Laboratories (UL), the American Gas Association (AGA), and the Canadian Gas Association (CGA). Some CGA standards have a CAN1 prefix.

ANSI Z21.11.1	Gas-Fired Room Heaters, Vented
ANSI Z21.11.2	Gas-Fired Room Heaters, Unvented
ANSI Z21.44	Gas-Fired Gravity and Fan-Type Direct-Vent Wall Furnaces
ANSI Z21.48	Gas-Fired Gravity and Fan-Type Floor Furnaces
ANSI Z21.49	Gas-Fired Gravity and Fan-Type Vented Wall Furnaces
ANSI Z21.60/ CSA 2.26-M96	Decorative Gas Appliances for Installation in Solid-Fuel Burning Fireplaces
ANSI Z21.76	Gas-Fired Unvented Catalytic Room Heaters for Use with Liquefied Petroleum (LP) Gases
ANSI Z21.50/ CSA 2.22-M98	Vented Gas Fireplaces
ANSI Z21.86/ CSA 2.32-M98	Vented Gas-Fired Space Heating Appliances
ANSI Z21.88/ CSA 2.33-M98	Vented Gas Fireplace Heaters
CAN1-2.1-M86	Gas-Fired Vented Room Heaters
CAN/CGA-2.5-M86	Gas-Fired Gravity and Fan Type Vented Wall Furnaces
CAN1/CGA-2.19-M81	Gas-Fired Gravity and Fan Type Direct Vent Wall Furnaces
NFPA 211	Chimneys, Fireplaces, Vents and Solid Fuel-Burning Appliances
NFPA/AGA 54	National Fuel Gas Code
ANSI/UL 127	Factory-Built Fireplaces
UL 574	Electric Oil Heaters
UL 647	Unvented Kerosene-Fired Heaters and Portable Heaters
ANSI/UL 729	Oil-Fired Floor Furnaces
ANSI/UL 730	Oil-Fired Wall Furnaces
UL 737	Fireplace Stoves
ANSI/UL 896	Oil-Burning Stoves
ANSI/UL 1042	Electric Baseboard Heating Equipment
ANSI/UL 1482	Heaters, Room Solid-Fuel Type
ASHRAE 62.1	Ventilation for Acceptable Indoor Air Quality

A PROPERLY designed chimney or vent system provides and controls draft to convey flue gas from an appliance to the outdoors. This chapter describes the design of chimneys and vent systems that discharge flue gas from appliances and fireplace systems.

Sustainability. Good chimney and vent design is not only a safety issue, but also can enhance a building's sustainability. This chapter explains how to design vent systems to optimize and minimize the materials used to construct fuel-burning appliance vents and chimneys for low cost and long reliability, reducing the need for vent or chimney replacement, thus saving natural resources. Also, systems designed to bring outdoor air directly into the appliance space for combustion and vent gas dilution, instead of relying on air infiltration into the building, reduce heat load and conserve fuel.

1. TERMINOLOGY

In this chapter, **appliance** refers to any furnace, boiler, or incinerator (including the burner). Unless the context indicates otherwise, the term **chimney** includes specialized vent products such as masonry, metal, and factory-built chimneys; single-wall metal pipe; type B gas vents; special gas vents; or masonry chimney liner systems (NFPA *Standard* 211). **Draft** is negative static pressure, measured relative to atmospheric pressure; thus, positive draft is negative static pressure. **Flue gas** is the mixture of gases discharged from the appliance and conveyed by the chimney or vent system.

Appliances can be grouped by draft conditions at the appliance flue gas outlet as follows (Stone 1971):

1. Those that require draft applied at the appliance flue gas outlet to induce air into the appliance
2. Those that operate without draft applied at the appliance flue gas outlet (e.g., a gas appliance with a draft hood in which the combustion process is isolated from chimney draft variations)
3. Those that produce positive pressure at the appliance flue gas outlet collar so that no chimney draft is needed; appliances that produce some positive outlet pressure but also need some chimney draft

In the first two configurations, hot flue gas buoyancy, induced-draft chimney fans, or a combination of both produces draft. The third configuration may not require chimney draft, but it should be considered in the design if a chimney is used. If the chimney system is undersized, draft inducers in the connector or chimney may supply draft needs. If the connector or chimney pressure requires control for proper operation, draft control devices must be used.

The preparation of this chapter is assigned to TC 6.10, Fuels and Combustion.

2. DRAFT OPERATING PRINCIPLES

Available draft D_a is the draft supplied by the vent system, available at the appliance flue gas outlet. It can be shown as

$$D_a = D_t - \Delta p - D_p + D_b \quad (1)$$

where

D_a = available draft, Pa
D_t = theoretical draft, Pa
Δp = flow losses, Pa
D_p = depressurization, Pa
D_b = boost (increase in static pressure by fan), Pa

This equation can account for a nonneutral (nonzero) pressure difference between the space surrounding the appliance or fireplace and the atmosphere. If the surrounding space is at a lower pressure than the atmosphere (space depressurized), the pressure difference D_p should also be subtracted from D_t when calculating available draft D_a, and vice versa. This equation applies to all three appliance draft conditions at the vent system inlets; for example, in the second condition with zero draft requirement at the appliance outlet, available draft required is zero, so theoretical draft of the chimney equals the flow resistance, if no depressurization or boost is present.

Satisfactory operation of the appliance and vent system depends on D_a staying within limits. If D_a is too small and the appliance design relies on D_a to draw combustion air into the burner system, incomplete combustion, flame rollout, and/or flue gas spillage can occur at the appliance. Even where combustion air is mechanically supplied to the burner, inadequate D_a can result in portions of the appliance and/or vent system operating under positive pressure. If those sections are not designed to be pressurized, flue gas can leak into the building.

Excessive D_a can cause excessive combustion air to be drawn into the burner system, which not only reduces combustion efficiency, but can also cause flame lifting or other detriments to combustion performance. Many vent systems limit D_a using a draft hood or draft regulator (integral to the appliance or field supplied); these devices limit draft by admitting dilution air into the vent system. The resulting increased flow through the vent system increases ΔP and reduces D_a. Such draft control devices are unsuitable for use in parts of vent systems that may operate with a negative D_a (positive pressure).

Various methods can be used identify the D_a limits within which an appliance can properly operate. Often, the appliance manufacturer publishes a D_a or range of D_as where the appliance is designed to operate. In other cases, acceptable values for D_a are not explicitly specified, but the manufacturer or installation code prescribes a vent system design in terms of length, chimney height, cross-sectional area, etc, that is known to provide the required D_a. An

example of the latter approach is that for Category I gas appliances (see the section on Gas Appliance Venting).

Theoretical draft D_t is the natural draft produced by the buoyancy of hot gases in the chimney relative to cooler gases in the surrounding atmosphere. It depends on chimney height, local barometric pressure, and the **mean chimney flue gas temperature difference** Δt_m, which is the difference in temperature between the flue gas and atmospheric gases. Therefore, cooling by heat transfer through the chimney wall is a key variable in chimney design. Precise evaluation of theoretical draft is not necessary for most design calculations because of the availability of chimney design charts, computer programs, and capacity tables in the references, building codes, and vent and appliance manufacturers' data sheets.

Chimney temperatures and acceptable combustible material temperatures must be known in order to determine safe clearances between the chimney and combustible materials. Safe clearances for some chimney systems, such as type B gas vents, are determined by standard tests and/or specified in building codes.

Losses from Flow Δp represent the friction losses imposed on the flue gas by flow resistance through the chimney.

Depressurization D_p is negative pressure in the space surrounding the appliance with respect to the atmosphere into which the chimney discharges. D_p can be caused by other appliances and fans operating in the building that remove or add air to the space surrounding the appliance, by building stack effect, by outdoor atmospheric effects such as wind impacting the chimney exit or the side of the building facing or leeward to the wind, and other building phenomena.

Boost D_b is the pressure boost from a mechanical-draft fan. A chimney with an forced-draft fan at the inlet of the chimney would have positive boost (increased static pressure). A chimney with an induced-draft fan at the outlet of the chimney would have negative boost (decreased static pressure).

The following sections cover the basis of chimney design for average steady-state appliance operating conditions, where significant condensation of flue products is not expected. For other appliance operating conditions, a rigorous cyclic evaluation of the flue gas and material surface temperatures in the chimney vent system can be obtained using the VENT-II computer program (GTI 2009). For oil-fired appliances, chimney flue gas and material surface temperature evaluations can be obtained using the OHVAP computer program (Krajewski 1996).

3. CHIMNEY FUNCTIONS

The proper chimney can be selected by evaluating factors such as draft, configuration, size, and operating conditions of the appliance; construction of surroundings; appliance usage classification; residential, low, medium, or high heat (NFPA *Standard* 211); and building height. The chimney designer should know the applicable codes and standards to ensure acceptable construction.

In addition to chimney draft, the following factors must be considered for safe and reliable operation: adequate air supply for combustion; building depressurization effects; draft control devices; chimney materials (corrosion and temperature resistance); flue gas temperatures, composition, and dew point; wind eddy zones; and particulate dispersion. Chimney materials must resist oxidation and condensation at both high and low fire levels at all design temperatures.

Start-Up

The equations and design charts in this chapter may be used to determine vent or chimney size for average vent system operating conditions where significant condensation of flue products is not expected. The equations and charts do not consider modulation, cycling, or time to achieve equilibrium flow conditions from a cold start. Whereas mechanical draft systems can start gas flow, gravity systems rely on the buoyancy of hot flue gases as the sole force to displace the cold air in the chimney. Priming follows Newton's laws of motion. The time to fill a system with hot flue gases, displace the cold air, and start flow is reasonably predictable and is usually a minute or less; however, unfavorable thermal differentials, building/chimney interaction, mechanical equipment (e.g., exhaust fans), or wind forces that oppose the normal flow of vent gases can overwhelm the buoyancy force. Then, rapid priming cannot be obtained solely from correct system design. The VENT-II computer program contains detailed analysis of gas vent and chimney priming and other cold-start considerations and allows for appliance cycling and pressure differentials that affect performance (GTI 2009).

Air Intakes

All rooms or spaces containing fuel-burning appliances must have a constant supply of combustion air from outdoors (either directly or indirectly) at adequate static pressure to ensure proper combustion. In addition, air (either directly or indirectly) is required to replace the air entering chimney systems through draft hoods and barometric draft regulators and to ventilate closely confined boiler and furnace rooms.

The ANSI-approved U.S. *National Fuel Gas Code* (NFPA *Standard* 54/AGA Z223.1) and the Canadian *Natural Gas and Propane Installation Code* (CSA *Standard* B149.1), along with appliance manufacturers, provide requirements for air openings. Any design must consider flow resistance of the air supply, including register-louver resistance, air duct resistance, and air inlet terminations. Compliance with these codes or the appliance manufacturers' instructions accounts for the air supply flow resistance.

Vent Size

Small residential and commercial natural-draft gas appliances need vent diameters of 75 to 300 mm. U.S. and Canadian codes recommend sizes or input capacities for most acceptable gas appliance venting materials. These sizes also apply to gas appliances with integral automatic vent dampers, as well as to appliances with field-installed automatic vent dampers. Field-installed automatic vent dampers should be listed for use with a specific appliance by a recognized testing agency and installed by qualified installers.

Draft Control

Pressure, temperature, and other draft controls have replaced draft hoods in many residential furnaces and boilers to attain higher steady-state and seasonal efficiencies. Appliances that use pulse combustion or forced- or induced-draft fans, as well as those designed for sealed combustion or direct venting, do not have draft hoods but may require special venting and special vent terminals. If fan-assisted burners deliver fuel and air to the combustion chamber and also overcome the appliance flow resistance, draft hoods or other control devices may be installed, depending on the design of the appliance. Many appliances do not use draft hoods; in such cases, the listed appliance manufacturer's vent system design requirements should be followed. The section on Vent and Chimney Accessories has information on draft hoods, barometric regulators, draft fans, and other draft control devices.

Frequently, a chimney must produce excess flow or draft. For example, dangerously high flue gas outlet temperatures from an incinerator (or normal noncondensing appliance flue gas temperatures) may be reduced by diluting the flue gas with air in the chimney (or PVC vent pipe) by applying excess draft.

Pollution Control

Where control of pollutant emissions is impossible, the chimney should be tall enough to ensure dispersion over a wide area to prevent objectionable ground-level concentrations. The chimney can

also serve as a passageway to carry flue gas to pollution control equipment. This passageway must meet the building code requirements for a chimney, even at the exit of pollution control equipment, because of possible exposure to heat and corrosion. A bypass chimney should also be provided to allow continued exhaust in the event of pollution control equipment failure, repair, or maintenance.

Equipment Location

Chimney materials may allow installation of appliances at intermediate or all levels of a high-rise building without imposing mass penalties. Some gas vent systems allow individual apartment-by-apartment heating systems.

Wind Effects

Wind and eddy currents affect discharge of gases from vents and chimneys. A vent or chimney must expel flue gas beyond the cavity or eddy zone surrounding a building to prevent reentry through openings and fresh air intakes. A chimney and its termination can stabilize the effects of wind on appliances and their equipment rooms. In many locations, the equipment room air supply is not at neutral pressure under all wind conditions. Locating the chimney outlet well into the undisturbed wind stream and away from the cavity and wake zones around a building both counteracts wind effects on the air supply pressure and prevents reentry through openings and contamination of fresh air intakes.

Chimney outlets below parapet or eaves level, nearly flush with the wall or roof surface, or in known regions of stagnant air may be subjected to downdrafts and are undesirable. Caps for downdraft and rain protection must be installed according to either their listings and the cap manufacturer's instructions or the applicable building code.

Wind effects can be minimized by locating the chimney terminal and the combustion air inlet terminal close together in the same pressure zone while taking care to minimize recirculation of combustion products into the combustion air inlet.

See Chapter 24 of the 2021 *ASHRAE Handbook—Fundamentals*, for more information on wind effects.

Safety Factors

Safety factors allow for uncertainties of vent and chimney operation. For example, flue gas must not spill from a draft hood or barometric regulator, even when the chimney has very low available draft. The Table 2 design condition for natural gas vents (i.e., vent gas at 165 K rise and 5.3% CO_2 concentration) allows gas vents to operate with reasonable safety above or below the suggested temperature and CO_2 limits.

Safety factors may also be added to the system friction coefficient to account for a possible extra fitting, soot accumulation, and air supply resistance. The specific gravity of flue gas can vary depending on the fuel burned. Natural gas flue gas, for example, has a density as much as 5% less than air, whereas coke flue gas may be as much as 8% greater. However, these density changes are insignificant relative to other uncertainties, so no compensation is needed.

4. STEADY-STATE CHIMNEY DESIGN EQUATIONS

Chimney design balances forces that produce flow against those that retard flow (e.g., friction). **Theoretical draft** is the pressure that produces flow in gravity or natural-draft chimneys. It is defined as the static pressure resulting from the difference in densities between a stagnant column of hot flue gas and an equal column of ambient air. In the design or balancing process, theoretical draft may not equal friction loss because the appliance is frequently built to operate with some specific pressure (positive or negative) at the appliance flue gas exit. This exit pressure is added to the **available draft**, which depends on chimney conditions, appliance operating characteristics, fuel, and type of draft control.

Flow losses caused by friction may be estimated by several formulas for flow in pipes or ducts, such as the equivalent length method or the loss coefficient (velocity head) method. Chapter 13 of the 2021 *ASHRAE Handbook—Fundamentals* covers computation of flow losses. This chapter emphasizes the loss coefficient method because fittings usually cause the greater portion of system pressure drop in chimney systems, and conservative loss coefficients (which are almost independent of piping size) provide an adequate basis for design.

A computer program called VENT-II (GTI 2009) dynamically predicts cyclic flows, temperatures, and pressures in venting systems. Similarly, Krajewski (1996) developed a computer program entitled OHVAP: Oil-Heat Vent Analysis Program.

For large gravity chimneys, available draft D_a may be calculated from Equation (1).The following equations may be derived and expressed in a form that is more readily applied to the problems of chimney design, size, and capacity by considering the following factors, which are the steps used to solve the problems in the section on Vent and Chimney Capacity Calculation Examples:

1. Mass flow of combustion products in chimney
2. Chimney gas temperature and density
3. Theoretical draft
4. System pressure loss caused by flow
5. Available draft
6. Chimney gas velocity
7. System resistance coefficient
8. Final input-volume relationships

For application to system design, the chimney gas velocity step is eliminated; however, actual velocity can be found readily, if needed.

Mass Flow of Combustion Products in Chimneys and Vents

Mass flow in a chimney or venting system may differ from that in the appliance, depending on the type of draft control or number of appliances operating in a multiple-appliance system. Mass flow is preferred to volumetric flow because it remains constant in any continuous portion of the system, regardless of changes in temperature or pressure. For the chimney gases resulting from any combustion process, mass flow can be expressed as

$$w = IM \tag{2}$$

where

w = mass flow rate, kg/s
I = appliance heat input, MJ/s (MW)
M = ratio of mass flow to heat input, kg of combustion products per MJ of fuel burned (M depends on fuel composition and percentage excess air [or CO_2] in the chimney)

Volumetric flow rate (m^3/min) Q can be found as follows:

$$Q = 60\frac{w}{\rho_m} \tag{3}$$

where ρ_m is gas density (kg/m^3).

In chimney system design, the composition and flow rate of the flue gas must be assumed to determine the ratio M of mass flow to input. When combustion conditions are given in terms of excess air, Figure 1 can be used to estimate CO_2. The mass flow equations in Table 1 illustrate the influence of fuel composition; however, additional guidance is needed for system design. The information provided with many heat-producing appliances is limited to whether they have been tested, certified, listed, or approved to comply with applicable standards. From this information and from the type of fuel and draft control, certain inferences can be drawn regarding the flue gas.

Table 1 Mass Flow Equations for Common Fuels

Fuel	Ratio M of Mass Flow to Input[a]: $M = \frac{\text{kg Total Combustion Products}^b}{\text{MJ Fuel Input}}$
Natural gas	$0.303\left(0.159 + \frac{10.72}{\%\ CO_2}\right)$
LPG (propane, butane, or mixture)	$0.304\left(0.144 + \frac{12.61}{\%\ CO_2}\right)$
No. 2 oil (light)	$0.31\left(0.12 + \frac{14.4}{\%\ CO_2}\right)$
No. 6 oil (heavy)	$0.31\left(0.12 + \frac{15.8}{\%\ CO_2}\right)$
Bituminous coal (soft)	$0.327\left(0.11 + \frac{18.2}{\%\ CO_2}\right)$
Type 0 waste or wood	$0.30\left(0.16 + \frac{19.7}{\%\ CO_2}\right)$

[a]Percent CO_2 is determined in combustion products with water condensed (dry basis).
[b]Total combustion products include combustion products and excess air.

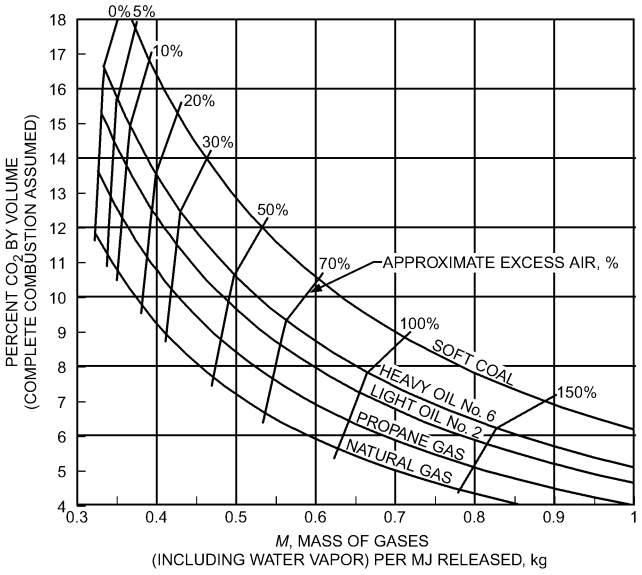

Fig. 1 Graphical Evaluation of Rate of Vent Gas Flow from Percent CO_2 and Fuel Rate

Table 2 suggests typical values for the vent or chimney systems for gaseous and liquid fuels when specific outlet conditions for the appliance are not known. If a gas appliance with draft hood is used, Table 2 recommends that dilution air through the draft hood reduce the CO_2 percentage to 5.3%. For appliances using draft regulators, the dilution and temperature reduction is a function of the draft regulator gate opening, which depends on excess draft. If the chimney system produces the exact draft necessary for the appliance, little dilution takes place.

For manifolded gas appliances that have draft hoods, dilution through draft hoods of inoperative appliances must be considered in precise system design. However, with forced-draft appliances having wind box or inlet air controls, dilution through inoperative appliances may be unimportant, especially if pressure at the outlet of inoperative appliances is neutral (atmospheric level).

Figure 2 can be used to estimate mass and volumetric flow. Flow conditions in the chimney connector, manifold, vent, and chimney vary with configuration and appliance design and are not necessarily the same as boiler or appliance outlet conditions.

Mass flow in incinerator chimneys must account for the probable heat value of the waste, its moisture content, and use of additional fuel to initiate or sustain combustion. Classifications of waste and corresponding values of M in Table 3 are based on recommendations from the Incinerator Institute of America. Combustion data given for types 0, 1, and 2 waste do not include any additional fuel. Where constant burner operation accompanies waste combustion, the additional quantity of products should be considered in the chimney design.

The system designer should obtain exact outlet conditions for the maximum rate operation of the specific appliance. This information can reduce chimney construction costs. For appliances with higher seasonal or steady-state efficiencies, however, special attention should be given to the manufacturer's venting recommendations because the flue gas may differ in composition and temperature from conventional values.

Mean Chimney Gas Temperature and Density

Chimney gas temperature depends on the fuel, appliance, draft control, chimney size, and configuration.

Density of gas within the chimney and theoretical draft both depend on gas temperature. Although the gases flowing in a chimney system lose heat continuously from entrance to exit, a single mean gas temperature must be used in either the design equation or the chart. Mean chimney gas density is virtually the same as air density at the same temperature. Thus, density may be found as

$$\rho_m = \rho_a\left(\frac{T_s}{T_m} \times \frac{B}{B_o}\right) = 0.00348\frac{B}{T_m} \quad (4)$$

where

ρ_m = chimney gas density, kg/m^3
T_s = standard temperature = 288.15 K
ρ_a = air density at T_s and B_o =1.225 kg/m^3
B = local barometric pressure, Pa
T_m = mean chimney gas temperature at average system conditions, K
B_o = standard pressure = 101 325 Pa

The density ρ_a in Equation (4) is a compromise value for typical humidity. The subscript m for density and temperature requires that these properties be calculated at mean gas temperature or vertical midpoint of a system (inlet conditions can be used where temperature drop is not significant).

Using a reasonably high ambient (e.g., 15°C) for design ensures improved operation of the chimney when ambient temperatures drop because temperature differentials and draft increase.

A design requires assuming an initial or inlet chimney gas temperature. In the absence of specific data, Table 4 provides a conservative temperature. For appliances that can operate over a range of temperatures, size should be calculated at both extremes to ensure an adequate chimney.

The drop in vent gas temperature from appliance to exit reduces capacity, particularly in sizes of 300 mm or less. In gravity type B gas vents, which may be as small as 75 mm in diameter, and in other systems used for venting gas appliances, capacity is best determined from NFPA *Standard* 54/AGA Z223.1 or CSA *Standard* B149.1. In these codes, the tables compensate for the particular characteristics of the chimney material involved, except for very high single-wall metal pipe. Between 300 and 460 mm diameters, the effect of heat loss diminishes greatly because there is greater gas flow relative to system surface area. For 500 mm and greater diameters, cooling has little effect on final size or capacity.

A straight vertical vent or chimney directly off the appliance requires little compensation for cooling effects, even with smaller sizes. However, a horizontal connector running from the appliance

Table 2 Typical Chimney and Vent Design Conditions[a]

Fuel	Appliance	% CO_2	Temperature Rise, K	Mass Flow/Input Ratio (M), kg Total Flue Gas[b] per MJ Fuel Input	Flue Gas Density,[c] kg/m³	Flow Rate/Unit Heat Input,[c] m³/s per (MJ/s) or m³/MJ at Flue Gas Temperature
Natural gas	Draft hood	5.3	165	0.661	0.777	0.851
Propane gas	Draft hood	6.0	165	0.683	0.777	0.878
Natural gas						
Low-efficiency	No draft hood	8.0	220	0.454	0.693	0.655
High-efficiency	No draft hood	7.0	135	0.512	0.832	0.615
No. 2 oil	Residential	9.0	280	0.533	0.620	0.860
Oil	Forced-draft, over 120 kW or 0.120 MJ/s	13.5	165	0.368	0.777	0.473
Waste, Type 0	Incinerator	9.0	740	0.705	0.343	2.056

[a]Values are for appliances with flue losses of 17% or more. For appliances with lower flue losses (high-efficiency types), see appliance installation instructions or ask manufacturer for operating data.
[b]Total flue gas includes combustion products and excess air.
[c]At sea level and 15.56°C ambient temperature.

Table 3 Mass Flow for Incinerator Chimneys

Type of Waste	Heat Value of Waste,[a] MJ/kg	Auxiliary Fuel[a] per Unit Waste, MJ/kg	Combustion Products		
			L/s per kg Waste at 760°C[b]	kg per kg Waste[c]	M, kg Products per MJ
0	19.8	0	11.17	13.76	0.697
1	15.1	0	8.74	10.80	0.714
2	10.0	0	6.18	7.68	0.770
3	5.8	3.5	5.12	6.25	1.075
4	2.3	7.0	4.31	5.33	2.292

[a]Auxiliary fuel may be used with any type of waste, depending on incinerator design.
[b]Specialized units may produce higher or lower outlet gas temperatures, which must be considered in chimney sizing, using Equation (12) or Equation (21).
[c]Multiply these values by kilograms of waste burned per second to establish mass flow.

Table 4 Mean Chimney Gas Temperature for Various Appliances

Appliance Type	Mean Temperature t_m* in Chimney, °C
Natural gas-fired heating appliance with draft hood (low-efficiency)	180
LP gas-fired heating appliance with draft hood (low-efficiency)	180
Gas-fired heating appliance, no draft hood	
Low-efficiency	240
Mid-efficiency	150
Oil-fired heating appliance (low-efficiency)	290
Conventional incinerator	760
Controlled air incinerator	980 to 1320
Pathological incinerator	980 to 1540
Turbine exhaust	480 to 760
Diesel exhaust	480 to 760
Ceramic kiln	980 to 1320

*Subtract 15°C ambient to obtain temperature rise.

to the base of the vent or chimney has enough heat loss to diminish draft and capacity. Figure 3 is a plot of temperature correction C_u, which is a function of connector size, length, and material for either conventional single-wall metal connectors or double-wall metal connectors.

For a more accurate method of calculating temperature loss in vents and chimneys, including effects from condensation, see Rutz et al. (1991).

To use Figure 3, estimate connector size and length and read the temperature multiplier. For example, a 5 m length of 175 mm diameter single-wall connector has a multiplier of 0.59. If inlet temperature rise Δt_e above ambient is 165 K, operating mean temperature rise Δt_m will be $0.59 \times 165 = 97$ K. This factor adequately corrects the temperature at the midpoint of the vertical vent for heights up to 30 m.

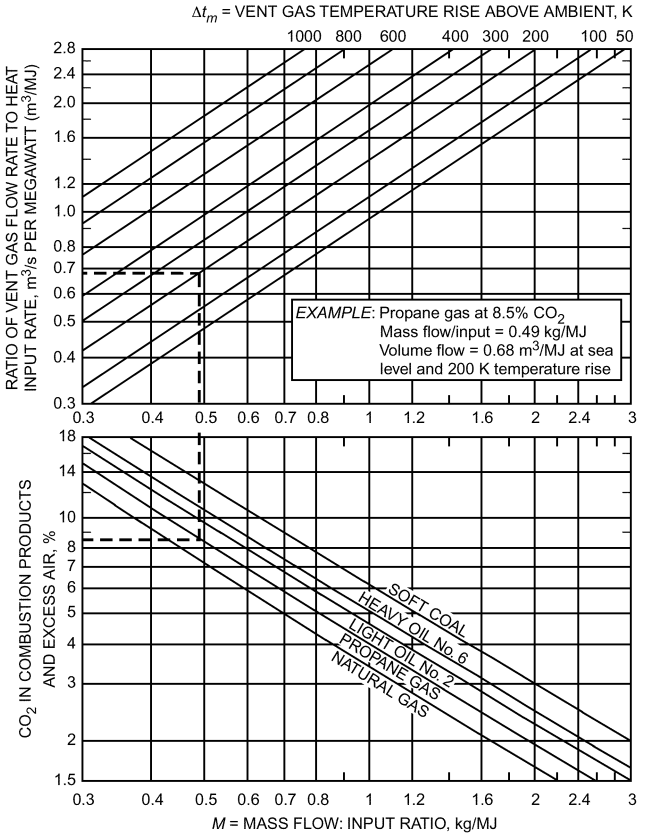

Fig. 2 Flue Gas Mass and Volumetric Flow

The correction procedure includes the assumption that the overall heat transfer coefficient of a vertical chimney is approximately 3.4 W/(m² · K) or less (the value for double-wall metal). This procedure does not correct for cooling in very high stacks constructed entirely of single-wall metal, especially those exposed to cold ambient temperatures. For severe exposures or excessive heat loss, a trial calculation assuming a conservative operating temperature shows whether capacity problems will be encountered.

For more precise heat loss calculations, Table 5 suggests overall heat transfer coefficients for various constructions installed in

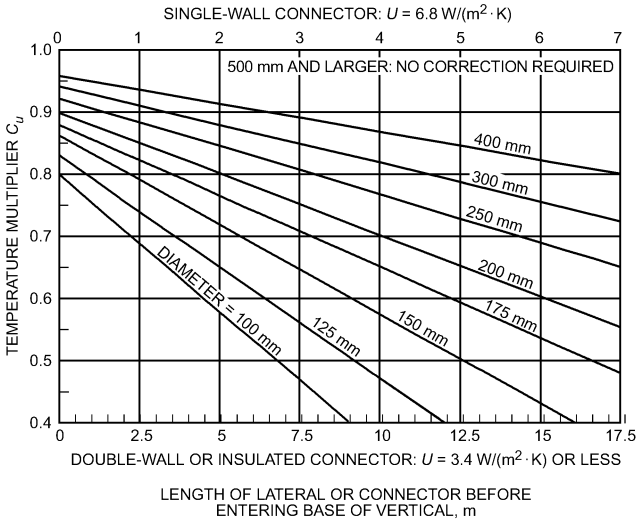

Fig. 3 Temperature Multiplier C_u for Compensation of Heat Losses in Connector

Table 5 Overall Heat Transfer Coefficients of Various Chimneys and Vents

Material	U, W/(m² · K)* Observed	Design	Remarks
Industrial steel stacks	—	7.4	Under wet wind
Clay or iron sewer pipe	7.4 to 7.9	7.4	Used as single-wall material
Asbestos-cement gas vent	4.09 to 8.06	6.8	Tested per UL *Standard* 441
Black or painted steel stove pipe	—	6.8	Comparable to weathered galvanized steel
Single-wall galvanized steel	1.76 to 7.84	5.7	Depends on surface condition and exposure
Single-wall unpainted pure aluminum	—	5.7	No. 1100 or other bright-surface aluminum alloy
Brick chimney, tile-lined	2.8 to 5.7	5.7	For gas appliances in residential construction per NFPA *Standard* 211
Double-wall gas vent, 6.4 mm air space	2.1 to 5.9	3.4	Galvanized steel outer pipe, pure aluminum inner pipe; tested per UL *Standard* 441
Double-wall gas vent, 12.7 mm air space	1.9 to 4.0	2.3	
Insulated prefabricated chimney	1.9 to 4.0	1.7	Solid insulation meets UL *Standard* 103 when chimney is fully insulated

*U-factors based on inside area of chimney.

typical environments at usual flue gas flow velocities (Segeler 1965). For masonry, any additional thickness beyond the single course of brick plus tile liner used in residential chimneys decreases the coefficient.

Equations (5) and (6) describe flow and heat transfer, respectively, in a venting system with $D_a = 0$.

$$q_m = T_s\sqrt{2g}c_p\frac{B}{B_o}\times\frac{A}{T_m}\left(\frac{H}{kT_o}\right)^{1/2}\Delta t_m^{1.5}\rho_m \quad (5)$$

$$\frac{q}{q_m} = \frac{\Delta t_e}{\Delta t_m} = \exp\left(\pi\overline{U}d_f\frac{L_m\Delta t_m}{q_m}\right) \quad (6)$$

where

A = area of passage cross section, m²
c_p = specific heat
d_i = inside diameter, m
$\exp x$ = e^x
g = gravitational constant = 9.806 65 m/s²
H = height of chimney above grade or inlet, m
k = fixed, dimensionless system flow resistance coefficient for pipe and fittings
L_m = length from inlet to location (in the vertical) of mean gas temperature, m
q = heat flow rate at vent inlet, J/s (W)
q_m = heat flow rate at midpoint of vent, J/s (W)
Δt_e = $(T - T_o)$ = temperature difference entering system, K
Δt_m = $(T_m - T_o)$ = chimney gas mean temperature rise, K
T = flue gas temperature at vent inlet, °C
T_m = chimney mean flue gas temperature, K
T_o = design ambient temperature, 288 K
T_s = 288.15 K
$\overline{U}$ = heat transfer coefficient, W/(m² · K)
ρ_m = mean flue gas density from Equation (4)

Assuming reasonable constancy of $\overline{U}$, the overall heat transfer coefficient of the venting system material, Equations (5) and (6) provide a solution for maximum vent gas capacity. They can also be used to develop cooling curves or calculate the length of pipe where internal moisture condenses. Kinkead (1962) details methods of solution and application to both individual and combined gas vents.

Theoretical Draft

The theoretical draft of a gravity chimney or vent is the difference in weight between a given column of warm (light) chimney gas and an equal column of cold (heavy) ambient air. Chimney gas density or temperature, chimney height, and barometric pressure determine theoretical draft; flow is not a factor. The equation for theoretical draft assumes chimney gas density is the same as that of air at the same temperature and pressure; thus,

$$D_t = 0.03413BH\left(\frac{1}{T_o} - \frac{1}{T_m}\right) \quad (7)$$

where

B = local barometric pressure, Pa
D_t = theoretical draft, Pa
H = height of chimney above grade or inlet, m
T_m = mean flue gas temperature at average conditions in system, K
T_o = ambient temperature, K

Theoretical draft thus increases directly with height and with the difference in density between the hot and cold columns, and is always positive (unless chimney gases are colder than ambient air).

Theoretical draft should be estimated and included in system calculations, even for appliances producing considerable positive outlet static pressure, to achieve the economy of minimum chimney size. Equation (7) may be used directly to calculate exact values for theoretical draft at any altitude. For ease of application, Table 6 lists approximate theoretical draft for typical gas temperature rises above 15°C ambient.

Appliances with fixed fuel beds, such as hand-fired coal stoves and furnaces, require positive available draft (negative gage pressure). Small oil heaters with pot-type burners, as well as residential furnaces with pressure-atomizing oil burners, need positive available draft, which can usually be set by following the manufacturer's

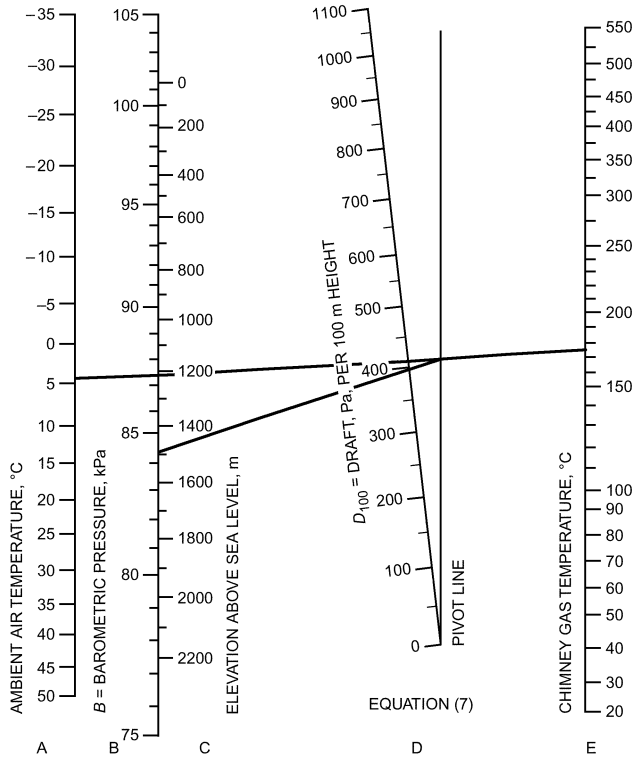

Fig. 4 Theoretical Draft Nomograph

Table 6 Approximate Theoretical Draft of Chimneys

Vent Gas Temperature Rise, K	D_t per Metre, Pa
60	2.0
100	3.0
150	4.0
200	5.0
300	6.0
400	7.0
600	8.0
900	9.0
1500	10.0

Notes: Ambient temperature = 15°C = 288 K
Chimney gas density = air density
Sea level barometric pressure = 101 325 Pa
Equation (7) may be used to calculate exact values for D_t at any altitude.

Table 7 Altitude Correction

Altitude, m	Barometric Pressure *B*, kPa	Factor*
Sea level	101.325	1.00
600	94.41	1.08
1000	89.87	1.13
2000	79.50	1.27
3000	70.11	1.45
4000	61.64	1.64

*Multiply operating input by factor to obtain design input.

instructions for setting the draft regulator. Available draft requirements for larger packaged boilers or appliances assembled from components may be negative, zero (neutral), or positive.

Compensation of theoretical draft for altitude or barometric pressure is usually necessary for appliances and chimneys functioning at elevations greater than 600 m. Depending on the design, one of the following approaches to pressure or altitude compensation is necessary for chimney sizing.

1. Equation (19): Use local theoretical draft with actual energy input, or use sea-level theoretical draft with energy input multiplied by ratio of sea level to local barometric pressure (Table 7 factor).
2. Equation (21): Use local theoretical draft and barometric pressure with volumetric flow at the local density.

The altitude correction multiplier for input (Table 7) is the only method of correcting to other elevations.

Equation (7) for theoretical draft is the basis for Figure 4, which can be used up to about 540°C and 2300 m elevation. For example, using this figure, ambient air temperature at 4.4°C and mean chimney gas temperature at 176°C provide D_{100} draft of 408 Pa per 100 m of height at 87.3 kPa (1219 m above sea level). For D_{100} draft at 84.42 kPa barometric pressure or 1493 m above sea level, follow the intersection to the pivot line and read the new D_{100} draft of 399 Pa.

Gas appliances with draft hoods, for example, are usually derated 4% per 300 m of elevation above sea level when they are operated at 610 m altitude or above (see NFPA *Standard* 54/AGA Z223.1 or CSA *Standard* B149.1). The altitude correction factor derates the design input so that the vent size at altitude for derated gas appliances is effectively the same as at sea level. For other appliances where burner adjustments or internal changes might be used to adjust for reduced density at altitude, the same factors produce an adequately compensated chimney size. For example, an appliance operating at 1830 m elevation at 2.930 MJ/s (2930 kW) input, but requiring the same draft as at sea level, should have a chimney selected on the basis of 1.244 times the operating input, or 3.645 MJ/s.

System Pressure Loss Caused by Flow

In any chimney system, flow losses, expressed as pressure drop Δp in pascals, are the difference between theoretical and available draft:

$$\Delta p = D_t - D_a \tag{8}$$

where Δp is always positive.

In any chimney or vent system, flow losses resulting from velocity and resistance can be determined from the Bernoulli equation:

$$\Delta p = \frac{k\rho_m V^2}{2} \tag{9}$$

where

k = dimensionless system resistance coefficient of piping and fittings
V = system gas velocity at mean conditions, m/s
ρ_m = mean flue gas density, kg/m^3

Pressure losses are thus directly proportional to the resistance factor and to the square of the velocity.

Available Draft

Starting with Equation (1), the difference between theoretical draft and flow losses without depressurization or boost is

$$D_a = D_t - \Delta p$$

Available draft D_a can therefore be defined as

$$D_a = 0.03413BH\left(\frac{1}{T_o} - \frac{1}{T_m}\right) - \frac{k\rho_m V^2}{2} \tag{10}$$

Table 8 Pressure Equations for Δp

Required Appliance Outlet Pressure or Available Draft D_a	Δp Equation[a]	
	Gravity Only	Gravity plus Inducer[b]
Negative, needs positive draft	$\Delta p = D_t - D_a$	$\Delta p = D_t - D_a + D_b$
Zero, vent with draft hood or balanced forced draft	$\Delta p = D_t$	$\Delta p = D_t + D_b$
Positive, causes negative draft	$\Delta p = D_t + D_a$	$\Delta p = D_t + D_a + D_b$

[a]Equations use absolute pressure for D_a.
[b]D_b = static pressure boost of inducer at flue gas temperature and rated flow.

Available draft D_a can be negative, zero, or positive. The pressure difference Δp, or theoretical minus available draft, overcomes the flow losses. Table 8 lists the pressure components for three draft configurations. Table 8 applies to still air (no wind) conditions and a neutral (zero) pressure difference between the space surrounding the appliance or fireplace and the atmosphere. Columns with and without boost are provided.

The effect of a nonneutral pressure difference on capacity or draft may be included by imposing a static pressure (either positive or negative). One way to circumvent a space-to-atmosphere pressure difference is to use a sealed-combustion system or direct-vent system (i.e., all combustion air is taken directly from the outdoor atmosphere, and all flue gas is discharged to the outdoor atmosphere with no system openings such as draft hoods). The effect of wind on capacity or draft may be included by imposing a static pressure (either positive or negative) or by changing the vent terminal resistance loss. However, a properly designed and located vent terminal should cause little change in Δp at typical wind velocities.

Although small static draft pressures can be measured at the entrance and exit of gas appliance draft hoods, D_a at the appliance is effectively zero. Therefore, all theoretical draft energy produces chimney flow velocity and overcomes chimney flow resistance losses.

Chimney Gas Velocity

Velocity in a chimney or vent varies inversely with flue gas density ρ_m and directly with mass flow rate. The equation for flue gas velocity at mean gas temperature in the chimney is

$$V = \frac{1000 \times 4w}{\pi \rho_m d_i^2} \tag{11}$$

where

V = flue gas velocity, m/s
d_i = inside diameter, mm
ρ_m = mean flue gas density, kg/m^3
w = mass flow rate, kg/s

To express velocity as a function of input and chimney gas composition, w in Equation (11) is replaced by using Equation (2):

$$V = \frac{1000 \times 4IM}{\pi \rho_m d_i^2} = \frac{1273IM}{\rho_m d_i^2} \tag{12}$$

The input capacity or diameter of a chimney may usually be found without determining flow velocity. Internal or exit velocity must occasionally be known, to ensure effluent dispersal or avoid flow noise. Also, the flow velocity of incinerator chimneys, turbine exhaust systems, and other appliances with high outlet pressures or velocities is needed to estimate piping loss coefficients.

Equations (9), (11), (12), and (20) can be applied to find velocity. The velocity may also be calculated by dividing volumetric flow rate Q by chimney area A. A similar calculation may be performed when the energy input is known. For example, a 500 mm diameter chimney serving a 4 kW propane gas appliance, at 8.5% CO_2 and 200 K above ambient in the chimney, produces (from Figure 2) 0.49 kg/MJ mass flow rate and 0.68 m^3/MJ volume flow rate at sea level. Chimney gas flow rate is

$$Q = 4 \times 0.68 = 2.72 \text{ m}^3/\text{s} \tag{13}$$

Dividing by area to obtain velocity, $V = 2.72/0.1963 = 13.86$ m/s.

Chimney gas velocity affects the piping friction factor k_L and roughness correction factor. The section on Resistance Coefficients has further information, and Example 2 illustrates how these factors are used in the velocity equations.

Chimney systems can operate over a wide range of velocities, depending on modulation characteristics of the burner system or the number of appliances in operation. Typical velocity in vents and chimneys ranges from 1.5 to 15 m/s. A chimney design developed for maximum input and maximum velocity should be satisfactory at reduced input because theoretical draft is roughly proportional to flue gas temperature rise, whereas flow losses are proportional to the square of the velocity. Thus, as input is reduced, flow losses decrease more rapidly than system motive pressures.

Effluent dispersal may occasionally require a minimum upward chimney outlet velocity, such as 15 m/s. A tapered exit cone can best meet this requirement. For example, to increase the outlet velocity from the 500 mm diameter chimney ($A = 0.1963$ m^3 area) from 12.8 to 15 m/s, the cone must have a discharge area of $0.1963 \times 12.8/15 = 0.168$ m^2 and a 460 mm diameter. An exit cone avoids excessive flow losses because the entire system operates at the lower velocity, and a resistance factor is only added for the cone. In this case, the added resistance for a gradual taper approximates the following (see Table 9):

$$k = \left(\frac{d_{i1}}{d_{i2}}\right)^4 - 1 = \left(\frac{500}{460}\right)^4 - 1 = 0.396 \tag{14}$$

Noise in chimneys may be caused by turbulent flow at high velocity or by combustion-induced oscillations or resonance. Noise is seldom encountered in gas vent systems or in systems producing positive available draft, but it may be a problem with forced-draft appliances. Turbulent flow noise can be avoided by designing for lower velocity, which may entail increasing the chimney size above the minimum recommended by the appliance manufacturer. Chapter 49 of the 2023 *ASHRAE Handbook—HVAC Applications* has more information on noise control.

System Resistance Coefficient

The velocity head method of determining resistance losses assigns a fixed numerical coefficient (independent of velocity) or k factor to every fitting or turn in the flow circuit, as well as to piping.

The resistance coefficient k that appears in Equations (19) and (21) summarizes the friction loss of the entire chimney system, including piping, fittings, and configuration or interconnection factors. Capacity of the chimney varies inversely with the square root of k, whereas diameter varies as the fourth root of k. The insensitivity of diameter and input to small variations in k simplifies design. Analyzing details such as pressure regain, increasers and reducers, and gas cooling junction effects is unnecessary if slightly high resistance coefficients are assigned to any draft diverters, elbows, tees, terminations, and, particularly, piping.

For any chimney with fittings, the total flow resistance is a constant plus variable piping resistance (a function of centerline length divided by diameter). Table 9 suggests moderately conservative resistance coefficients for common fittings. Elbow resistance may be lowered by long-radius turns; however, corrugated 90° elbows may have resistance values at the high end of the scale. Table 9 shows resistance as a function of inlet diameter d_{i1} and outlet diameter d_{i2}.

Table 9 Resistance Loss Coefficients

Component	Suggested Design Value, Dimensionless*	Estimated Span and Notes
Inlet acceleration (k_1)		
Gas vent with draft hood	1.5	1.0 to 3.0
Barometric regulator	0.5	0.0 to 0.5
Direct connection	0.0	Also dependent on blocking damper position
Round elbow (k_2)		
90°	0.75	0.5 to 1.5
45°	0.3	—
Tee or 90° connector (k_3)	1.25	1.0 to 4.0
Y connector	0.75	0.5 to 1.5
Cap, top (k_4)		
Open straight	0.0	—
Low-resistance (UL)	0.5	0.0 to 1.5
Other	—	1.5 to 4.5
Spark screen	0.5	—
Converging exit cone	$(d_{i1}/d_{i2})^4 - 1$	System designed using d_{i1}
Tapered reducer (d_{i1} to d_{i2})	$1 - (d_{i2}/d_{i1})^4$	System designed using d_{i2}
Increaser	—	See Chapter 2, 2021 *ASHRAE Handbook—Fundamentals.*
Piping (k_L)	$0.033L/d_f$	Numerical coefficient (friction factor F) from 0.017 to 0.042; see Figure 12, Chapter 2, 2021 *ASHRAE Handbook—Fundamentals* for size, roughness, and velocity effects.

* Initial assumption, when size is unknown: $k = 5.0$ for entire system, for first trial; $k = 7.5$ for combined gas vents only

Note: For combined gravity gas vents serving two or more appliances (draft hoods), multiply total k (components + piping; see Equations [15], [16], and [17]) by 1.5 to obtain gravity system design coefficient. (This rule does not apply to forced- or induced-draft vents or chimneys.)

System resistance k may be expressed as follows:

$$k = k_f + k_L \tag{15}$$

with

$$k_f = k_1 + n_2k_2 + n_3k_3 + k_4 + \cdots \tag{16}$$

and

$$k_L = \frac{FL}{d_i} \tag{17}$$

where

k_f = fixed fitting loss coefficient
k_L = piping resistance loss function (Figure 13, Chapter 3 of the 2021 *ASHRAE Handbook—Fundamentals*, adjusted for units)
k_1 = inlet acceleration coefficient
k_2 = elbow loss coefficient, n_2 = number of elbows
k_3 = tee loss coefficient, n_3 = number of tees
k_4 = cap, top, or exit cone loss coefficient
F = friction factor
L = length of all piping in chimney system, m
d_i = inside diameter, m

For combined gas vents using appliances with draft hoods, the summation k must be multiplied by a diversity factor of 1.5 (see Table 9 note and Example 4). This multiplier does not apply to forced- or induced-draft vents or chimneys.

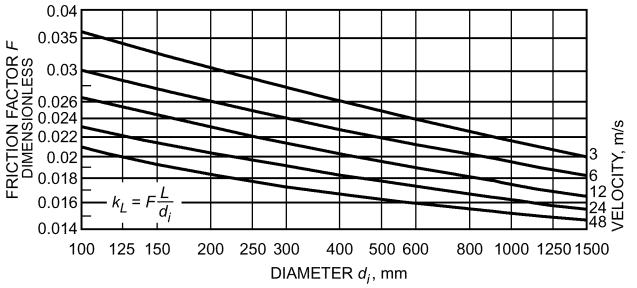

Fig. 5 Friction Factor for Commercial Iron and Steel Pipe

(Lapple 1949)

When size is unknown, the following k values may be used to run a first trial estimate:

k = 5.0 for the entire system
k = 7.5 for combined gas vents only

The resistance coefficient method adapts well to systems in which the fittings cause significant losses. Even for extensive systems, an initial assumption of $k = 5.0$ gives a tolerably accurate vent or chimney diameter in the first trial solution. Using this diameter with the piping resistance function (Equation [17]) in a second trial normally yields the final answer.

The minimum system resistance coefficient in a gas vent with a draft hood is always 1.0 because all gases must accelerate through the draft hood from almost zero velocity to vent velocity.

For a system connected directly to the outlet of a boiler or other appliance where the capacity is stated as full-rated heat input against a positive static pressure at the chimney connection, minimum system resistance is zero, and no value is added for existing velocity head in the system.

For simplified design, a value of 0.4 for F in Equation (17) applies for all sizes of vents or chimneys and for all velocities and temperatures. As diameter increases, this function becomes increasingly conservative, which is desirable because larger chimneys are more likely to be made of rough masonry construction or other materials with higher pressure losses. The 0.033 constant also introduces an increasing factor of safety for flow losses at greater lengths and heights.

Figure 5 is a plot of friction factor F versus velocity and diameter for commercial iron and steel pipe at a flue gas temperature of 150°C above ambient (Lapple 1949). The figure shows, for example, that a 1.2 m diameter chimney with a flue gas velocity of 24 m/s may have a friction factor as low as 0.016. In most cases, $k_L = 0.025\ L/d_i$ gives reasonable design results for chimney sizes 460 mm and larger because systems of this size usually operate at flue gas velocities greater than 3 m/s.

At 540°C or over, the factors in Figure 5 should be multiplied by 1.2. Because Figure 5 is for commercial iron and steel pipe, an additional correction for greater or less surface roughness may be imposed. For example, the factor for a very rough 300 mm diameter pipe may be doubled at a velocity as low as 10 m/s.

For most chimney designs, a friction factor F of 0.033 gives a conservative solution for diameter or input for all sizes, types, and operating conditions of prefabricated and metal chimneys; alternatively, $F = 0.025$ is reasonable if the diameter is 460 mm or more. Because neither input nor diameter is particularly sensitive to the total friction factor, the overall value of k requires little correction.

Masonry chimneys, including those lined with clay flue tile, may have rough surfaces, tile shape variations that cause misalignment, and joints at frequent intervals with possible mortar protrusions. In addition, the inside cross-sectional area of liner shapes may be less than expected because of local manufacturing variations, as well as

differences between claimed and actual size. To account for these characteristics, the estimate for k_L should be on the high side, regardless of chimney size or velocity.

Computations should be made by assuming smooth surfaces and then adding a final size increase to compensate for shape factor and friction loss. Performance or capacity of metal and prefabricated chimneys is generally superior to that of site-constructed masonry.

Configuration and Manifolding Effects

The most common configuration is the individual vent, stack, or chimney, in which one continuous system carries products from appliance to terminus. Other configurations include the combined vent serving a pair of appliances, the manifold serving several, and branched systems with two or more lateral manifolds connected to a common vertical system. As the number of appliances served by a common vertical vent or chimney increases, the precision of design decreases because of diversity factors (variation in the number of appliances in operation) and the need to allow for maximum and minimum input operation (Stone 1957). For example, the vertical common vent for interconnected gas appliances must be larger than for a single appliance of the same input to allow for operating diversity and draft hood dilution effects. Connector rise, headroom, and configuration in the equipment room must be designed carefully to avoid draft hood spillage and related oxygen depletion problems.

For typical combined vents, the diversity effect must be introduced into the equations by multiplying system resistance loss coefficient k by 1.5 (see Table 9 note and Example 4). This multiplier compensates for junction effect and part-load operation.

Manifolds for appliances with barometric draft regulators can be designed without allowing for dilution air through inoperative appliances. In this case, because draft regulators remain closed until regulation is needed, dilution under part load is negligible. In addition, airflow through any inoperative appliance is negligible because the combustion air inlet dampers are closed and the multiple-pass heat exchanger has a high internal flow resistance.

Manifold systems of oil-burning appliances, for example, have a lower flow velocity and, hence, lower losses. As a result, they produce reasonable draft at part load or with only one of several appliances in operation. Therefore, diversity of operation has little effect on chimney design. Some installers set each draft regulator at a slightly different setting to avoid oscillations or hunting possibly caused by burner or flow pulsations.

Calculation of the resistance coefficient of any portion of a manifold begins with the appliance most distant from the vertical portion. All coefficients are then summed from its outlet to the vent terminus. The resistance of a series of tee joints to flow passing horizontally straight through them (not making a turn) is the same as that of an equal length of piping (as if all other appliances were off). This assumption holds whether the manifold is tapered (to accommodate increasing input) or of a constant size large enough for the accumulated input.

Coefficients are assigned only to inlet and exit conditions, to fittings causing turns, and to the piping running from the affected appliance to the chimney exit. Initially, piping shape (round, square, or rectangular) and function (for connectors, vertical piping, or both) are irrelevant.

Some high-pressure, high-velocity packaged boilers require special manifold design to avoid turbulent flow noise. Figure 6 shows a typical configuration for this application. The loss coefficients listed in Table 9 for standard tees and elbows are higher than necessary for long-radius elbows or Y entries. Occasionally, on appliances with high chimneys augmenting boiler outlet pressure, it may appear feasible to reduce the diameter of the vertical portion to below the size recommended by the manufacturer. However, any reduction may cause turbulent noise, even though all normal design parameters have been considered.

With the simplifying assumption that the maximum velocity of the flue gas (which exists in the smaller of the two portions) exists throughout the entire system, and Equations (18) and (19) can be used to calculate the size of a vertical portion smaller in area than the manifold or of a chimney connector smaller than the vertical. This assumption leads to a conservative design because true losses in the larger area are lower than assumed. Further, if the size change is small, either as a contraction or expansion, the added loss coefficient for this transition fitting (see Table 9) is compensated for by reduced losses in the enlarged part of the system.

These comments on size changes apply more to individual than to combined systems because it is undesirable to reduce the vertical area of the combined type, and, more frequently, it is desirable to enlarge it. If an existing vertical chimney is slightly undersized for the connected load, the complete chart method must be applied to determine whether a pressure boost is needed, because size is no longer a variable.

Sectional gas appliances with two or more draft hoods do not pose any special problems if all sections fire simultaneously. In this case, the designer can treat them as a single appliance. The appliance installation instructions either specify the size of manifold for interconnecting all draft hoods or require a combined area equal to the sum of all attached draft hood outlet areas. Once the manifold has been designed and constructed, it can be connected to a properly sized chimney connector, vent, or chimney. If the connector and chimney size is computed as less than manifold size (as may be the case with a tall chimney), the operating resistance of the manifold will be lower than the sum of the assigned component coefficients because of reduced velocity.

The general rule for conservative system design, in which manifold, chimney connector, vent, or chimney are different sizes, can be stated as follows: Always assign full resistance coefficient values to all portions carrying combined flow, and determine system capacity from the smallest diameter carrying the combined flow. In addition, horizontal chimney connectors or vent connectors should pitch upward toward the stack at a minimum of 20 mm per metre of connector length.

Input, Diameter, and Temperature Relationships

To obtain a design equation in which all terms are readily defined, measured, or predetermined, the gas velocity and density terms must be eliminated. Using Equation (4) to replace ρ_m and Equation (12) to replace V in Equation (9) gives

$$\Delta p = \frac{k}{2}\left(\frac{T_m B_o}{\rho_o T_s B}\right)\left(\frac{4 \times 10^6\, IM}{\pi d_i^2}\right)^2 \tag{18}$$

Rearranging to solve for I and including the values of π, T_o, ρ_o, and B_o gives

$$I = 6.55 \times 10^{-8} \frac{d_i^2}{M}\left(\frac{\Delta p B}{k T_m}\right) \tag{19}$$

Solving for input using Equation (19) is a one-step process, given the diameter and configuration of the chimney. More frequently, however, input, available draft, and height are given and the diameter d_i must be found. Because system resistance is a function of the chimney diameter, a trial resistance value must be assumed to calculate a trial diameter. This method allows for a second (and usually accurate) solution for the final required diameter.

Volumetric Flow in Chimney or System

Volumetric flow Q may be calculated in a chimney system for which Equation (19) can be solved by solving Equation (9) for velocity at mean density (or temperature) conditions:

$$V = \sqrt{\frac{2\Delta p}{k\rho_m}} \tag{20}$$

This equation can be expressed in terms of the same variables as Equation (19) by using the density value ρ_m of Equation (4) in Equation (20) and then substituting Equation (20) for velocity V. Area is expressed in terms of d_i. Multiplying area and velocity and adjusting for units,

$$Q = 18.8 \times 10^{-6}\, d_i^2 \left(\frac{\Delta p T_m}{kB}\right)^{1/2} \tag{21}$$

where Q = volumetric flow rate, m^3/s. The volumetric flow obtained from Equation (21) is at mean gas temperature T_m and local barometric pressure B. Equations (19) and (21) do not account for the effects of heat transfer or cooling on flow, draft, or capacity.

Equation (21) is useful in the design of forced-draft and induced-draft systems because draft fans are usually specified in terms of volumetric flow rate at some standard ambient or selected gas temperature. An induced-draft fan is necessary for chimneys that are undersized, that are too low, or that must be operated with draft in the manifold under all conditions.

5. STEADY-STATE CHIMNEY DESIGN GRAPHICAL SOLUTIONS

Design ambient temperature is 15.6°C (288.9 K), and all temperatures given are in terms of rise above this ambient.

Theoretical draft may be corrected for altitude or reduced air density by multiplying the operating input by the factor in Table 7.

The resistance coefficient k summarizes the friction loss of the entire chimney system, including piping, fittings, and configuration or interconnection factors.

Figure 2 can be used to estimate mass and volumetric flow.

Table 6 lists approximate theoretical draft for typical gas temperature rises above 15.6°C ambient.

The equations are based on the fuel combustion products and temperatures in the chimney system.

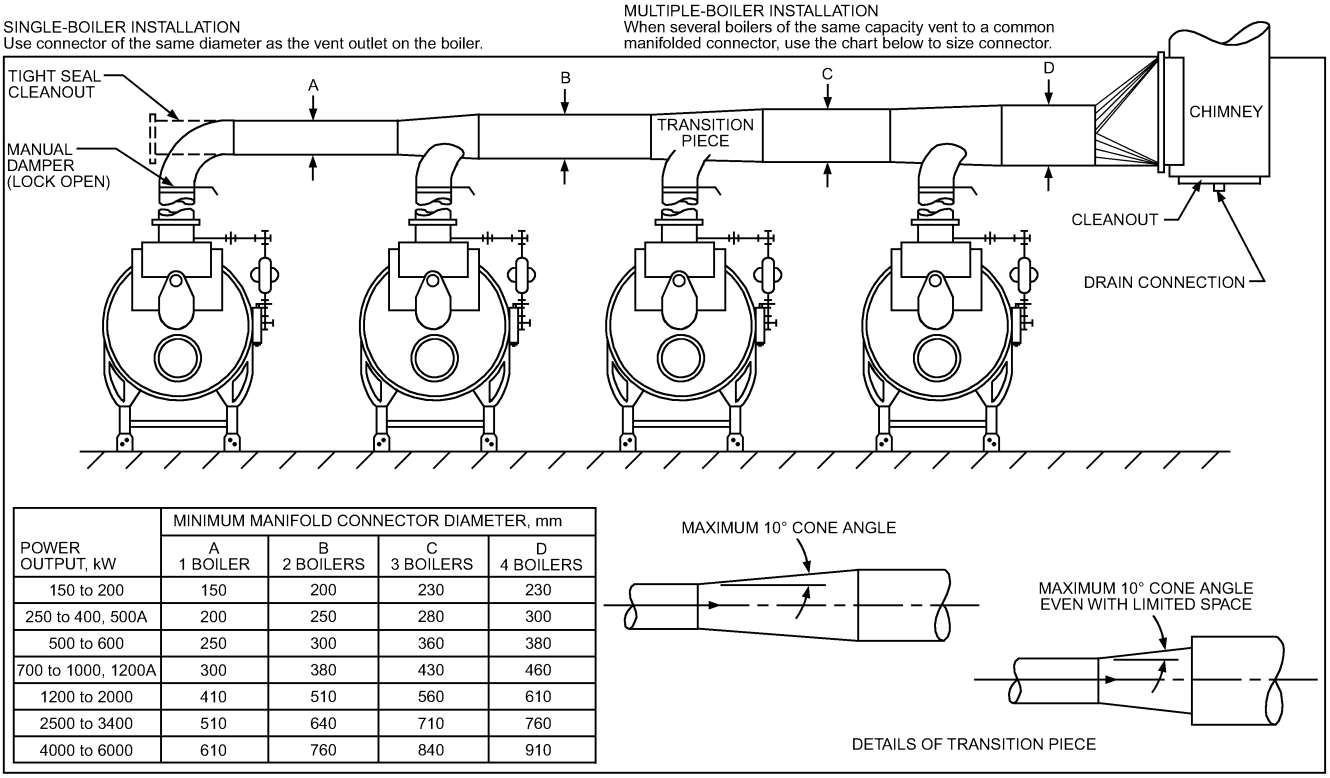
The first trial solution for diameter, using Equations (19) and (21), need not consider the cooling temperature multiplier, even for small sizes. A first approximate size can be used for the temperature multiplier for all subsequent trials because capacity is insensitive to small changes in temperature.

The equations do not contain the same number or order of steps as the derivation; for example, a step disappears when theoretical and available drafts are combined into Δp. Similarly, the examples selected vary in their sequence of solution, depending on which parameters are known and on the need for differing answers, such as diameter for a given input, diameter versus height, or the amount of pressure boost D_b from a forced-draft fan.The following sample calculation illustrates the direct solution for input, velocity, and volume.

Example 1. Find the input capacity (MJ/s) of a vertical, double-wall type B gas vent, 600 mm in diameter, 30 m high at sea level. This vent is used with draft hood natural-gas-burning appliances.

Solution:

1. Mass flow from Table 2. $M = 0.661$ kg/MJ for natural gas, if no other data are given.
2. Temperature from Table 4. Temperature rise = 165 K and $T_m = 180 + 273 = 453$ K for natural gas.



POWER OUTPUT, kW	MINIMUM MANIFOLD CONNECTOR DIAMETER, mm			
	A 1 BOILER	B 2 BOILERS	C 3 BOILERS	D 4 BOILERS
150 to 200	150	200	230	230
250 to 400, 500A	200	250	280	300
500 to 600	250	300	360	380
700 to 1000, 1200A	300	380	430	460
1200 to 2000	410	510	560	610
2500 to 3400	510	640	710	760
4000 to 6000	610	760	840	910

Fig. 6 Typical Connector Design

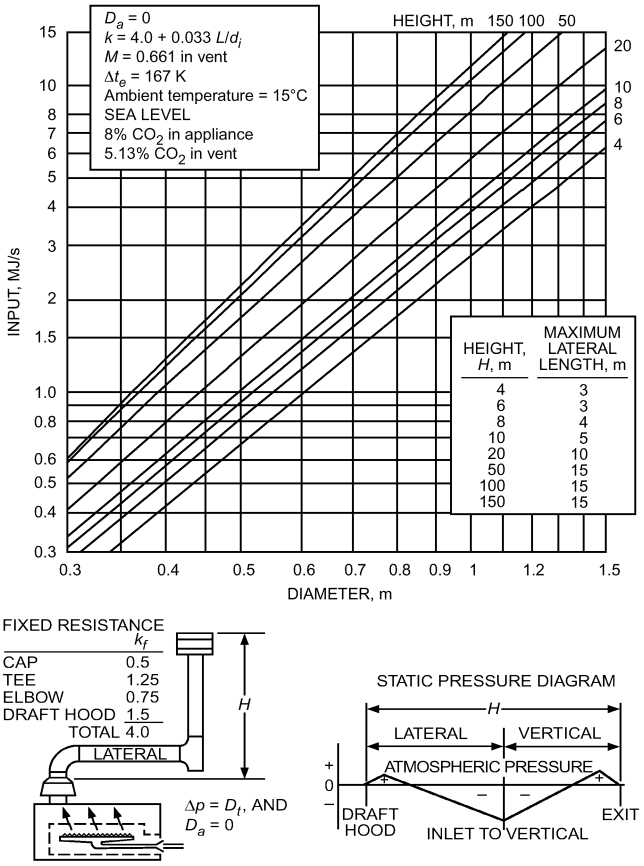


Fig. 7 Gas Vent with Lateral

3. Theoretical draft from Table 6 or Equation (7). For 30 m height at 165 K rise, D_t = 131 Pa.
4. Available draft for draft hood appliances: D_a = 0.
5. Flow losses from Table 8. $\Delta p = D_t$ = 131 Pa; flow losses for a gravity gas vent equal theoretical draft at mean gas temperature.
6. Resistance coefficients from Table 9. For a vertical vent,

Draft hood	k_1 =	1.5
Vent cap	k_4 =	1.0
30 m piping	$k_L = 0.033(30/0.6)$ =	1.65
System total	k =	4.15

7. Solution for input.

   Altitude: Sea level, B = 101 325 Pa from Table 7. d_i = 600 mm. These values are substituted into Equation (19) as follows:

$$I = 6.55 \times 10^{-8} \frac{(600)^2}{0.661}\left(\frac{(131)(101\ 325)}{(4.15)(453)}\right)^{1/2}$$

$$I = 3.00 \text{ MJ/s input capacity}$$

8. A solution for velocity requires a prior solution for input to apply to Equation (12). First, using Equation (4),

$$\rho_m = 0.00348\left(\frac{101\ 325}{453}\right) = 0.778 \text{ kg/m}^3$$

From Equation (12),

$$V = \frac{4 \times 10^6 (3.00)(0.661)}{(3.14)(0.778)(600)^2} = 9.01 \text{ m/s}$$

9. Volume flow can now be found because velocity is known. The flow area of 600 mm diameter is 0.283 m^2, so

$$Q = 0.283 \times 9.01 = 2.55 \text{ m}^3/\text{s}$$

No heat loss correction is needed to find the new flue gas temperature because the size is greater than 500 mm, and this vent is vertical with no horizontal connector.

6. VENT AND CHIMNEY CAPACITY CALCULATION EXAMPLES

Figures 7 to 10 show chimney capacity for individually vented appliances computed by the methods presented. These capacity curves may be used to estimate input or diameter for Equation (19) or Equation (21). These capacity curves apply primarily to individually vented appliances with a lateral chimney connector; systems with two or more appliances or additional fittings require a more detailed analysis. Figures 7 to 10 assume the length of the horizontal connector is (1) at least 3 m and (2) no longer than 50% of the height or 15 m, whichever is less. For chimney heights of 3 to 6 m, a fixed 3 m long connector is assumed. Between 6 and 30 m, the connector is 50% of the height. If the chimney height exceeds 30 m, the connector is fixed at 15 m long.

For a chimney of similar configuration but with a shorter connector, the size indicated in the figures is slightly larger than necessary. In deriving the data for Figures 7 to 10, additional conservative assumptions were used, including the temperature correction C_u for double-wall laterals (see Figure 3) and a constant friction factor (0.033) for all sizes.

The loss coefficient k_4 for a low resistance cap is included in Figures 7, 8, and 9. If no cap is installed, these figures indicate a larger size than needed.

Figure 7 applies to a gas vent with draft hood and a lateral that runs to the vertical section. Maximum static draft is developed at the base of the vertical, but friction reduces the observed value to less than the theoretical draft. Areas of positive pressure may exist at the elbow above the draft hood and at the inlet to the cap. The height of the system is the vertical distance from the draft hood outlet to the vent cap.

Figure 8 applies to a typical boiler system requiring both negative combustion chamber pressure and negative static outlet pressure. The chimney static pressure is below atmospheric pressure, except for the minor outlet reversal caused by cap resistance. Height of this system is the difference in elevation between the point of draft measurement (or control) and the exit. (Chimney draft should not be based on the height above the boiler room floor.)

Figure 9 shows the use of a negative static pressure connector serving a forced-draft boiler. This system minimizes flue gas leakage in the equipment room. The draft is balanced or neutral, which is similar to a gas vent, with zero draft at the appliance outlet and pressure loss Δp equal to theoretical draft.

Figure 10 applies to a forced-draft boiler capable of operating against a positive static outlet pressure of up to 125 Pa. The chimney system has no negative pressure, so outlet pressure may be combined with theoretical draft to get minimum chimney size. For chimney heights or system lengths less than 125 Pa, the effect of adding 125 Pa positive pressure to theoretical draft causes all curves to fall into a compressed zone. An appliance that can produce 125 Pa positive forced draft (negative draft) is adequate for venting any simple arrangement with up to 30 m of flow path and no wind back pressure, for which additional forced draft is required.

The following examples illustrate the use of the corresponding equations.

Example 2. Gravity incinerator chimney (see Figure 11).

Located at 2400 m elevation, the appliance burns 75 g/s of type 0 waste with 100% excess air at 760°C outlet temperature. Ambient

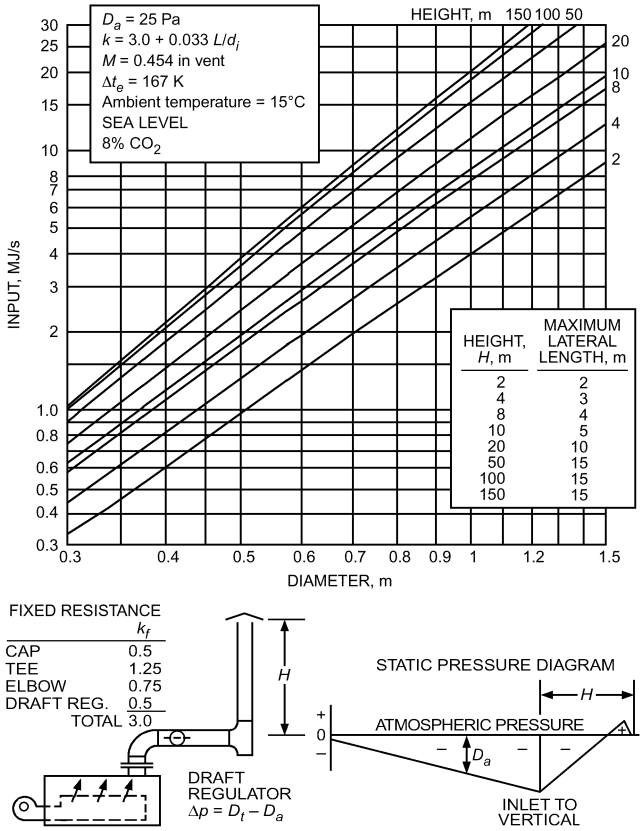

Fig. 8 Draft-Regulated Appliance with 25 Pa Available Draft Required

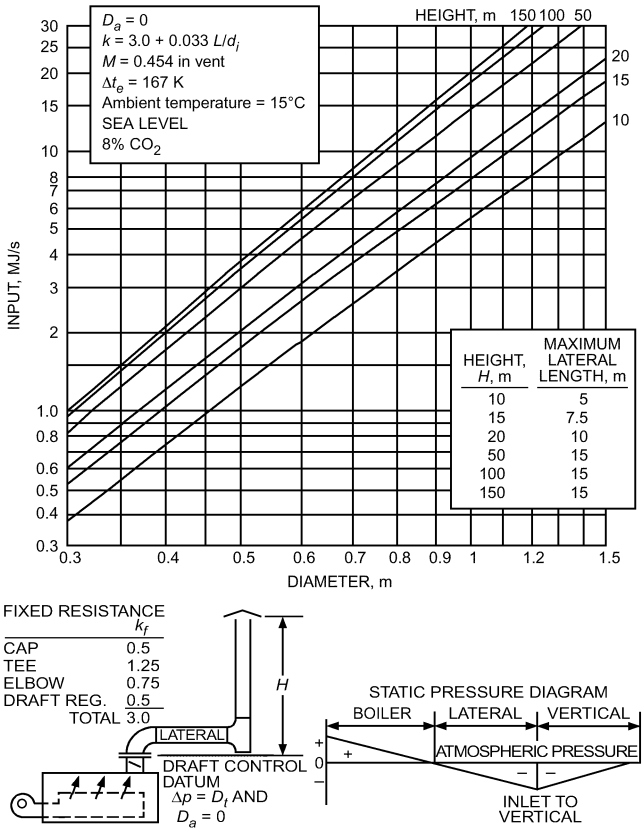

Fig. 9 Forced-Draft Appliance with Neutral (Zero) Draft (Negative Pressure Lateral)

temperature T_o is 15°C. Outlet pressure is zero at low fire, and +75 Pa at high fire. The chimney will be a prefabricated medium-heat type with an 18 m connector and a roughness factor of 1.2. The incinerator outlet is 460 mm in diameter, and it normally uses a 6 m vertical chimney. Find the diameter of the chimney and the connector and the height required to overcome flow and fitting losses.

Solution:

1. Find mass flow from Table 3 as 13.76 kg combustion products per kilogram of waste, or $w = 75 \times 13.76 = 1032$ g/s total.
2. Find mean chimney gas temperature. Based on 18 m length of 460 mm diameter double-wall chimney, $C_u = 0.83$ (see Figure 3). Temperature rise $\Delta t_e = 760 - 15 = 745$ K; thus, $\Delta t_m = 745(0.83) = 618$ K rise above 15°C ambient. $T_m = 618 + 15 + 273 = 906$ K. Use this temperature in Equation (4) to find flue gas density at 2400 m elevation (from Table 7, $B = 75.7$ kPa):

$$\rho_m = 0.00348\left(\frac{75\ 700}{906}\right) = 0.291 \text{ kg/m}^3$$

3. Find the required height by finding theoretical draft per metre from Equation (7) (Table 6 applies only to sea level).

$$\frac{D_t}{H} = (0.0314)(75\ 700)\left(\frac{1}{288} - \frac{1}{906}\right)$$

$$= 6.12 \text{ Pa per metre of height}$$

4. Find allowable pressure loss Δp in the incinerator chimney for a positive-pressure appliance having an outlet pressure of +25 Pa. From Table 8, $\Delta p = D_t + D_a$, where $D_t = 6.12H$, $D_a = 0.25$, and $\Delta p = 6.12H + 25$ Pa.
5. Calculate flow velocity at mean temperature from Equation (11) to balance flow losses against diameter/height combinations:

$$V = \frac{(1000 \times 4)(1032)}{(3.14)(0.291)(460)^2} = 21.4 \text{ m/s}$$

This velocity exceeds the capability of a gravity chimney of moderate height and may require a draft inducer if a 460 mm chimney must be used. Verify velocity by calculating resistance and flow losses by the following steps.

6. From Table 9, resistance coefficients for fittings are

1 Tee	$k_3 = 1.25$
1 Elbow	$k_2 = 0.75$
Spark screen	$k_4 = 0.50$
Fitting total	$k_f = 2.50$

The piping resistance, adjusted for length, diameter, and a roughness factor of 1.2, must be added to the total fitting resistance. From Figure 5, find the friction factor F at 460 mm diameter and 21.4 m/s as 0.0183. Assuming 6 m of height with an 18 m lateral, piping friction loss is

$$k_L = \frac{1.2FL}{d_i} = \frac{(1.2)(0.0183)(18+6)}{460/1000} = 1.15$$

and total $k = 2.50 + 1.15 = 3.65$

Use Equation (9) to find Δp, to determine whether this chimney height and diameter are suitable.

$$\Delta p = \frac{(3.65)(0.291)(21.4)^2}{2} = 243 \text{ Pa flow loss}$$

For these operating conditions, theoretical draft plus available draft yields

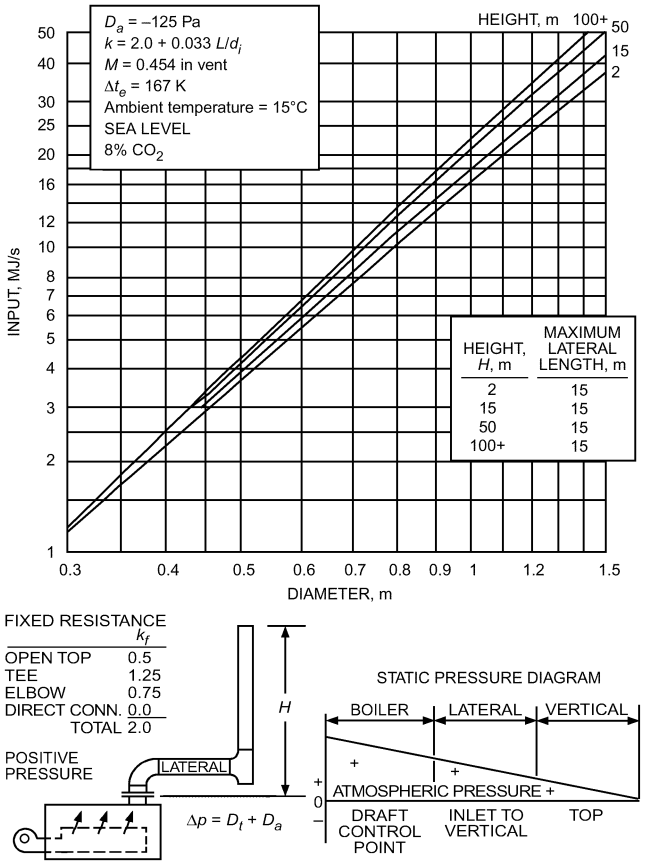

Fig. 10 Forced-Draft Appliance with Positive Outlet Pressure (Negative Draft)

$$\Delta p = (6.12 \times 6) + 25 = 62 \text{ Pa driving force}$$

Flow losses of 243 Pa exceed the 62 Pa driving force; thus, the selected diameter, height, or both are incorrect, and this chimney will not work. This can also be shown by comparing draft per metre with flow losses per metre for the 460 mm diameter configuration:

Flow losses per metre of 460 mm chimney = 243/(18 + 6) = 10 Pa

Draft per metre of height = 6.12 Pa

Regardless of how high the chimney is, losses caused by a 21.4 m/s velocity build up faster than draft.

7. A draft inducer could be selected to make up the difference between losses of 243 Pa and the 62 Pa driving force. Operating requirements are

$$Q = \frac{w}{(1000\rho_m)} = \frac{1032}{(1000 \times 0.291)} = 3.55 \text{ m}^3/\text{s}$$

Δp = 243 – 62 = 181 Pa at 3.55 m^3/s and 618 K rise

If the inducer selected (see Figure 25C) injects single or multiple air jets into the gas stream, it should be placed only at the chimney top or outlet. This location requires no compensation for additional air introduced by an enlargement downstream from the inducer.

Because 460 mm is too small, assume that a 610 mm diameter may work at a 6 m height and recalculate with the new diameter.

1. As before, w = 1032 g/s.
2. At 610 mm diameter, no temperature correction is needed for the 18 m connector. Thus, T_m = 760 + 273 = 1033 K (see Table 4), and density is

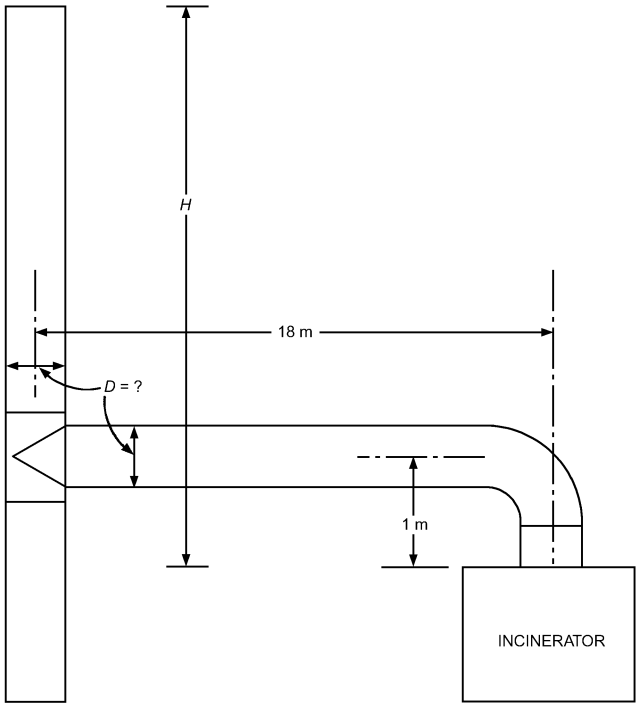

Fig. 11 Illustration for Example 2

$$\rho_m = 0.00348\left(\frac{75\ 700}{1033}\right) = 0.255 \text{ kg/m}^3$$

3. Theoretical draft per metre of chimney height is

$$\frac{D_t}{H} = 0.03413\ (75\ 700)\left(\frac{1}{288} - \frac{1}{1033}\right) = 6.47 \text{ Pa/m}$$

4. Velocity is

$$V = \frac{(1000 \times 4)(1032)}{(3.14)(0.255)(610)^2} = 13.86 \text{ m/s}$$

5. From Figure 5, the friction factor is 0.0188, which, when multiplied by a roughness factor of 1.2 for the piping used, becomes 0.0226. For the entire system with k_f = 2.50 and 24 m of piping, find k = 2.5 + 0.0226(24/0.610) = 3.39. From Equation (9),

$$\Delta p = \frac{(3.39)(0.255)(13.86)^2}{2} = 83.0 \text{ Pa flow losses}$$

$D_t + D_a$ = 6 × 6.47 + 25 = 64 Pa, so driving force is less than losses. The small difference indicates that, although 6 m of height is insufficient, additional height may solve the problem. The added height must make up for 19 Pa additional draft. As a first approximation,

Added height = Additional draft/draft per metre
= 19/6.47 = 2.94 m
Total height = 6 + 2.94 = 8.94 m

This is less than the actual height needed because resistance changes have not been included. For an exact solution for height, the driving force can be equated to flow losses as a function of H. Substituting H = +18 for L in Equation (15) to find k for Equation (9),

$$k = k_f + k_L = k_f + (FL/d_i) = 2.5 + (0.0226 \times 18/0.610) = 3.17$$

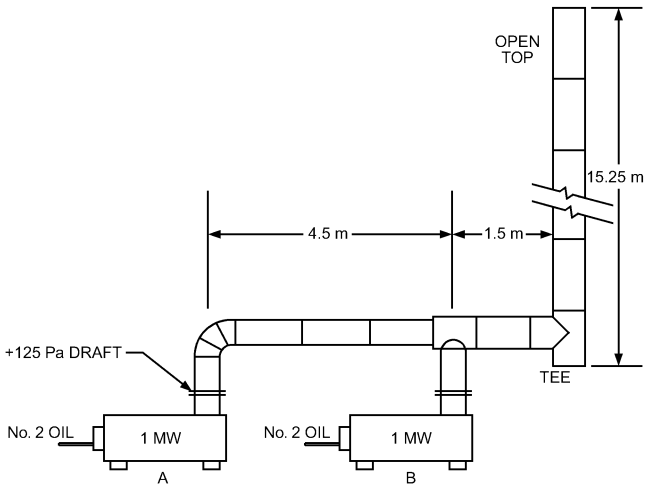

Fig. 12 Illustration for Example 3

$$\text{Driving force} = \Delta p = \frac{k\rho_m V^2}{2}$$

$$25 + 6.47H = \frac{\left[3.17 + (0.0226)\left(\frac{1}{0.610}\right)H\right](0.255)(13.86)^2}{2}$$

$H = 9.464$ m at 610 mm diameter.

Checking by substitution, total driving force = 85.95 Pa and total losses, based on a system with 27.415 m of piping, equal 85.95 Pa.

The value of $H = 9.464$ m is the minimum necessary for proper system operation. Because of the great variation in fuels and firing rate with incinerators, greater height should be used to ensure adequate draft and combustion control. An acceptable height would be from 12 to 15 m.

Example 3. Two forced-draft boilers (see Figure 12).

This example shows how multiple-appliance chimneys can be separated into subsystems. Each boiler is rated 1 MJ/s (1 MW) on No. 2 oil. The manufacturer states flue gas operation at 13.5% CO_2 and 165 K temperature rise against 125 Pa positive static pressure at the outlet. The 15.25 m high chimney has a 6 m single-wall manifold and is at sea level. Find the size of connectors, manifold, and vertical.

Solution: First, find the capacity or size of the piping and fittings from boiler A to the tee over boiler B. Then, size the boiler B tee and all subsequent portions to carry the combined flow of A and B. Also, check the subsystem for boiler B; however, because its shorter length compensates for greater fitting resistance, its connector may be the same size as for boiler A.

Find the size for combined flow of A and B either by assuming $k = 5.0$ or by estimating that the size will be twice that found for boiler A operating by itself. Estimate system resistance for the combined portion by including those fittings in the B connector with those in the combined portion.

Data needed for the solution of Equation (19) for boiler A for No. 2 oil at 13.5% CO_2 include the following:

$$M = 0.31\left(0.12 + \frac{14.4}{13.5}\right) = 0.368 \text{ kg/MJ} \qquad \text{(from Table 1)}$$

For a temperature rise of 165 K and an ambient of 15°C,

$$T_m = 165 + 15 + 273 = 453 \text{ K}$$

Interpolating from Table 6, theoretical draft = 4.3 Pa per metre of height; for 15.25 m height, $D_t = (4.3)(15.25) = 65.6$ Pa.

Using a positive outlet pressure of 125 Pa as available draft, $\Delta p = 65.6 + 125 = 190.6$ Pa.

Assume $k = 5.0$. Assuming 80% efficiency, input is 1.25 MJ/s. Substitute in Equation (19):

$$I = 1.25 - 6.55 \times 10^{-8}\,\frac{d_i^2}{0.368}\left(\frac{190.6 \times 101\,325}{5.0 \times 453}\right)^{1/2}$$

Solving, $d_i = 276$ mm as a first approximation. From Table 9, find correct k using next largest diameter, or 300 mm:

Inlet acceleration (direct connection)	k_1	= 0.0
90° Elbow	k_2	= 0.75
Tee	k_3	= 1.25
21.25 m piping	k_L	= 0.033(21.25) = 2.34
System total	k	= 4.34

Note: Assume tee over boiler B has $k = 0$ in subsystem A.

Corrected temperature rise (see Figure 3 for 6 m single-wall connector) = 0.75 × 165 = 124 K, and $T_m = 124 + 15 + 273 = 412$ K. This corrected temperature rise changes D_t to 3.61 Pa/m (Table 6 or Equation [7]), or 55.1 Pa for 15.25 m. Thus, Δp becomes 55.1 + 125 = 180.1 Pa.

$$125 = 6.55 \times 10^{-8}\,\frac{d_i^2}{0.368}\left(\frac{180.1 \times 101\,325}{4.34 \times 412}\right)^{1/2}$$

So $d_i = 264$ mm, or a 300 mm diameter is adequate.

For size of manifold and vertical, starting with the tee over boiler B, assume 400 mm diameter (see also Figure 10).

System $k = 3.88$ for the 16.75 m of piping from B to outlet:

Inlet acceleration	k_1	= 0.0
Two tees (boiler B subsystem)	k_3	= 2.5
16.75 m piping	k_L	= 0.033(16.75/0.4) = 1.38
System total	k	= 3.88

Temperature and Δp will be as corrected (a conservative assumption) in the second step for boiler A. Having assumed a size, find input.

$$I = 6.55 \times 10^{-8}\,\frac{400^2}{0.368}\left(\frac{180.1 \times 101\,325}{3.88 \times 412}\right)^{1/2} = 3.04 \text{ MJ/s}$$

A 400 mm diameter manifold and vertical is more than adequate. Solving for the diameter at the combined input, $d_i = 364$ mm; thus, a 400 mm chimney must be used.

Note: Regardless of calculations, do not use connectors smaller than the appliance outlet size in any combined system. Applying the temperature correction for a single-wall connector has little effect on the result because positive forced draft is the predominant motive force for this system.

Example 4. Six gas boilers manifolded at 1825 m elevation (see Figure 13).

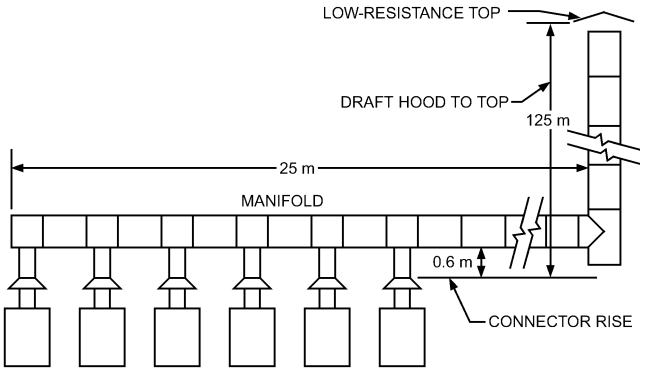

Fig. 13 Illustration for Example 4

Each boiler is fired at 0.5 MJ/s, with draft hoods and an 25 m long manifold connecting into a 125 m high vertical. Each boiler is controlled individually. Find the size of the constant-diameter manifold, vertical, and connectors with a 0.6 m rise. All are double-wall.

Solution: Simultaneous operation determines both the vertical and manifold sizes. Assume the same appliance operating conditions as in Example 1: CO_2 = 5.3%, natural gas, flue gas temperature rise = 165 K. Initially assume k = 5.0 is multiplied by 1.5 for combined vent (see note at bottom of Table 9); thus, design k = 7.5. For a gas vent at 125 m height, $\Delta p = D_t = H \times D_t/m = 125 \times 4.3 = 537$ Pa rise 165 K in Table 6; D_t = 4.3 Pa/m. At 1825 m elevation, operating input must be multiplied by an altitude correction (Table 7) of 1.25. Total design input is 0.5(6)(1.25) = 3.75 MW. From Table 2, M = 0.661 kg/MJ at operating conditions. T_m = 165 + 15 + 273 = 453 K, and B = 101 325 Pa because the 1.25 input multiplier corrects back to sea level. From Equation (19),

$$0.5 \times 6 \times 1.25 = 3.75 = 6.55 \times 10^{-8} \frac{d_i^2}{0.661}\left(\frac{537 \times 101\ 325}{7.5 \times 453}\right)^{1/2}$$

$$d_i = 547 \text{ mm}$$

Because the diameter is greater than 500 mm, no temperature correction is needed.

Recompute k for 25 + 125 m of 600 mm diameter (Table 9):

Draft hood inlet acceleration		k_1 = 1.5
Two tees (connector and base of chimney)		$2k_3$ = 2.5
Low-resistance top		k_4 = 0.5
150 m piping	$k_L = 0.033(150/0.6)$	= 8.25
System total		k = 12.75

Combined gas vent design k = multiple vent factor 1.5 × 12.75 = 19.12. Substitute again in Equation (19):

$$3.75 = 6.55 \times 10^{-8} \left(\frac{d_i^2}{0.661}\right)\left(\frac{537 \times 101\ 325}{19.12 \times 453}\right)^{1/2}$$

$$d_i = 691 \text{ mm; thus use 700 mm}$$

$$k_f = 4.5$$
$$k_L = 0.033(150/0.700) = 7.1$$
$$k = 11.6$$

$$(1.5)(11.6) = 17.4$$

Substitute in Equation (19) to obtain the third trial:

$$3.75 = 6.55 \times 10^{-8} \frac{d_i^2}{0.661}\left(\frac{537 \times 101\ 325}{17.4 \times 453}\right)^{1/2}$$

$$d_i = 675 \text{ mm}$$

The third trial is less than the second and again shows the manifold and vertical chimney diameter to be between 600 and 700 mm.

For connector size, see the *National Fuel Gas Code* (NFPA *Standard* 54/AGA *Standard* Z223.1) for double-wall connectors of combined vents. The height limit of the (I-P only) table is 30.48 m (100 ft); do not extrapolate and read the capacity of 457 mm (18 in.) connector as 510 MJ/s (MW) (1 740 000 Btu/h) at 610 mm (2 ft) rise. Use 457 mm connector or draft hood outlet, whichever is larger. No altitude correction is needed for connector size; the draft hood outlet size considers this effect.

Note: Equation (19) can also be solved at local elevation for exact operating conditions. At 1825 m, the local barometric pressure is 81.3 kPa (interpolated from Table 7), and assumed theoretical draft must be corrected in proportion to the reduction in pressure:

D_t = 537(81.3/101 325) = 431 Pa. Operating input of 6 × 0.5 = 3 MJ/s is used to find d_i, again taking final k = 17.4:

$$0.5 \times 6 = 6.55 \times 10^{-8} \left(\frac{d_i^2}{0.661}\right)\left(\frac{431 \times 81\ 300}{17.4 \times 453}\right)^{1/2}$$

$$d_i = 674 \text{ mm (virtually the) same as above)}$$

This example illustrates the equivalence of the two solutions. Equation (19) gives the correct solution using either method 1, with only the fuel input corrected back to sea-level condition, or method 2, correcting Δp for local barometric pressure and using operating input at altitude.

Example 5. Pressure boost for undersized chimney (not illustrated).

A natural gas boiler at sea level (no draft hood) is connected to an existing 300 mm diameter chimney. Input is 1.15 MJ/s with flue gas at 10% CO_2 and 165 K temperature rise above ambient. System resistance loss coefficient k = 5.0 with 6 m high chimney. The appliance operates with neutral outlet static draft, so, D_a = 0 Pa.

a. How much draft boost is needed at operating temperature?
b. What fan rating is required at 15°C ambient temperature?
c. Where in the system should the fan be located?

Solution: Combustion data: from Figure 2, 10% CO_2 at 165 K temperature rise indicates 0.48 m^3/s per megawatt (m^3/MJ).

Total flow rate $Q = 0.48 \times 1.15 = 0.552$ m^3/s at chimney gas temperature. Then, Equation (21) can be solved for the only unknown, Δp:

$$0.552 = 18.8 \times 10^{-6}(300)^2 \left[\frac{\Delta p(165 + 15 + 273)}{5.0 \times 101\ 325}\right]^{1/2}$$

Δp = 119 Pa needed at 165 K temperature rise. For 6 m of height at 165 K temperature rise (Table 6 or Equation [7]),

(per Table 6) $D_t = 4.3 \times 6 = 25.8$ Pa

(per Equation [7])

$$D_t = 0.03413\ BH\ [(1/T_o) - (1/T_m)]$$
$$= 0.03413 \times 101\ 325 \times 6\ \{[1/288] - [1/(288 + 165)]\}$$
$$= 26.2 \text{ Pa}$$

a. Pressure boost D_b supplied by the fan must equal Δp minus theoretical draft (Table 8) when available draft is zero. $D_b = \Delta p - D_t$ = 119 – 26 = 93 Pa at operating temperature.

b. Draft fans are usually rated for standard ambient (15°C) air. Pressure is inversely proportional to absolute flue gas temperature. Thus, for ambient air,

$$D_b = 93\frac{T_m}{T_o} = 93\left(\frac{165 + 15 + 273}{15 + 273}\right) = 146 \text{ Pa}$$

This pressure is needed to produce 93 Pa at operating temperature. In specifying power ratings for draft fan motors, a safe policy is to select one that operates at the required flow rate at ambient temperature and pressure (see Example 6).

c. A fan can be located anywhere from boiler outlet to chimney outlet. Regardless of location, the amount of boost is the same; however, chimney pressure relative to atmosphere will change. At boiler outlet, the fan pressurizes the entire connector and chimney. Thus, the system should be gastight to avoid leaks. At the chimney outlet, the system is below atmospheric pressure; any leaks flow into the system and seldom cause problems. With an ordinary sheet metal connector attached to a gastight vertical chimney, the fan may be placed close to the vertical chimney inlet. Thus, the connector leaks safely inward, while the vertical chimney is under pressure.

Example 6. Draft inducer selection (see Figure 14).

A third gas boiler must be added to a two-boiler system at sea level with an 450 mm diameter, 4.6 m horizontal, and 23 m of total height of connector and chimney system. Outlet conditions for natural gas draft hood appliances are 5.3% CO_2 at 165 K temperature rise. Boilers are controlled individually, each with 0.5 MJ/s, for 1.5 MJ/s total input. The system is currently undersized for gravity full-load operation. Find capacity, pressure, size, and power rating of a draft inducer fan installed at the outlet.

Solution: Using Equation (21) requires evaluating two operating conditions: (1) full input at 165 K rise and (2) no input with ambient air. Because the boilers are controlled individually, the system may operate

at nearly ambient temperature (55 K flue gas temperature rise or less) when only one boiler operates at part load. Use the system resistance k for boiler 3 as the system value for simultaneous operation. It needs no compensating increased draft, as with gravity multiple venting, because a fan induces flow at all flue gas temperatures. From Table 9, the resistance summation is

Inlet acceleration (draft hoods)	k_1 =	1.50
Tee above boiler	k_3 =	1.25
Tee at base of vertical	k_3 =	1.25
27.6 m of 450 mm diameter pipe	$k_L = 0.033(27.6/0.45)$ =	2.02
System total	k =	6.02

At full load, $T_m = 165 + 15 + 273 = 453$ K; $B = 101\,325$ Pa. Flow rate Q must be found for operating conditions of 0.661 kg/MJ (Table 2) at density ρ_m and full input 1.5 MJ/s.

From Equation (4),

$$\rho_m = 0.00348B/T_m = 0.00348(101\,325/453) = 0.778 \text{ kg/m}^3$$

Volumetric flow rate is

$$Q = \frac{0.661 \times 1.5}{0.778} = 1.27 \text{ m}^3/\text{s}$$

For 165 K flue gas temperature rise, $D_t = 4.3 \times 23 = 98.9$ Pa theoretical draft in the system (Table 6). Solving Equation (21) for Δp,

$$\Delta p = \frac{(6.02)(101\,325)(1.27)^2}{(18.8 \times 10^{-6})^2 (450)^4 (453)} = 150 \text{ Pa}$$

Thus, a fan is needed because Δp exceeds D_t. Required static pressure boost (Table 8) is

$D_b = 150 - 98.9 = 51.1$ Pa at 165 K flue gas temperature rise or a flue gas density of 0.778 kg/m^3

Fans are rated for ambient or standard air (15 to 20°C) conditions. Flue gas pressure is directly proportional to density or inversely proportional to absolute temperature. Moving 1.27 m^3/s of flue gas at 165 K temperature rise against 51.1 Pa pressure requires the static pressure boost with standard air to be

$$D_b = 51.1(453/288) = 80.4 \text{ Pa}$$

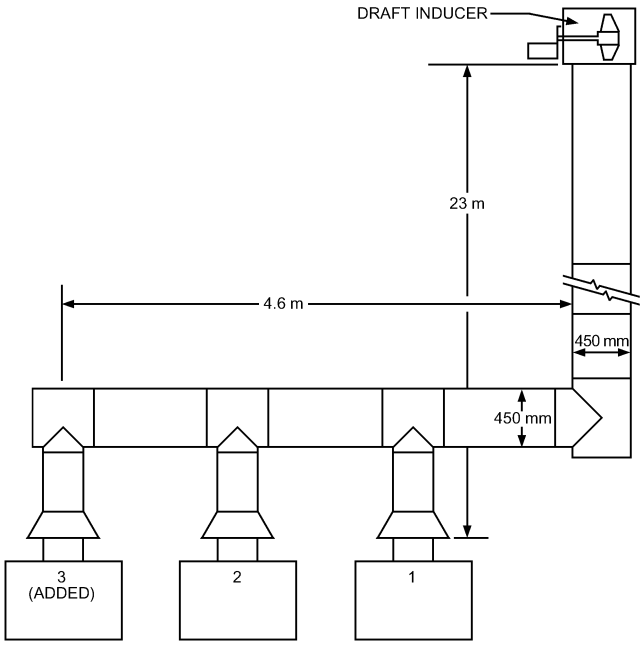

Fig. 14 Illustration for Example 6

Thus, a fan that delivers 1.27 m^3/s of flue gas at 80.4 Pa at 15°C is required. Figure 15 shows the operating curves of a typical fan that meets this requirement. The exact volume flow rate and pressure developed against a system k of 6.02 can be found for this fan by plotting airflow rate versus Δp from Equation (21) on the fan curve. The solution, at point C, occurs at 0.92 m^3/s, where both the system Δp and fan static pressure equal 130 Pa.

Although some fan manufacturers' ratings are given at standard air conditions, the motors selected will be overloaded at temperatures below 165 K air temperature rise. Figure 15 shows that power required for two conditions with ambient air is as follows:

1. 0.92 m^3/s at 130 Pa static pressure requires 0.42 kW
2. 1.27 m^3/s at 80.4 Pa static pressure requires 0.40 kW

Thus, the minimum size motor will be 0.40 kW brake power and run at 1590 rpm.

Manufacturers' literature must be analyzed carefully to discover whether the sizing and selection method is consistent with appliance and chimney operating conditions. Final selection requires both a thorough analysis of fan and system interrelationships and consultation with the fan manufacturer to verify the fan and motor capacity and power ratings.

7. GAS APPLIANCE VENTING

In much of the United States, gas-burning appliances requiring venting of combustion products are installed and vented in accordance with the *National Fuel Gas Code* (NFPA *Standard* 54/AGA Z223.1), and in Canada with the *Natural Gas and Propane Installation Code* (CAN/CSA *Standard* B149.1). This standard includes capacity data and definitions for commonly used gas vent systems. In addition, these codes group vented gas-fired appliances by draft and flue gas conditions as follows:

- Category I appliances operate with nonpositive vent static pressure and a vent gas temperature that avoids excessive condensate production in the vent.

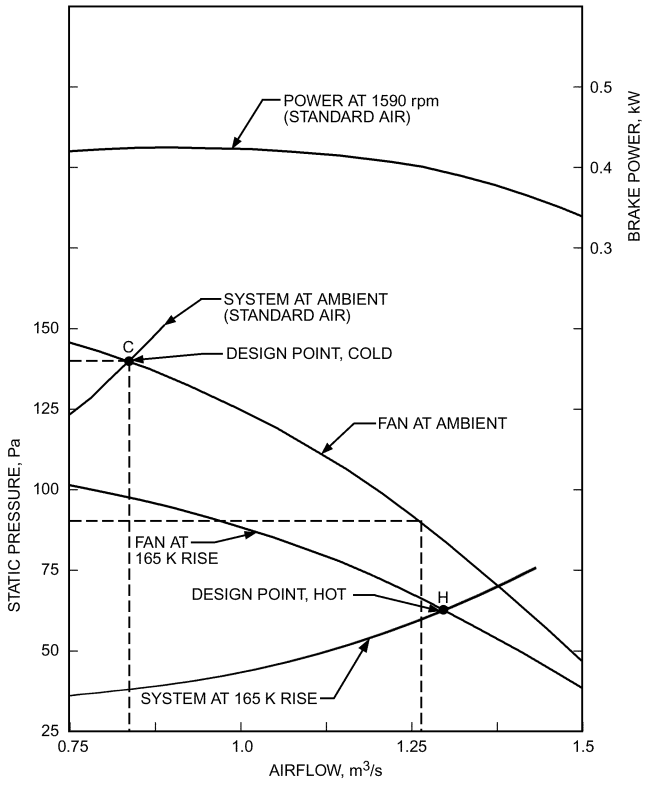

Fig. 15 Typical Fan Operating Data and System Curves

- Category II appliances operate with nonpositive vent static pressure and a vent gas temperature that may cause condensate production in the vent.
- Category III appliances operate with positive vent static pressure and a vent gas temperature that avoids excessive condensate production in the vent.
- Category IV appliances operate with positive vent static pressure and a vent gas temperature that may cause condensate production in the vent.

Category I appliances are further divided into two broad types: **natural-draft** appliances rely solely on flue gas buoyancy to draw combustion air through the appliance/vent system and are equipped with draft hood (integral or external to the appliance itself) used to limit draft at the outlet of the appliance. **Fan-assisted** appliances use a blower to move combustion air through the appliance, but rely on flue gas buoyancy alone to move flue products through the vent system (vent pressure at the outlet of the appliance is zero or negative). From a vent design standpoint, the difference between these two types of Category I appliances is important because the vent systems used with natural-draft Category I appliances must handle not only the products of combustion, but also dilution air drawn into the system through the draft hood. Dilution air increases the total gas volume that must be handled by the vent system, and therefore reduces the capacity of a given size vent system. However, a given vent system handling less dilution air tends to be more prone to forming flue gas condensate, particularly under transient conditions, which can cause corrosion or drainage problems when present in excessive amounts.

Both the National Fuel Gas Code (ANSI/NFPA *Standard* 54/ANSI/AGA Z223.1) and the Natural Gas and Propane Installation Code (CAN/CSA *Standard* B149.1) include tables and other information that can be used to design vent systems for one or more Category I appliances. These tables include maximum capacities, representing the largest appliance input rating that could safely be vented using a given vent diameter, height, lateral, and material. For reasons discussed previously, these capacities are larger for fan-assisted appliances than they are for natural draft appliances. At the same time, these tables specify a *minimum* capacity for a given size chimney used to vent fan assisted appliances to minimize condensate formation. Minimizing condensate formation, as well as the time required to "prime" the chimney (establish draft when the chimney is initially cold) are the reasons for limitations placed by the above codes on the use of single wall vent connectors, and masonry chimneys.

Category I guidelines in these codes were developed using the VENT-II computer program (GTI 2009) to perform transient analysis with the appliance(s) cycling. Gas-fired central furnace cycle times of 3.87 min on, 13.3 min off, 17.17 min total, were determined based on a design outdoor ambient of –14.7°C with an oversize factor of 1.7. One criterion used in developing these guidelines is that the vent connector dry before the end of the appliance on cycle, whereas the vertical portion of the vent is required to dry out before the end of the total cycle.

Methods for determining the category of a given gas appliance vary. ANSI *Standards* Z21.13, Z21.47, and Z21.10 include category determination tests for boilers, furnaces, and water heaters and include a requirement that the resulting category be marked on the appliance's data plate. Appliances not certified to one of these standards may not be categorized at all or may be categorized in a way inconsistent with ANSI test procedures. In such cases, caution should be exercised in attempting to use the venting guidelines mentioned in this section.

No universal venting guidelines exist for Category II, III, or IV appliances. In many cases, guidelines for such an appliance are defined by the appliance manufacturer in terms of an acceptable range of vent length, diameter, material, and terminal design. In such cases, the appliance manufacturer may also specify the means of condensate disposal and vent terminal location. Criteria used to develop these guidelines primarily include maintaining draft (or pressure) at the appliance outlet within acceptable limits, avoiding corrosion damage caused by condensate, and withstanding wind loads. ANSI *Standards* Z21.13, Z21.47, and Z21.10 include performance tests to establish these guidelines and require the manufacturer to publish them in the installation manual. In some cases the appliance manufacturer may specify an acceptable range of draft (or pressure) at the appliance outlet, rather than defining the vent system geometry.

Vent Connectors

Vent connectors connect gas appliances to the gas vent, chimney, or single-wall metal pipe, except when the appliance flue outlet or draft hood outlet is connected directly to one of these vent systems. Materials for vent connectors for conversion burners or other appliances without draft hoods must have resistance to corrosion and heat not less than that of galvanized 0.701 mm thick sheet steel. Where a draft hood is used, the connector must have resistance to corrosion and heat not less than that of galvanized 0.475 mm thick sheet steel or type B vent material.

Masonry Chimneys for Gas Appliances

A masonry chimney serving a gas-burning appliance should have a tile liner and should comply with applicable building codes such as NFPA *Standard* 211. The *National Fuel Gas Code* has other provisions pertaining to masonry chimneys. An additional chimney liner may be needed to avoid slow priming and/or condensation, particularly for an exposed masonry chimney with high mass and low flue gas temperature. A low-temperature chimney liner may be a single-wall passage of pure aluminum or stainless steel or a double-wall type B vent.

Type B and Type L Factory-Built Venting Systems

Factory-prefabricated vents are listed by Underwriters Laboratories for use with various types of fuel-burning appliances. These vents should be installed according to the manufacturer's instructions and the appliance's listing.

Type B gas vents are listed for vented gas-burning appliances. They should not be used for incinerators, appliances readily converted to the use of solid or liquid fuel, or combination gas-oil burning appliances. They may be used in multiple gas appliance venting systems.

Type BW gas vents are listed for vented wall furnaces certified as complying with the pertinent ANSI standard.

Type L venting systems are listed by Underwriters Laboratories in 75 to 150 mm sizes and may be used for those oil- and gas-burning appliances (primarily residential) certified or listed as suitable for this type of venting. Under the terms of the listing, a single-wall connector may be used in open accessible areas between the appliance's outlet and the type L material in a manner analogous to type B. Type L piping material is recognized in the *National Fuel Gas Code* and NFPA *Standard* 211 for certain connector uses between appliances such as domestic incinerators and chimneys.

Gas Appliances Without Draft Hoods

The equations may be used to calculate chimney size for nonresidential gas appliances with the draft configurations listed as 1 and 3 at the beginning of this chapter. Draft conditions 1 and 3 (see draft conditions 1, 2, and 3 under Terminology and Table 8) for residential gas appliances, such as boilers and furnaces, may require special vent systems. The appliance test and certification standards include evaluation of manufacturers' appliance installation instructions (including the vent system) and of operating and application conditions that affect venting. The instructions must be followed strictly.

Conversion to Gas

Installation of conversion burner equipment requires evaluating for proper chimney draft and capacity by the methods in this chapter or by conformance to local regulations. The physical condition and suitability of an existing chimney must be checked before it is converted from a solid or liquid fuel to gas. For masonry chimneys, local experience may indicate how well the construction will withstand the lower temperature and higher moisture content of natural or liquefied petroleum gas combustion products. The section on Masonry Chimneys for Gas Appliances has more details.

The chimney should be relined, if required, with corrosion-resistant masonry or metal to prevent deterioration. The liner must extend beyond the top of the chimney. The chimney drop-leg (bottom of the chimney) must be at least 100 mm below the bottom of the connection to the chimney. The chimney should be inspected and, if needed, cleaned. The chimney should also have a cleanout at the base.

8. OIL-FIRED APPLIANCE VENTING

Oil-fired appliances requiring venting of combustion products must be installed and vented in accordance with ANSI/NFPA *Standard* 31. The standard offers recommendations for metal relining of masonry chimneys.

Recommendations for minimum chimney areas for oil-fired natural-draft appliances are offered in Tables 3 and 4 in the HYDI (1989).

Implementation of the U.S. National Appliance Energy Conservation Act (NAECA) of 1987 brought attention to heating appliance efficiency and the effect of NAECA on existing chimney systems. Oil-fired appliances maintained a steady growth in efficiency since the advent of the retention-head oil burner and its broad application in both new appliances and the replacement of older burners in existing appliances. Higher appliance efficiencies brought about lower flue gas temperatures. Reduced firing rates became more common as heating appliances were more closely matched to the building heating load. Burner excess air levels also dropped, which resulted in lower mass flows through the chimney and additional reductions in the flue gas temperature. However, the improvements in overall appliance efficiency have not been accompanied by upgrades in existing chimney systems, and upgraded systems are not commonly applied in new construction. An upgrade in a vent system probably involves application of corrosion-resistant materials and/or the reduction in heat loss from the vent system to maintain draft and reduce condensation on interior surfaces of the vent system.

Condensation and Corrosion

Condensation and corrosion within the vent system are of growing concern as manufacturers of oil-fired appliances strive to improve equipment efficiencies. The conditions for condensation of the corrosive components of the flue gas produced in oil-fired appliances involve a complex interaction of the water formed in the combustion process and the sulfur trioxide formed from small quantities of sulfur in the fuel oil. The sulfur is typically less than 0.5% by mass for no. 2 fuel oil. The dew point of the two-component system (sulfuric acid and water) in the flue gas resulting from the combustion of this fuel is about 107 to 116°C. This is similar to the effect on dew point of fuel gas sulfur (see Figure 5 in Chapter 28 of the 2021 *ASHRAE Handbook—Fundamentals*). In determining the proper curve for fuel oil in that figure, a value of 111 may be used. This value applies to no. 2 fuel oil with 0.5% sulfur by mass.

The effect of post-combustion air dilution on the dew point characteristics of flue gas from oil-fired appliances is highly dependent on the presence of sulfur in the fuel. Verhoff and Banchero (1974) developed an equation relating flue gas dew point to the partial pressures of both water and sulfuric acid present in the flue gas. Predictions obtained using this equation are in good agreement with experimental data. Applying this equation to the flue gas from the combustion of no. 2 fuel oil without sulfur and with varying sulfur contents reveals that a broad range of dew point temperatures is possible.

For a fuel oil with zero sulfur and 20% excess combustion air, dew point of the combustion products is calculated as approximately 45.6°C, typical for the presence of water formed in combustion. With the addition of post-combustion dilution air to a level equivalent to increasing the excess air in the flue gas to 100%, the apparent water dew point is reduced to 37.2°C. For fuel oil with 0.25% sulfur and 20% excess combustion air, the dew point is elevated to 109.4°C because of formation of dilute sulfuric acid in the flue gas. With the addition of post-combustion dilution air, the dew point is 113.9°C at 100% excess air and 112.2°C at 200% excess air. The implication of these calculations is that, for combustion of fuel oil, the flue gas dew-point temperature can range from a low at the apparent water dew point (calculated with no fuel sulfur) up to some elevated dew point caused by the presence of sulfur in the fuel. With no sulfur in the fuel, adding post-combustion dilution air to the flue gas has some effect on depressing the apparent water dew-point temperature. Adding post-combustion dilution air has no significant effect on the elevated flue gas dew point when sulfur is present in the fuel.

It is difficult to meet the flue-gas-side material surface temperatures required to exceed the elevated dew point at all points in the venting system of an oil-fired appliance. Even if the dew-point temperature is not reached at these surfaces, however, a surface temperature approaching 93.3°C allows condensation of sulfuric acid at higher concentrations and results in lower rates of corrosion.

The condensed acid concentration is critical to the applicability of plain carbon and stainless steels in vent connectors and chimney liners. The flue-gas-side surface temperatures of conventional connectors and masonry chimney tile liners are often at or below the dew point for some portion of the burner on period. During cooldown (burner off period), these surface temperatures can drop to below the apparent water dew point and, in some cases, to ambient conditions. This is of great concern because, while system surfaces are below the apparent water dew point during burner operation, the condensed sulfuric acid is formed in concentrations well below limits acceptable for steel connectors. This can be seen from an interpretation of a sulfuric acid/water phase diagram presented by Land (1977). An estimate of the condensed liquid sulfuric acid concentration at a condensing surface temperature of 48.9°C, for example, shows a concentration for the condensed liquid acid of about 10 to 20%.

According to Fontana and Greene (1967), the relative corrosion of plain carbon steel rises rapidly at sulfuric acid concentrations below 65%. According to Land (1977), for the condensed liquid acid concentration to rise above 65%, the condensing surface temperature must be above 93.3°C. However, according to Fontana and Greene, at acid concentrations above 65%, corrosion rates increase at metal surface temperatures above 79.4°C. This presents the designer with a restrictive operating range for steel surfaces (i.e., between 79.4 and 93.3°C). This is a compromise that does not completely satisfy either the acid concentration or the metal temperature criterion, but should minimize the corrosion rates induced by each.

Another important phenomenon is that when vent system surfaces are at or below the apparent water dew point, a large amount of water condensation occurs on these surfaces. This condensate contains, in addition to sulfuric acid, quantities of sulfurous, nitrous, carbonic, and hydrochloric acids. Under these conditions, the corrosion rate of commonly used vent materials is severe. Koebel and

Elsener (1989) found that corrosion rates increase by a factor of 10 when material temperatures on the flue gas side are allowed to fall below the apparent water dew point.

The applicability of ordinary stainless steels is very limited and generally follows that of plain carbon steel. Nickel-molybdenum and nickel-molybdenum-chromium alloys show good corrosion resistance over a wide range of sulfuric acid concentrations for surface temperatures up to 104.4°C. This is also true for high-silicon cast iron, used in heat exchangers for oil-fired appliances, and which might find application as a liner system for masonry and metal chimneys.

Connector and Chimney Corrosion

Water and acid condensation can each result in corrosion of the connector wall and deterioration of the chimney material. Although there is little documentation of specific failures, concern in the industry is growing. The volume of anecdotal information regarding corrosive failures is significant and well supported by findings from the heating industry.

For oil-fired appliances, the rate of acid corrosion in the connector and chimney is a function of combustion factors and operational factors. The sulfur content of the fuel and the percent excess combustion air are the major combustion-related factors. The frequency and duration of equipment on and off periods, draft control dilution air, and rate of heat loss from the vent system are the major operational factors. In terms of combustion, Butcher and Celebi (1993) found a direct correlation of acid deposition (condensation) rate and subsequent corrosion to fuel sulfur content and excess combustion air. In general, reductions in fuel sulfur and excess combustion air reduce the amount of sulfuric acid produced in combustion and delivered to condensing surfaces in the appliance heat exchanger and carried over into the vent system. From an operational standpoint, long equipment on and short off periods and low vent system heat loss result in shorter warm-up transients and higher end-point temperatures for surfaces exposed to the flue gas. Within the limits of frictional loss, reduced vent sizes increase flue gas velocities and vent surface temperatures.

Vent Connectors

An oil-fired appliance is commonly connected to a chimney through a connector pipe. Generally, a draft control device in the form of a barometric damper is included as a component part of the connector assembly. With the advent of new power burners having high static pressure capability, draft control devices in the vent system have become less important, although many local codes still require their use. The portion of the connector assembly between the appliance flue collar and the draft control is called the flue connector; the portion between the draft control and the chimney is called the stack or chimney connector.

Chimney connectors are usually of single-wall galvanized steel. The required wall thickness for these connectors varies as a function of pipe diameter. For example, in accordance with Table 9.2.2.3 in NFPA *Standard* 211, the material thickness for galvanized steel pipe connectors between 150 and 250 mm in diameter is set at 0.58 mm.

In accordance with the 2015 *National Fuel Gas Code*, Paragraph 12.11.2.3(2), vent, chimney, stack, and flue connectors should not be covered with insulation except listed insulated connectors installed according to the terms of their listing. Because single-wall connectors must remain uninsulated for inspection, substantial cooling of the connector wall and the flue gas can occur, especially with long connector runs through spaces with low ambient temperatures. Close examination of the connector joints, seams, and surfaces is essential whenever the heating appliance is serviced. If the connector is left unrepaired, corrosion damage can cause a complete separation failure of the connector and leakage of flue gas into the occupied space.

Where corrosion in the connector has proven to be a chronic problem, consider replacing the connector with a type L vent pipe or its listed equivalent. One product configuration consists of connector pipe with a double wall (stainless steel inner and galvanized steel outer with 6.4 mm gap). The insulated gap of this type of double-wall connector elevates inner wall surface temperature and reduces the overall connector heat loss.

Masonry Chimneys for Oil-Fired Appliances

A masonry chimney serving an oil-fired appliance should have a tile liner and should comply with applicable building codes such as NFPA *Standard* 211. An additional listed chimney liner may be needed to improve thermal response (warm-up) of the inner chimney surface, thereby reducing transient low draft during start-up and acid/water condensation during cyclic operation. This is particularly true for exposed exterior high-mass chimneys but does not exclude cold interior chimneys serving oil-fired appliances that produce relatively low flue gas temperatures. Application of insulation around tile liners within masonry chimneys is common in Europe and may be worth considering in chimney replacement or new construction.

A computational analysis by Krajewski (1996) using the U.S. Department of Energy's *Oil Heat Vent Analysis Program* (OHVAP; version 3.1) to analyze a series of masonry chimney systems with various firing rates and exit temperatures revealed that current applications of modern oil-fired heating appliances may have problems with acid/water condensation during winter operation. For residential oil-fired heating appliance firing rates below 1.3 to 1.6 mL/s with flue-loss steady-state efficiencies of 82% or higher, exterior masonry chimneys may need special treatment to reduce condensation. For conservative design, listed chimney liners and listed type L connectors may be required for some exterior chimneys serving equipment operating under these conditions.

Replacement of Appliances

The physical condition and suitability of an existing chimney must be checked before installation of a new oil-fired appliance. The chimney should be inspected and, if necessary, cleaned. In accordance with NFPA *Standard* 211, the chimney drop-leg (bottom of the chimney flue) must be at least 200 mm below the bottom of the appliance connection to the chimney. The liner must be continuous, properly aligned, and intact and must extend beyond the top of the chimney. The chimney should also have a properly installed, reasonably airtight clean-out at the base.

For masonry chimneys, local experience may indicate how well the construction has withstood the lower temperatures produced by a modern oil-fired appliance. Visual examination reveals evidence of potential or existing chimney damage. Exterior indicators such as missing or loose mortar/bricks, white deposits (efflorescence) on brickwork, a leaning chimney, or water stains on interior building walls should be investigated further. Interior chimney examination with a mirror or video camera can reveal damaged or missing liner material. Any debris collected in the chimney base, drop-leg, or connector should be removed and examined. If any doubt exists about the chimney's condition, examination by an experienced professional is recommended. Kam et al. (1993) offer specific guidance on the examination and evaluation of existing masonry chimneys in the field.

9. FIREPLACE CHIMNEYS

This section is condensed from an *ASHRAE Journal* article; for more details, please see Stone (1969).

Fireplaces with natural-draft chimneys follow the same gravity fluid flow law as gas vents and thermal flow ventilation systems. All thermal or buoyant energy is converted into flow, and no draft exists

over the fire or at the fireplace inlet. Formulas have been developed to study a wide range of fireplace applications, but the material in this section covers general cases only.

Mass flow of hot flue gases through a vertical pipe is a function of rate of heat release and the chimney area, height, and system pressure loss coefficient k. The flow induced in a vertical pipe has a limiting value. A fireplace may be considered as a gravity duct inlet fitting with a characteristic entrance-loss coefficient and an internal heat source. A fireplace functions properly (does not smoke) when adequate intake or face velocity across those critical portions of the frontal opening nullifies external drafts and internal convection effects.

In a fireplace-chimney system, the equations assume that all potential buoyant energy is converted into flow as controlled by various losses. This system is analogous to a gas venting system with a draft hood, thereby allowing use of similar concepts as a starting point for size or capacity analysis. The amount of available draft ahead of the fireplace opening is insignificant and need not be considered. Because chimney efficiency, by one definition, equals available draft divided by theoretical draft, the numerical efficiency value approaches zero. Thus, the flow conversion basis is preferable for design over the efficiency approach.

System parameters for preventing flue gas spillage from a draft hood or similar collection fitting, can be computed with considerable certainty when heat input is constant or cannot exceed a predictable limiting value. Fireplaces, however, can be fired at extremes ranging from smoldering embers to flash fires of newspapers or dry kindling. Normal opening width and length allow greater access of combustion air to fires than a typical chimney can carry away; thus, combustion overloading occasionally leads to some smoking. At low rates of combustion, airflow velocities into the fireplace face are less than the velocity of natural convection currents induced at side walls by heat stored in the brick, allowing wisps of smoke to stray away from the combustion products' main flow path. Smoking tendencies are compounded at low firing rates by indoor/outdoor pressure differentials caused by winds, thermal forces, or fans, because the accompanying thermal force (buoyancy) of low combustion products temperature is insufficient to overcome strong wind or fan effects.

In the following analysis, note that fireplaces are primarily air-collecting hoods, diluting a small amount of combustion products with large amounts of air. Maximum mass flow of air into any given fireplace chimney is limited, and diminishes past a certain maximum. Thus, as combustion rate increases, combustion product temperatures rise to the point where masonry cracks; metals overexpand, warp, and oxidize; and steady smoking can occur because heated flue gases evolve beyond the limited capacity of the chimney.

An inoperative fireplace is completely at the mercy of indoor/outdoor pressure differences caused by winds, building stack effects, and operation of forced-air heating systems or mechanical ventilation. Thus, smoking during start-up can have complex causes seldom related to the chimney. Increasingly in new homes and especially in high-rise multiple family construction, fireplaces of normal design cannot cope with mechanically induced reverse flow or shortages of combustion air. It is mandatory in these circumstances to treat and design a fireplace as a constantly operating mechanical exhaust system, with induced-draft blowers (mechanical-draft systems) that can overpower other mechanized air-consuming systems, and can develop sufficient flow to avoid smoking and excessive flue temperatures.

The gravity-flow capacity equation (Kinkead 1962) of a fireplace-chimney system equates mass flow with the resultant system driving forces and losses.

$$w = A_c \left(\frac{2gH}{k}\right)^{1/2} [\rho_m (\rho_o - \rho_m)]^{1/2} \tag{22}$$

where

w = flue gas flow rate, kg/s
A_c = chimney flue cross-sectional area, m^2
g = gravitational constant, 9.8 m/s^2
H = height of chimney above lintel, m
k = system equivalent resistance coefficient, dimensionless
ρ_m = flue gas density at mean temperature, kg/m^3
ρ_o = air density of ambient temperature, kg/m^3

From Equation (22), it is possible to develop a relationship for average frontal velocity, maximum chimney capacity, and variation of gas temperature with changes in fuel input rate.

Using resistance coefficients in these compact systems is preferable to the usual method of equivalent lengths. The summation term k in a vertical chimney is the total of four individual resistance factors:

- Acceleration k_a of ambient air to flue gas velocity, a constant value that must always be included in the total; $k_a = 1.0$
- Inlet loss coefficient k_i for fireplace configuration, including smoke shelf

Cone-type fireplaces	$k_i = 0.5$
Masonry (damper throat = 2 × flue area)	$k_i = 1.0$
Masonry (damper throat = flue area)	$k_i = 2.5$

- Chimney flue pipe friction k_c at a typical Reynolds number of 10 000 and roughness of 0.001, where r_h = hydraulic radius, m

$$k_c = 0.0083 \left(\frac{H}{r_h}\right)$$

- Termination coefficient k_t

For open top pipe or tile, same size as chimney	$k_t = 0$
Disk or cone cap at $D/2$ above outlet	$k_t = 0.5$
Manufactured caps	$k_t = 0$ to 4.0

For a 3.6 mhigh open top chimney, 300 mm in diameter on a typical fireplace, the system resistance is

k_a =	1.0
k_i =	2.5
$k_c = 0.0083(12/0.25)$ =	0.4
k_t =	0.0
	k = 3.9 summation

Note that in a short chimney, the wall friction coefficient k_c is only 0.4 and has a minor effect on system flow. Greater or lesser chimney roughness, or a change from low to high heat loss materials will have little bearing on fireplace effectiveness in short chimneys. In some situations, it may be necessary, for completeness, to include a k term for air supply resistance.

To determine the frontal velocity V_F of ambient air, the term w is replaced using the substitution

$$w = \rho_o A_F V_F \tag{23}$$

where

A_F = fireplace frontal opening area, m^2
V_F = fireplace mean frontal velocity, m/s

Accordingly, mean frontal velocity V_F becomes

$$V_F = \frac{A_c}{A_F}\left(\frac{2gH}{k}\right)^{1/2}\left[\frac{\rho_m(\rho_o - \rho_m)}{\rho_o}\right]^{1/2} \tag{24}$$

For present purposes, the relative molecular mass or density of dilute combustion products is practically the same as that of air, and

both can be expressed with adequate accuracy in terms of absolute gas temperature by the same relationship:

$$\rho_o = 3.48\frac{B_o}{T_o} \quad (25)$$

$$\rho_m = 3.48\frac{B_o}{T_m} \quad (26)$$

where

B_o = existing barometric pressure, kPa
T_o = ambient air temperature, K
T_m = mean combustion products temperature, K

Substitution of the density/temperature relationships (Equations [25] and [26]) into Equation (24) allows further simplification, leading to the general frontal velocity expression:

$$V_F = \frac{A_c}{A_F}\left(\frac{2gH}{k}\right)^{1/2}\frac{[T_o(T_m - T_o)]^{1/2}}{T_m} \quad (27)$$

Here, frontal velocity is a function of the product of three terms:

- Dimensionless area ratio A_c/A_F
- Height/resistance term $(2gH/k)^{1/2}$
- Dimensionless temperature effects $[T_o(T_m - T_o)]^{1/2}/T_m$

For the 3.6 m high example chimney, assume ambient temperature (for calculation purposes) is 21°C, or T_o = 294 K indoors and outdoors, with no air supply resistance. Equation (27) expresses variation in V_F with gas temperature as shown in Figure 17. Assume also A_c/A_F = 0.10, so that frontal opening is ten times chimney area.

The mean airflow velocity into a fireplace frontal opening is nearly constant from 165 K flue gas temperature rise up to any higher temperature. Local velocities vary within the opening. Depending on design, air typically enters horizontally along the hearth and then flows into the fire and upward, clinging to the back wall (see Figure 16). A recirculating eddy forms just inside the upper front half of the opening, induced by the high velocity of flow along the back. Restrictions or poor construction in the throat area between the lintel and damper also increase the eddy. Because the eddy moves smoke out of the zone of maximum velocity, the tendency of this smoke to escape must be counteracted by some minimum inward air movement over the entire front of the fireplace, particularly under the lintel.

Construction of a fireplace, its internal configuration, damper location, height and location of lintel, slope of back and sides, and so on all affect minimum frontal velocity to prevent smoking with ordinary fires. It seems desirable to maintain a smooth, gradual tapering transition between the hearth or flame region up into the damper location. A sudden transition, unless it is well above the lintel, induces velocity components that tend to increase eddying. With a shallow chamber between lintel and damper zone, there is insufficient volume for convection currents, and some flue gases may be diverted horizontally before being captured by the main flow. Masons following the dimensional parameters recommended by Ramsey and Sleeper (1956) or in damper literature can avoid these design flaws. With prefabricated fireplace systems, which often tend to be unconventional, careful testing is essential to ensure safe, smoke-free performance at minimum chimney height.

A minimum mean frontal inlet velocity of 0.244 m/s, in conjunction with a chimney flue gas temperature of at least 165 to 280 K above ambient, should control smoking in a well-constructed conventional masonry fireplace. As noted in Figure 17, this velocity can be achieved even in low chimneys by system resistance of 2.9 or less, in conjunction with rates of combustion producing flue gas temperatures above a certain minimum level.

Figure 17 also illustrates why increases in flue gas temperature rise greater than 165 K have no perceptible effect on fireplace smoking, because combustion air mass flow and face velocity actually

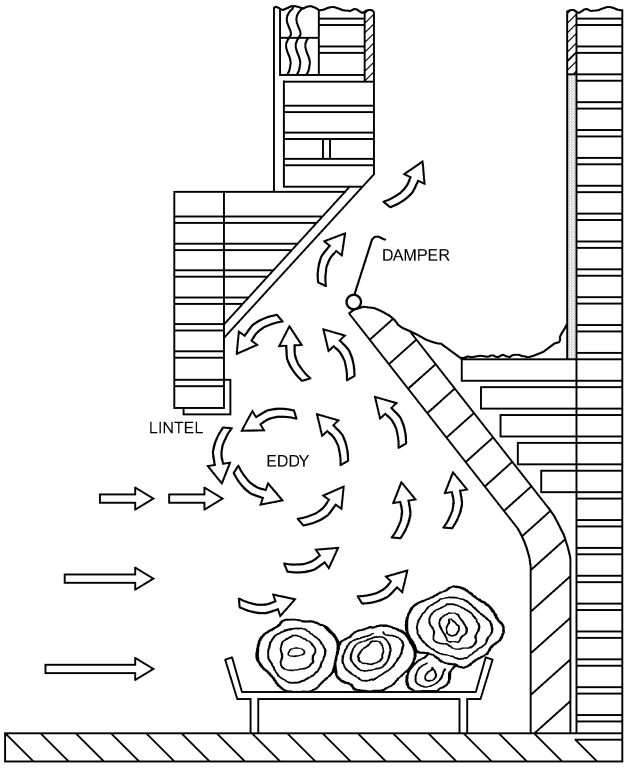

Fig. 16 Eddy Formation

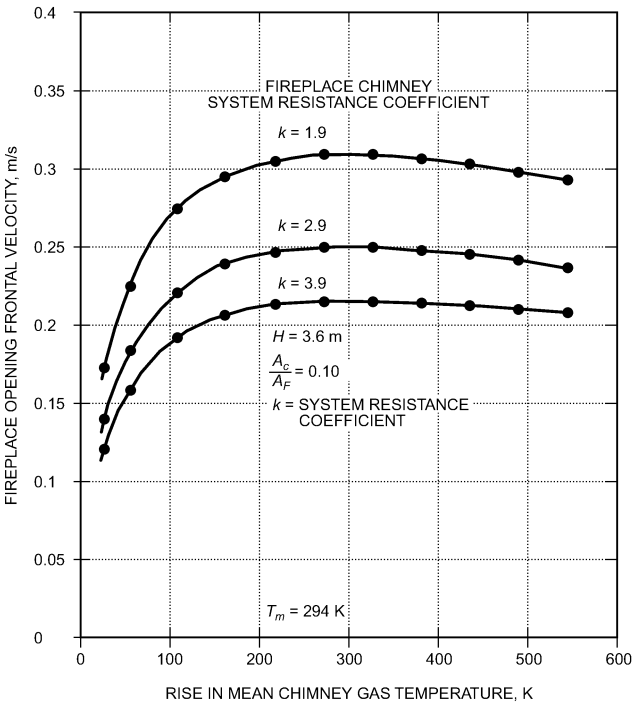

Fig. 17 Effect of Chimney Gas (Combustion Products) Temperature on Fireplace Frontal Opening Velocity

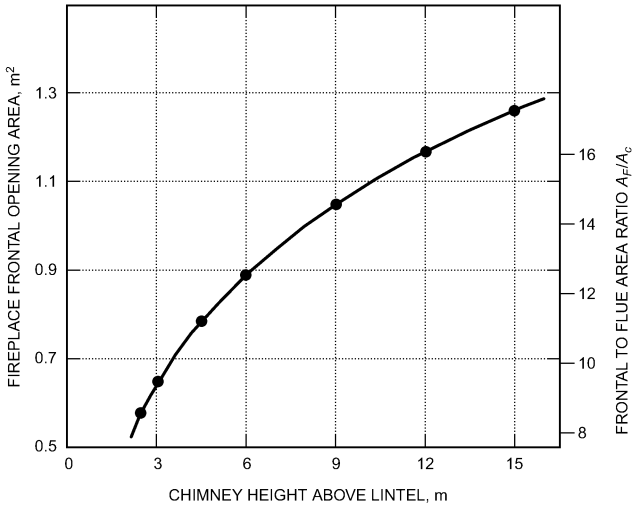

Fig. 18 Permissible Fireplace Frontal Opening Area for Design Conditions (0.24 m/s mean frontal velocity with 0.3 m inside diameter round flue)

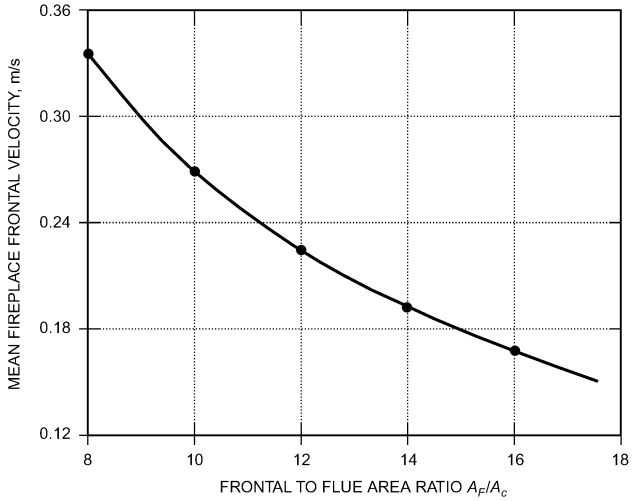

Fig. 19 Effect of Area Ratio on Frontal Velocity (for chimney height of 4.6 m with 0.3 m inside diameter round flue)

decrease at flue gas temperature rises higher than 280 K. For practical purposes, chimney flue gas temperature has little influence on fireplace performance, if flue gas temperature is at least 165 K above ambient. Fireplace performance analysis thus can be continued assuming a constant flue gas temperature of 280 K rise above ambient:

$$\frac{[T_o(T_m - T_o)]^{1/2}}{T_m} = 0.5$$

where $T_m = 572$ K and $T_o = 294$ K.

Assuming 21°C ambient (T_o = 294 K), and factoring out $2g$, Equation (27) becomes roughly

$$V_F = 2.21 \frac{A_c}{A_F}\left(\frac{H}{k}\right)^{1/2} \tag{28}$$

This expression states that relative fireplace performance is purely a matter of geometry. It allows evaluation of the opening size to maintain minimum frontal velocity as a function of height, as well as quick analysis of effect of frontal area on velocity.

Figure 18 shows that 0.24 m/s face velocity requires a relatively small A_F/A_c area ratio at 2.4 m chimney height, whereas the fireplace frontal opening area can be nearly twice as large with a 12 m high chimney. To compute this curve, system resistance is assumed as

$$k = 2.5 + 0.033H/D$$
$$D = 0.3 \text{ m diameter}$$

This expression of resistance assumes the fully open free area of the damper throat to be twice chimney flue area.

A corollary application of Equation (28) assumes fixed chimney size and height, and explores variation in frontal velocity with changes in area ratio. Figure 19 shows that a 0.3 m diameter, 4.6 m high chimney cannot produce adequate velocities for frontal area ratios greater than 11. These curves point out the possibility of further simplification to yield a fireplace-chimney design equation for a constant face velocity of 0.24 m/s.

$$A_F = 9.06Ac\left(\frac{H}{k}\right)^{1/2} \tag{29}$$

This equation allows permissible frontal area A_F to be determined as a function of chimney area, height, and system resistance. It can also be used to determine A_c, if A_F is known. However, in this latter case, Equations (30) and (31) are preferable, because chimney size (D_c, A_c, and R_h) appears twice in the right-hand side of each equation.

For circular flues,

$$A_F = 7.12\ D_c^2\left(\frac{H}{2.5 + 0.033\frac{H}{D_c}}\right)^{1/2} \tag{30}$$

For other flue shapes,

$$A_F = 9.06A_c\left(\frac{H}{2.5 + 0.0083\frac{H}{R_h}}\right)^{1/2} \tag{31}$$

where D_c is chimney inside diameter, m, R_h is inside hydraulic radius, m, frontal velocity V_F is 0.244 m/s at maximum combustion air mass flow rate, and damper opening free area is twice chimney flue area combustion air A_F.

These relationships clearly reveal the origin of rules of thumb specifying opening area as 8, 10, or 12 times chimney area. Some design guides go beyond and classify chimneys by height groups so that short ones serve smaller fireplace openings. Using a mean face velocity of 0.244 m/s yields ratios and heights that fall well within the limits of such rules, as well as providing a unifying concept for computing design charts.

The previous relationships primarily apply to masonry single-face fireplaces of conventional construction, but are applicable to other types with considerable validity if face or opening area is properly treated. Corner or double-face designs and many free-standing types embody conventional smokeshelf construction with similar resistance coefficients.

The preceding equations can be applied to illustrate the effect of excessive firing rates on chimney flue gas temperature. Masonry fireplaces are highly inefficient as heating devices, and tests show that, over a wide range of controlled fuel inputs using a drilled-port

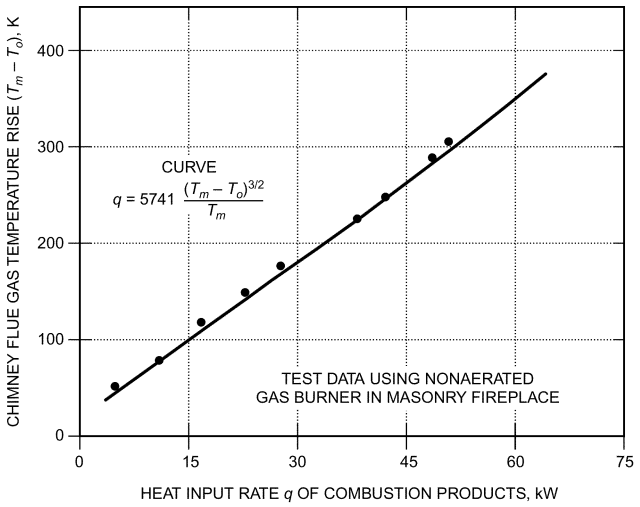

Fig. 20 Variation of Chimney Flue Gas Temperature with Heat Input Rate of Combustion Products

nonaerated gas burner, 75 to 80% of the gross heating value goes up the chimney. With constant flue heat loss of 80%, 70% of heat loss is sensible heat, which produces the rise in flue gas temperature. This heat input/temperature relationship may be developed by expressing the system flow relationship in terms of heat input:

$$w = \frac{q}{c_p(T_m - T_o)} \tag{32}$$

where

q = heat content of chimney flue gases, kW
c_p = specific heat of chimney gases, assumed to be approximately 1.046 kJ/(kg·K)

Equating Equations (32) and (22), and eliminating w,

$$\frac{q}{c_p(T_m - T_o)} = A_c \left(\frac{2gH}{k}\right)^{1/2} [\rho_m (\rho_o - \rho_m)]^{1/2} \tag{33}$$

Substituting Equations (25) and (26) for density and solving for q,

$$q = \frac{3.48 B_o A_c c_p}{(T_o)^{0.5}} \left(\frac{2gH}{k}\right)^{1/2} \frac{(T_m - T_o)^{3/2}}{T_m} \tag{34}$$

For any given system, all terms except $(T_m - T_o)^{3/2}/T_m$ may be considered fixed; therefore, gas temperature rise for a fireplace can be obtained as a concise function of heat input:

$$q = \overline{C} \frac{(T_m - T_o)^{1.5}}{T_m} \tag{35}$$

where $\overline{C}$ is a constant.

The flow-temperature function of a carefully controlled experimental fireplace (Equation [34] or [35]) in which $\overline{C}$ as fixed is plotted in Figure 20 as chimney flue gas temperature versus heat input rate. Data taken on a fireplace-chimney system in this way may readily be evaluated to determine system resistance coefficient k.

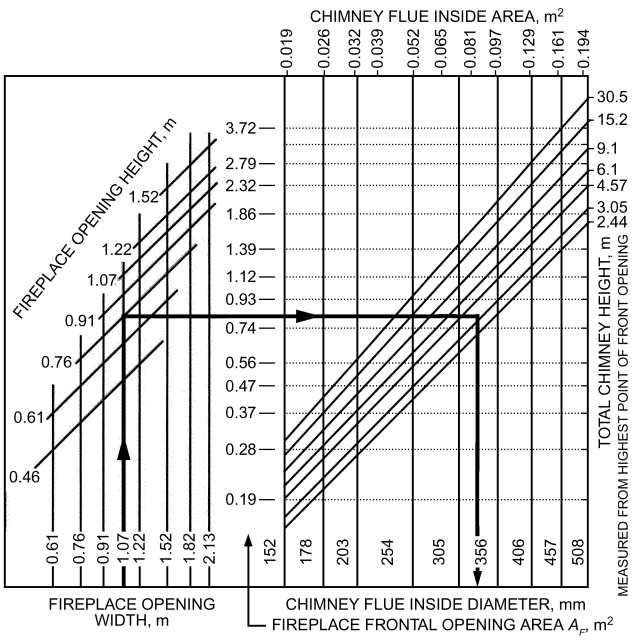

Fig. 21 Chimney Sizing Chart for Fireplaces

Mean face velocity = 0.244 m/s
(Stone 2005)

Figure 21 shows fireplace and chimney dimensions for the specific conditions of circular flues at 0.244 m/s frontal velocity. This chart solves readily for maximum frontal opening for a given chimney, as well as for chimney size and height with a predetermined opening. For example, a 1050 mm high by 750 mm wide opening for a 4 m high chimney (measured from the highest point of front opening) requires a 350 mm flue. Figure 21 assumes no wind or air supply difficulties. For other face velocities, A_F is found by multiplying frontal area (center scale) by velocity ratio $0.244/V_F$. To confirm the example results, calculate from Equation (30) as follows:

$$A_F = 7.12 \; D_c^2 \frac{H}{(2.5 + 0.033H)/D_c}^{1/2}$$

where H is 44 m and D_c is 0.35 m.

$$A_F = 0.788 \text{ m}^2 = 0.75 \text{ m} \times 1.05 \text{ m}$$

Although derived specifically for circular flues, A_F applies with negligible sacrifice in performance to chimney flue cross sections such as squared or rounded ovals, because flue area is a much more important factor than friction caused by changes in hydraulic radius. For example, in a 6.1 m high chimney, assuming a square flue section equal in area to a 203 mm circle, frontal area is reduced from 0.386 m² with the round, to 0.380 m² with the square, or about 2%, a difference that is hardly observable. For some typical constructions, Figure 22 suggests methods of estimating frontal area.

These relationships apply to steady-state conditions, which are obtained only after warm-up. Igniting a rapidly flammable charge in a cold system creates pulses of expanding hot combustion products, which frequently escape from the fireplace. In a typical chimney, priming time (time to accelerate from no flow to full upward velocity) is around 5 to 10 s. Thus, initial or intermittent smoking caused by momentarily excessive combustion rates occurs because of system inability to increase flue gas velocity in pace with combustion surges.

Flue or chimney material is of little relevance to fireplace-chimney operation. Materials to which these equations and charts apply

include the very hazardous uninsulated single-wall metal, through conventional masonry, as well as the various constructions of lightweight, insulated, factory-built low-heat-space-appliance chimneys. (Safety standards classify fireplaces as low-heat appliances.) Because most fireplace chimneys are short and vertical, neither heat loss nor wall roughness has any important effect on flow. The governing factors in chimney selection for fireplaces are mainly safety, installation, convenience, and esthetics.

Indoor/outdoor pressure differences caused by winds, kitchen or bath exhaust fans, building stack effects, and operation of forced-air heating systems or mechanical ventilation affect the operation of a fireplace. Thus, smoking during start-up can be caused by factors unrelated to the chimney. Frequently, in new homes (especially in high-rise multiple-family construction), fireplaces of normal design cannot cope with mechanically induced reverse flow or shortages of combustion air. In these circumstances, a fireplace should include an induced-draft blower able to overpower other mechanized air-consuming systems. An inducer for this purpose is best located at the chimney outlet and should produce 0.244 to 0.305 m/s fireplace face velocity of ambient air in an individual flue or 3.05 to 3.66 m/s chimney velocity.

In conventional fireplaces, the greater the frontal velocity, the more freedom from smoking. The damper free area, together with its resultant resistance coefficient, are thus major factors in obtaining good masonry fireplace performance, especially with short chimneys. Tests show that damper free area need not exceed twice the required flue area, because little further resistance reduction occurs past this limit.

If the damper selected has a free area equal to or less than the required area, it will be definitely restrictive, despite complete adequacy of other factors. Manufacturers' literature seldom includes damper free area or opening dimensions, and the dimensions may vary further after installation because of interferences with lintels and other parts. It is expedient to select dampers of adequate free area for best results.

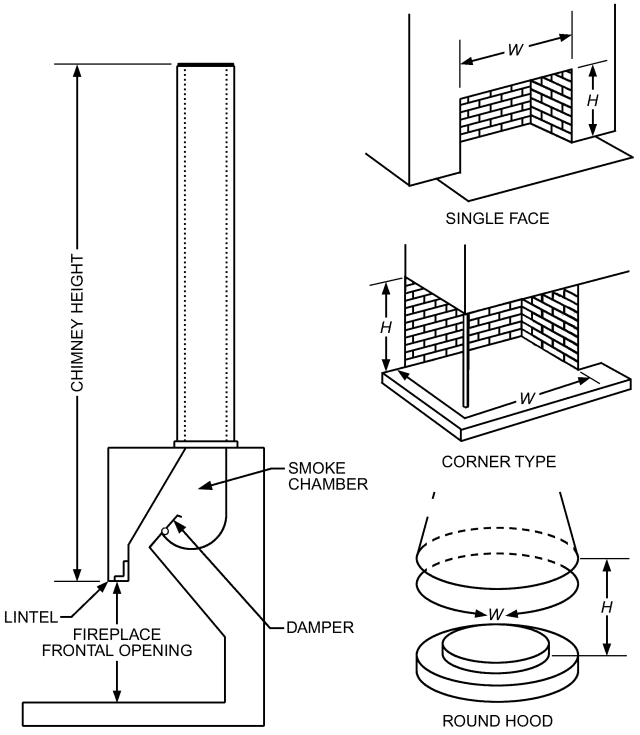

Fig. 22 Estimation of Fireplace Frontal Opening Area

Partially closing a damper during a vigorous fire illustrates this point; what is not so obvious is that greater damper openings may be needed in some cases to control smoke by achieving adequate frontal velocities.

Many free-standing fireplaces are built without the usual smokeshelf/throat damper configuration. The same parameters and relationships apply to free-standing fireplaces as to masonry fireplaces; however, in many designs it is difficult to assign a true frontal area for velocity analysis. Where freestanding fireplaces include back outlets, or require a horizontal run to reach the chimney, compensation is necessary for the flow resistance or pressure losses caused by turns. As a rough approximation, increase the system resistance coefficient k about 1.5 for two 90° elbows, or a back outlet with lateral run into a tee.

Losses caused by lateral connectors and tees generally mean a one-size increase (e.g., moving from 150 to 200) is sufficient. Collar sizes generally determine correct chimney size, and instructions are furnished to cover special situations. More sophisticated prefabricated fireplace designs are provided with matching correctly sized chimneys, and are intended for installation in conventional wood-frame residences.

The equations and design charts presented here assume no wind or air supply difficulties. Lack of replacement air, competing ventilation exhaust fans, and negative interior pressures caused by winds are all obvious causes of smoking or poor fireplace priming. Even when fully primed and hot, thermal forces in a fireplace chimney can be overpowered by a combination of adverse influences. In modern high-rise residential apartments, where an effort has been made to provide all amenities, fireplaces may have to cope simultaneously with all these troubles. Continuous induced draft for the chimney alleviates most of these problems by maintaining a chimney prime at all times. An inducer for this purpose should be able to produce 0.24 to 0.30 m/s fireplace frontal velocity of ambient air in any individual flue. Where multiple flues are installed in a chase, a single, larger inducer serving the chase can be sized for the combined fireplace frontal opening area. Even where flues are of different heights and sizes, a draft inducer selection, assuming all flues to be some compromise median height and size, produces far greater user satisfaction than reliance on gravity alone.

In single-family dwellings, fireplace problems are more often caused by reduced interior pressures from wind effects than by poor chimney terminal location or characteristics. Efforts to cure smoking, slow priming, or blowback of ashes usually involve one of the myriad forms of stationary or rotating caps, cowls, or chimney pots. This questionable expedient has contradictory effects. Usually, the added still-air resistance of a cap reduces fireplace frontal velocity, which limits combustion airflow rate, and thus may tend to increase smoking. On the other hand, a cap reduces air dilution of smaller fires, raises chimney temperature, and improves stability of flame, thus tending to mitigate wind impulses that cause momentary flow reduction. The usual fireplace damper can also be used to restrict flow, and thus raise temperature.

Remedies for fireplace malfunctions may be analyzed using Equation (28). For example, it is apparent that any change of parameters on the right-hand side that might decrease V_F can increase smoking tendencies. If frontal area A_F or k increases, there will be a corresponding decrease in V_F. Similarly, if chimney area A_c or chimney height H are reduced, then V_F decreases. Further, because frontal velocity varies as the square root of the term H/k, it is more effective to reduce frontal area, thereby increasing A_c/A_F, than to increase H or reduce k.

Logical expedients for increasing V_F frontal velocity, and thus improving performance of fireplaces and chimneys, include the following:

- Increase chimney height (using the same flue area) and extend the last tile 150 mm upward, or more.
- Decrease frontal opening by lowering the lintel, or raising the hearth. (Glass doors may help by increasing V_F.)
- Increase free area through damper. (Check that it opens fully without interferences.)

CSA *Standard* P.4.1-02 can be used for measuring annual efficiency in Canada.

10. AIR SUPPLY TO FUEL-BURNING APPLIANCES

Failure to supply outdoor air for combustion may result in erratic or even dangerous operating conditions. A correctly designed gas appliance with a draft hood can function with short vents (1.5 m high) using an outdoor air supply opening as small in area as the vent outlet collar. Such an orifice, when equal to vent area, has a resistance coefficient in the range of 2 to 3. If the air supply opening is as much as twice the vent area, however, the coefficient drops to 0.5 or less.

The following rules may be used as a guide:

- Residential heating appliances installed in unconfined spaces in buildings of conventional construction do not ordinarily require ventilation other than normal air infiltration. In any residence or building that has been built or altered to conserve energy or minimize infiltration, the heating appliance area should be considered a confined space. The air supply should be installed in accordance with NFPA *Standard* 54/AGA Z223.1, CSA *Standard* B149.1, or the following recommendations.
- Residential heating appliances installed in a confined space having unusually tight construction require two permanent openings to an unconfined space or to the outdoors. An unconfined space has a volume of at least 4.8 m^3 per kilowatt (m^3 per kJ/s) of the total input rating of all appliances installed in that space. Free opening areas must be greater than 550 mm^2 per kilowatt input with vertical ducts or 1100 mm^2 per kilowatt with horizontal ducts to the outdoors. The two openings communicating directly with sufficient unconfined space must be greater than 2200 mm^2 per kilowatt. Upper openings should be within 300 mm of the ceiling; lower openings should be within 300 mm of the floor.
- Complete combustion of natural and propane gas or fuel oil requires approximately 0.27 m^3 of air, at standard conditions, for each megajoule of fuel burned, but excess air is usually required for proper burner operation.
- The size of these air openings may be modified if special engineering ensures an adequate supply of air for combustion, dilution, and ventilation or if local ordinances apply to boiler and machinery rooms.
- In calculating free area of air inlets, consider the blocking effect of louvers, grilles, or screens protecting openings. Screens should not be smaller than 6.4 mm mesh. If the free area through a particular louver or grille is known, use that in calculating the size opening required to provide the free area specified. If the free area is not known, assume that wood louvers have 20 to 25% free area and metal louvers and grilles have 60 to 75% free area.
- Mechanical ventilation systems serving the fuel-burning appliance room or adjacent spaces should not be allowed to create negative appliance room air pressure. The appliance room may require tight self-closing doors and provisions to supply air to spaces under negative pressure so fuel-burning appliances and venting operate properly.
- Fireplaces may require special consideration. For example, a residential attic fan can be hazardous if it is inadvertently turned on while a fireplace is in use.
- In buildings where large quantities of combustion and ventilation or process air are exhausted, a sufficient supply of fresh uncontaminated makeup air, warmed if necessary to the proper temperature, should be provided. It is good practice to provide about 5 to 10% more makeup air than the amount exhausted.

11. VENT AND CHIMNEY MATERIALS

Factors to be considered when selecting chimney materials include (1) the temperature of flue gases; (2) their composition and propensity for condensation of water vapor from combustion products (dew point); (3) presence of sulfur, halogens, and other fuel and air contaminants that lead to corrosion of the chimney vent system; and (4) the appliance's operating cycle (condensate dwell time).

Materials for vents and chimneys in the 100 to 1220 mm size range include single-wall metal, various multiwall air- and mass-insulated types, and precast and site-constructed masonry. Each has different characteristics (e.g., frequency of joints, roughness, heat loss), but the type of materials used for systems 360 mm and larger is relatively unimportant in determining draft or capacity. This does not preclude selecting a safe product or method of construction that minimizes heat loss and fire hazard in the building.

National codes and standards classify heat-producing appliances as low, medium, and high heat, with appropriate reference to chimney and vent constructions permitted with each. These classifications are mainly based on size, process use, or combustion temperature. Often, the appliance classification gives little information about outlet gas temperature or venting needed. The designer should, wherever possible, obtain gas outlet temperature conditions and properties that apply to the specific appliance, rather than going by code classification only.

Where building codes allow engineered chimney systems, chimney material selection based on gas outlet temperature can save space as well as reduce structural and material costs. For example, in some jurisdictions, approved gas-burning appliances with draft hoods operating at inputs over 117 kW (kJ/s) may be placed in a heat-producing classification that prohibits use of type B gas vents. An increase in input may not cause an increase in outlet temperature or in venting hazards, and most building codes recommend correct matching appliance and vent.

Single-wall uninsulated steel stacks can be protected from condensation and corrosion internally with refractory firebrick liners or by spraying calcium aluminate cement over a suitable interior expanded metal mesh or other reinforcement. Another form of protection applies proprietary silica or other prepared refractory coatings to pins or a support mesh on the steel. The material must then be suitably cured for moisture and heat resistance.

Moisture condensation on interior surfaces of connectors, vents, stacks, and chimneys is a more serious cause of deterioration than heat. Chimney wall temperature and flue gas velocity, temperature, and dew point affect condensation. Contaminants such as sulfur, chlorides, and fluorides in the fuel and combustion air raise the flue gas dew point. Studies by Beaumont et al. (1970), Mueller (1968), Pray et al. (1942-53), and Yeaw and Schnidman (1943) indicate the variety of analytical methods as well as difficulties in predicting the causes and probability of actual condensation.

Combustion products from any fuel containing hydrogen condense onto cold surfaces or condense in bulk if the main flow of flue gas is cooled sufficiently. Because flue gas loses heat through walls, condensation occurs first on interior wall surfaces cooled to the flue gas dew point, forming a dew and then a liquid film and, with further cooling, flowing down into zones where condensation would not normally occur.

Start-up of cold interior chimney surfaces is accompanied by transient dew formation, which evaporates on heating above the dew point. This phenomenon causes little corrosion when very low

sulfur fuels are used. Proper selection of chimney dimensions and materials minimizes condensation and thus corrosion.

Experience shows a correlation between the sulfur content of the fuel and the deterioration of interior chimney surfaces. Figure 5 in Chapter 28 of the 2021 *ASHRAE Handbook—Fundamentals* illustrates one case, which applies to any fuel gas. The figure shows that the flue gas dew point increases at 40% excess air from 53°C with zero sulfur to 71°C with 16.75 mg of sulfur per megajoule of fuel having a heat value of 20.49 MJ/m^3.

The figure can also be used to approximate the effect of fuel oil sulfur content on flue gas dew point. For example, fuel oil with a sulfur content of 0.5% (by mass) contains about of sulfur per gallon or 4.31 kg of sulfur per cubic metre of fuel. If the fuel heat value is 559 kJ/m^3, the ratio that defines the curves in the figure gives a curve value of 111. Estimates for lower percentages of sulfur (0.25, 0.05) can be formed as factors of the value 111.

Because the corrosion mechanism is not completely understood, judicious use of resistant materials, suitably insulated or jacketed to reduce heat loss, is preferable to low-cost single-wall construction. Refractory materials and mortars should be acid-resistant, and steels should be resistant to sulfuric, hydrochloric, and hydrofluoric acids; pitting; and oxidation. Where low flue gas temperatures are expected together with low ambients, an air space jacket or mineral fiber lagging, suitably protected against water entry, helps maintain surface and flue gas temperatures above the dew point. Using low-sulfur fuel, which is required in many localities, reduces both corrosion and air pollution.

Type 1100 aluminum alloy or any other non-copper-bearing aluminum alloy of 99% purity or better provides satisfactory performance in prefabricated metal gas vent products. For chimney service, flue gas temperatures from appliances burning oil or solid fuels may exceed the melting point of aluminum; therefore, steel is required. Stainless steels such as type 430 or 304 give good service in residential construction and are referenced in UL-listed prefabricated chimneys. Where more corrosive substances (e.g., high-sulfur fuel or chlorides from solid fuel, contaminated air, refuse) are anticipated, type AL 29-4CR® or equivalent stainless steel offers a good match of corrosion resistance and mechanical properties.

As an alternative to stainless steel, porcelain enamel offers good resistance to corrosion if two coats of acid-resistant enamel are used on all surfaces. A single coat, which always has imperfections, allows base metal corrosion, spalling, and early failure.

Prefabricated chimneys and venting products are available that use light corrosion-resistant materials, both in metal and masonry. The standardized, prefabricated, double-wall metal type B gas vent has an aluminum inner pipe and a coated steel outer casing, either galvanized or aluminized. Standard air space from 6.35 to 12.7 mm is adequate for applicable tests and a wide variety of exposures.

Air-insulated all-metal chimneys are available for low-heat use in residential construction. Thermosiphon air circulation or multiple reflective shielding with three or more walls keeps these units cool. Insulated, double-wall residential chimneys are also available. The annulus between metal inner and outer walls is filled with insulation and retained by coupler end structures for rapid assembly.

Prefabricated, air-insulated, double-wall metal chimneys for multifamily residential and larger buildings, classed as building heating appliance chimneys, are available (Figure 23). Refractory-lined prefabricated chimneys (medium-heat type) are also available for this use.

Commercial and industrial incinerators, as well as heating appliances, may be vented by prefabricated metal-jacketed cast refractory chimneys, which are listed in the medium-heat category and are suitable for intermittent flue gas temperatures to 1100°C. All prefabricated chimneys and vents carrying a listing by a recognized testing laboratory have been evaluated for class of service regarding temperature, strength, clearance to adjacent combustible materials, and suitability of construction in accordance with applicable national standards.

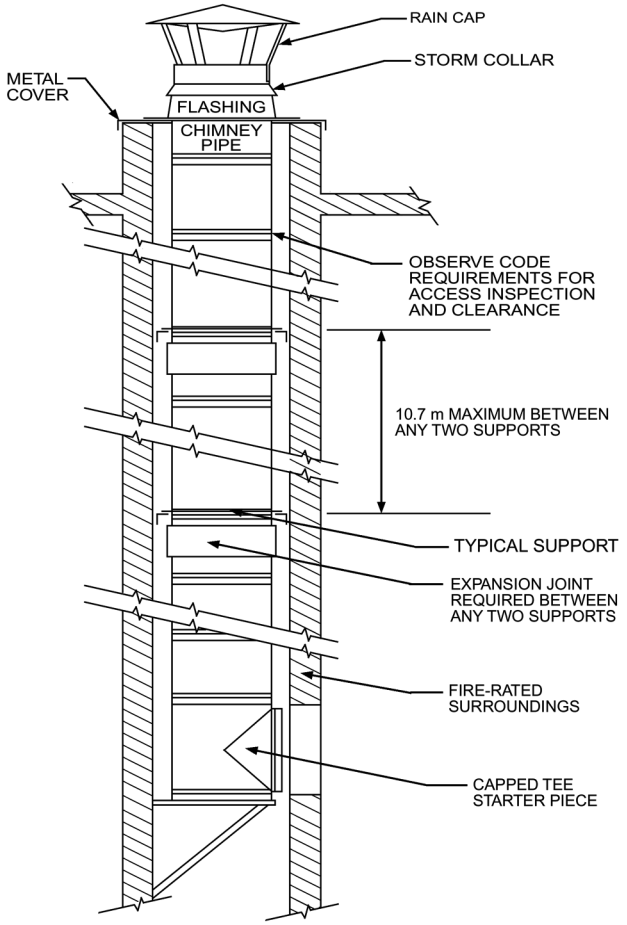

Fig. 23 Building Heating Appliance, Medium-Heat Chimney

Table 10 Underwriters Laboratories Test Standards

No.	Subject	Steady-State Appliance Flue Gas Temperature Rise, °F	Fuel
103	Chimneys, factory-built, residential type (includes building heating appliances)	517	All
127	Fireplaces, factory-built	517	Solid or gas
311	Roof jacks for manufactured homes and recreational vehicles	517	Oil, gas
378	Draft equipment (such as regulators and inducers)	—	All
441	Gas vents (type B, BW)	267	Gas only
641	Low-temperature venting systems (type L)	278	Oil, gas
959	Chimneys, factory-built, medium-heat	961	All
1738	Venting systems for gas-burning appliances, categories II, III, and IV	78 to 267	Gas only

Underwriters Laboratories (UL) standards, listed in Table 10, describe the construction and temperature testing of various classes of prefabricated vent and chimney materials. Standards for some related parts and appliances are also included in Table 10 because a listed factory-built fireplace, for example, must be used with a specified type of factory-built chimney. The temperature given for the steady-state operation of chimneys is the lowest in the test sequence. Factory-built chimneys under UL *Standard* 103 are also required to demonstrate adequate safety during a 1 h test at 740 K rise and to withstand a 10 min simulated soot burnout at either 906 or 1128 K rise.

These product tests determine minimum clearance to combustible surfaces or enclosures, based on allowable temperature rise on combustibles. They also ensure that the supports, spacers, and parts of the product that contact combustible materials remain at safe temperatures during operation. Product markings and installation instructions of listed materials are required to be consistent with test results, refer to types of appliances that may be used, and explain structural and other limitations.

12. VENT AND CHIMNEY ACCESSORIES

Vent or chimney system design must consider the existence of or need for accessories such as draft diverters, draft regulators, induced-draft fans, blocking dampers, expansion joints, and vent or chimney terminals. Draft regulators include barometric draft regulators and furnace sequence draft controls, which monitor automatic flue dampers during operation. The design, materials, and flow losses of chimney and vent connectors are covered in previous sections.

Draft Hoods

The draft hood isolates the appliance from venting disturbances (updrafts, downdrafts, or blocked vent) and allows combustion to start without venting action. Suggested general dimensions of draft hoods are given in ANSI *Standard* Z21.12, which describes certification test methods for draft hoods. In general, the pipe size of the inlet and outlet flues of the draft hood should be the same as that of the appliance outlet connection. The vent connection at the draft hood outlet should have a cross-sectional area at least as large as that of the draft hood inlet.

Draft hood selection comes under the following two categories:

- **Those supplied with a design-certified gas appliance:** certification of a gas appliance design under pertinent national standards includes its draft hood (or draft diverter). Consequently, the draft hood should not be altered or replaced without consulting the manufacturer and local code authorities.
- **Those supplied separately for gas appliances:** listed draft hoods for existing vent or chimney connectors should be installed by experienced installers in accordance with accepted practice standards.

Every design-certified gas appliance requiring a draft hood must be accompanied by a draft hood or provided with a draft diverter as an integral part of the appliance. The draft hood is a vent inlet fitting as well as a safety device for the appliance, and assumptions can be made regarding its interaction with a vent. First, when the hood is operating without spillage, the heat content of flue gases (enthalpy relative to dilution air temperature) leaving the draft hood is almost the same as that entering. Second, safe operation is obtained with 40 to 50% dilution air. It is unnecessary to assume 100% dilution air for gas venting conditions. Third, during certification tests, the draft hood must function without spillage, using a vent with not over 1.5 m of effective height and one or two elbows. Therefore, if vent heights appreciably greater than 1.5 m are used, an individual vent of the same size as the draft hood outlet may be much larger than necessary.

When vent size is reduced, as with tall vents, draft hood resistance is less than design value relative to the vent; the vent tables in the *National Fuel Gas Code* (NFPA *Standard* 54/AGA Z223.1) give adequate guidance for such size reductions.

Despite its importance as a vent inlet fitting, the draft hood designed for a typical gas appliance primarily represents a compromise of the many design criteria and tests solely applicable to that appliance. This allows considerable variation in resistance loss; thus, catalog data on draft hood resistance loss coefficients do not exist. The span of draft hood loss coefficients, including inlet acceleration, varies from the theoretical minimum of 1.0 for certain low-loss bell or conical shapes to 3 or 4, where the draft hood relief opening is located within a hot-air discharge (as with wall furnaces) and high resistance is needed to limit sensible heat loss into the vent.

Draft hoods must not be used on appliances having draft configuration 1 or 3 (see conditions 1, 2, and 3 under Terminology and Table 8) that is operated with either power burners or forced venting, unless the appliances have fan-assisted burners that overcome some or most of the appliance flow resistance and create a pressure inversion ahead of the draft hood or barometric regulator.

Gas appliances with draft hoods must have excess chimney draft capacity to draw in adequate draft hood dilution air. Failure to provide adequate combustion air can cause oxygen depletion and spillage of flue gases and flame rollout from the combustion air inlet at the burner(s).

Draft Regulators

Appliances requiring draft at the appliance flue gas outlet generally use barometric regulators for combustion stability. A balanced hinged gate in these devices bleeds air into the chimney automatically when pressure decreases. This action simultaneously increases vent gas flow and reduces temperature. Well-designed barometric regulators provide constant flue gas static pressure over a span of impressed vent gas draft (i.e., the draft that would exist without regulation) of about 50 Pa. A regulator can maintain 15 Pa draft for impressed drafts from 15 to 65 Pa. If the chimney system is very high or otherwise capable of generating available draft in excess of the pressure span capability of a single regulator, additional or oversize regulators may be used. Figure 24 shows proper locations for regulators in a chimney manifold.

Barometric regulators are available with double-acting dampers, which also swing out to relieve momentary internal pressures or divert continuing downdrafts. In the case of downdrafts, temperature safety switches actuated by hot gases escaping at the regulator sense and limit malfunctions.

Vent Dampers

Electrically, mechanically, and thermally actuated automatic vent dampers can reduce energy consumption and improve seasonal efficiency of gas- and oil-burning appliances. Vent dampers reduce loss of heated air through gas appliance draft hoods and loss of specific heat from the appliance after the burner stops firing. These dampers may be retrofit devices or integral components of some appliances.

Electrically and mechanically actuated dampers must open before main burner gas ignition and must not close during burner operation. These safety interlocks, which electrically interconnect with existing control circuitry, may include an additional main control valve or special gas-pressure-actuated controls.

Vent dampers that are thermally actuated with bimetallic elements and have spillage-sensing interlocks with burner controls are available for draft hood-type gas appliances. These dampers open in response to gas temperature after burner ignition. Because thermally actuated dampers may exhibit some flow resistance, even at equilibrium operating conditions, carefully follow instructions regarding allowable heat input and minimum required vent or chimney height.

Take special care to ensure that safety interlocks with appliance controls are installed according to instructions. Spillage-free gas venting after the damper has been installed must be verified with all damper types.

Energy savings of a vent damper can vary widely. Dampers reduce energy consumption under one or a combination of the following conditions:

- Heating appliance is oversized.
- Chimney is too high or oversized.
- Appliance is located in heated space.
- Two or more appliances are on the same chimney (a damper must be installed on each appliance connected to that chimney).
- Appliance is located in building zone at higher pressure than outdoors. This positive pressure can cause steady flow losses through the chimney.

Energy savings may not justify the cost of installing a vent damper if one or more of the following conditions exist:

- All combustion and ventilation air is supplied from outdoors to direct-vent appliances or to appliances located in an isolated, unheated room.
- Appliance is in an unheated basement that is isolated from the heated space.
- A one-story flat-roof house has a short vent, which is unlikely to carry away a significant amount of heated air.

For vents or chimneys serving two or more appliances, dampers (if used) should be installed on all attached appliances for maximum effectiveness. If only one damper is installed in such systems, loss of heated air through an open draft hood may negate a large portion of the potential energy savings.

Heat Exchangers or Flue Gas Heat Extractors

Sensible heat available in flue gas of properly adjusted furnaces burning oil or gas is about 10 to 15% of the rated input. Small accessory heat exchangers that fit in the connector between the appliance outlet and the chimney can recover some of this heat for localized use; however, they may cause some adverse effects.

All gas vent and chimney size or capacity tables assume the gas temperature or heat available to create theoretical draft is not reduced by a heat transfer device. In addition, the tables assume flow resistance for connectors, vents, and chimneys, comprising typical values for draft hoods, elbows, tees, caps, and piping with no allowance for added devices placed directly in the flue gas stream. Thus, heat exchangers or flue gas extractors should offer no flow resistance or negligible resistance coefficients when they are installed.

A heat exchanger that is reasonably efficient and offers some flow resistance may adversely affect the system by reducing both flow rate and flue gas temperature. This may cause moisture condensation in the chimney, draft hood spillage, or both. Increasing heat transfer efficiency increases the probability of the simultaneous occurrence of both effects. An accessory heat exchanger in a solid-fuel system, especially a wood stove or heater, may collect creosote or cause its formation downstream.

Retrofitting heat exchangers in gas appliance venting systems requires careful evaluation of heat recovered versus both installed cost and the potential for chimney safety and operating problems. Every heat exchanger installation should undergo the same spillage tests given a damper installation. In addition, the flue gas temperature should be checked to ensure it is high enough to avoid condensation between the exchanger outlet and the chimney outlet.

13. DRAFT FANS

The selection of draft fans, blowers, or inducers must consider (1) types and combinations of appliances, (2) types of venting material, (3) building and safety codes, (4) control circuits, (5) gas temperature, (6) permissible location, (7) noise, and (8) power cost. Besides specially designed fans and blowers, some conventional fans can be used if the wheel and housing materials are heat- and corrosion-resistant and if blower and motor bearings are protected from adverse effects of the flue gas stream.

Small draft inducers for residential gas appliance and unit heater use are available with direct-drive blower wheels and an integral device to sense flow (Figure 25A). The control circuit for these applications must provide adequate vent gas flow both before and while fuel flows to the main burner. Other types of small inducers are either saddle-mounted blower wheels (Figure 25B) or venturi ejectors that induce flow by jet action (Figure 25C). An essential safety requirement for inducers serving draft hood gas appliances does not permit appliance interconnections on the discharge or outlet side of the inducer. This requirement prevents backflow through an inoperative appliance.

With prefabricated sheet metal venting products such as type B gas vents, the vent draft inducer should be located at or downstream from the point the vent exits the building. This placement keeps the indoor system below atmospheric pressure and prevents flue gas from escaping through seams and joints. If the inducer cannot be placed on the roof or outdoor wall, metal joints must be reliably sealed in all pressurized parts of the system.

Pressure capability of residential draft inducers is usually less than 250 Pa at rated flow. Larger inducers of the fan, blower, or ejector type have greater pressure capability and may be used to reduce

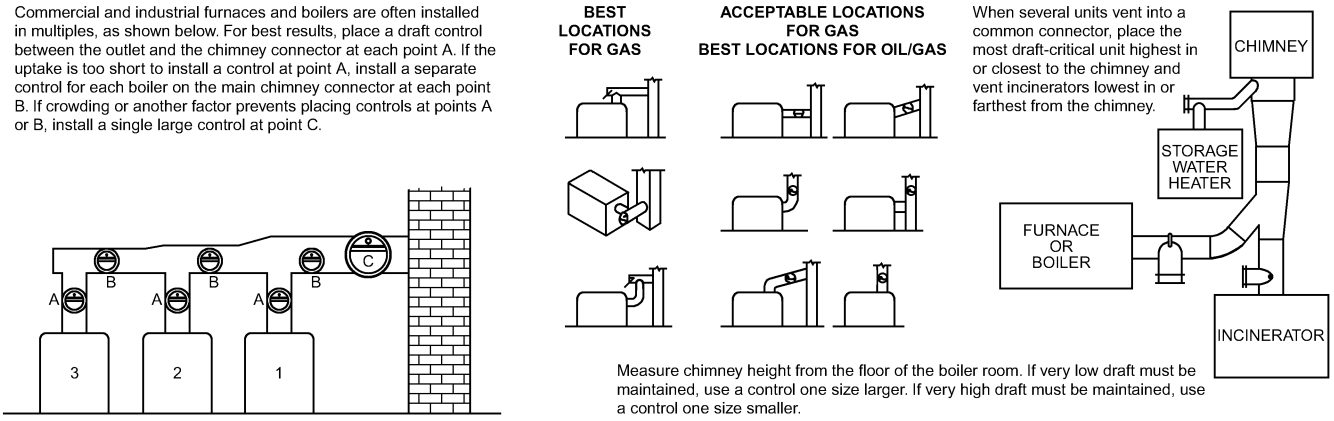

Fig. 24 Use of Barometric Draft Regulators

system size as well as supplement available draft. Figure 25D shows a specialized axial-flow fan capable of higher pressures. This unit is structurally self-supporting and can be mounted in any position in the connector or stack because the motor is in a well, separated from the flue gas stream. A right-angle fan, as shown in Figure 25E, is supported by an external bracket and adapts to several inlet and exit combinations. The unit uses the developed draft and an insulated tube to cool the extended shaft and bearings.

Pressure, volume, and power curves should be obtained to match an inducer to the application. For example, in an individual chimney system (without draft hood) in which a directly connected inducer only handles combustion products, calculation of the power required for continuous operation need only consider volume at operating flue gas temperature. An inducer serving multiple, separately controlled draft hood gas appliances must be powered for ambient temperature operation at full flow volume in the system. At any input, the inducer for a draft hood gas appliance must handle about 50% more standard chimney gas volume than a directly connected inducer. At constant volume with a given size inducer or fan, these demands follow the Fan Laws (see Chapter 21) applicable to power venting as follows:

- Pressure difference developed is directly proportional to gas density.
- Pressure difference developed is inversely proportional to absolute gas temperature.
- Pressure developed diminishes in direct proportion to drop in absolute atmospheric pressure, as with altitude.
- Required power is directly proportional to gas density.
- Required power is inversely proportional to absolute gas temperature.

Centrifugal and propeller draft inducers in vents and chimneys are applied and installed the same as in any heat-carrying duct system. Venturi ejector draft boosters involve some added consideration. An advantage of the ejector is that motor, bearings, and blower blades are outside the contaminated flue gas stream, thus eliminating a major source of deterioration. This advantage causes some loss of efficiency and can lead to reduced capacity because undersized systems, having considerable resistance downstream, may be unable to handle the added volume of the injected airstream without loss of performance. Ejectors are best suited for use at the chimney or vent exit or where there is an adequately sized chimney or vent to carry the combined discharge.

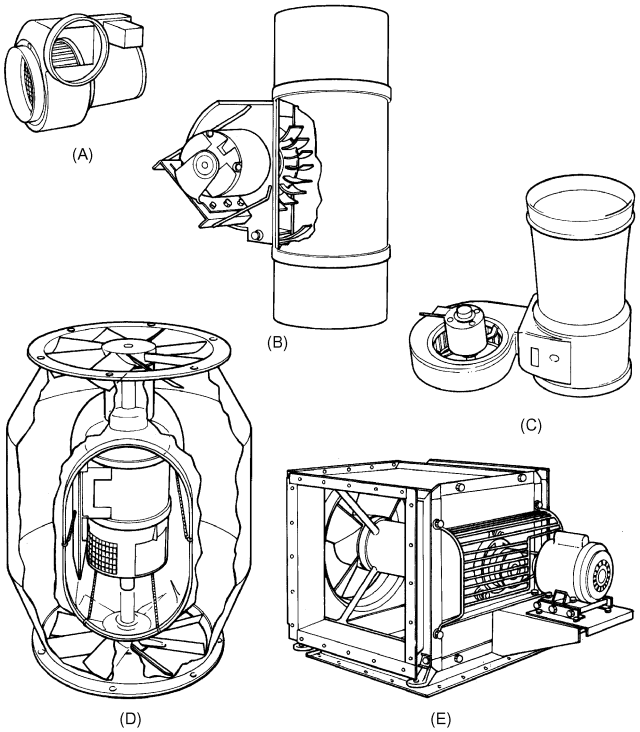

Fig. 25 Draft Inducers

If total pressure defines outlet conditions or is used for fan selection, the relative amounts of static pressure and velocity pressure must be factored out; otherwise, the velocity head method of calculation does not apply. To factor total pressure into its two components, either the discharge velocity in an outlet of known area or the flow rate must be known. For example, if an appliance or blower produces a total pressure of 67 Pa at 7.6 m/s discharge velocity and the velocity pressure calculates to 35 Pa at ambient standard conditions, then static pressure is 62 – 35 = 27 Pa. Because this static pressure is part of the system driving force, it combines with theoretical draft to overcome losses in the system.

Draft inducer fans can be operated either continuously or on demand. In either case, a safety switch that senses flue gas flow or pressure is needed to interrupt burner controls if adequate draft fails. Demand operation links the thermostat with the draft control motor. Once flow starts, as sensed with a flow or pressure switch, the burner is allowed to start. A single draft inducer, operating continuously, can be installed in the common vent of a system serving several separately controlled appliances. This simplifies the circuitry because only one control is needed to sense loss of draft. However, the single fan increases appliance standby loss (especially in boilers) and heat losses via ambient air drawn through inoperative appliances.

14. TERMINATIONS: CAPS AND WIND EFFECTS

The vent or chimney height and method of termination is governed by a variety of considerations, including fire hazard; wind effects; entry of rain, debris, and birds; and operating considerations such as draft and capacity. For example, the 0.9 m height required for residential chimneys above a roof is necessary so that small sparks will burn out before they fall on the roof shingles.

Many vent and chimney malfunctions are attributed to interactions of the chimney termination or its cap with winds acting on the roof or with adjoining buildings, trees, or mountains. Because winds fluctuate, no simple method of analysis or reduction to practice exists for this complex situation. Figures 26 to 28 show some of the complexities of wind flow contours around simple structural shapes.

Figure 26 shows three zones with differing degrees of flue gas dispersion around a rectangular building: the cavity or eddy zone, the wake zone, and the undisturbed flow zone (Clarke 1967). In addition, a fourth flow zone of intense turbulence is located downwind of the cavity. Chimney flue gases discharged into the wind at a point close to the roof surface in the cavity zone may be recirculated locally. Higher in the cavity zone, wind eddies can carry more dilute flue gas to the lee side of the building. Flue gases discharged into the wind in the wake zone do not recirculate into the immediate vicinity, but may soon descend to ground level. Above the wake zone, dispersal into the undisturbed wind flow carries and dilutes the flue gases over a wider area. The boundaries of these zones vary with building configuration and wind direction and turbulence; they are strongly influenced by surroundings.

The possibility of air pollutants reentering the cavity zone because of plume spread or of air pollution intercepting downwind cavities associated with adjacent structures or downwind buildings should be considered. Thus, the design criterion of elevating the stack discharge above the cavity is not valid for all cases. Consult a

meteorologist experienced with dispersion processes near buildings for complex cases and for cases involving air contaminants.

As chimney height increases through the three zones, draft performance improves dispersion, while additional problems of gas cooling, condensation, and structural wind load are created. As building height increases (Figure 27), the eddy forming the cavity zone no longer descends to ground level. For a low, wide building (Figure 28), wind blowing parallel to the long roof dimension can reattach to the surface; thus, the eddy zone becomes flush with the roof surface (Evans 1957). For satisfactory dispersion with low, wide buildings, chimney height must still be determined as if $H = W$ (Figure 26).

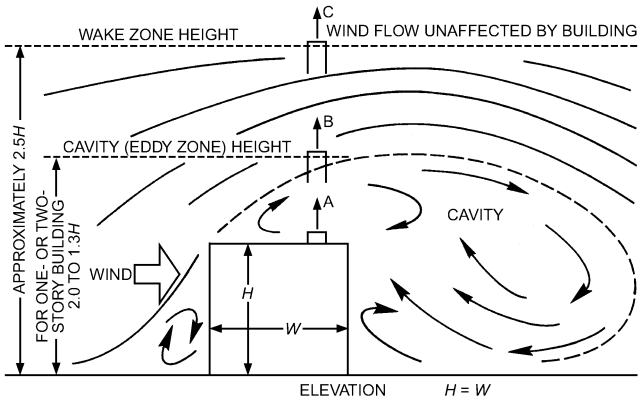
Chien et al. (1951) and Evans (1957) studied pitched roofs in relation to wind flow and surface pressures. Because the typical residence has a pitched roof and probably uses natural gas or a low-sulfur fossil fuel, dispersion is not important because combustion products are relatively free of pollutants. For example, NFPA *Standard* 54/AGA Z223.1 requires a minimum distance between the gas vent termination and any air intake, but it does not require penetration above the cavity zone.

Flow of wind over a chimney termination can impede or assist draft. In regions of stagnation on the windward side of a wall or a steep roof, winds create positive static pressures that impede established flow or cause backdrafts in vents and chimneys. Locating a chimney termination near the surface of a low, flat roof can aid draft because the entire roof surface is under negative static pressure. Velocity is low, however, because of the cavity formed as wind sweeps up over the building. With greater chimney height, termination above the low-velocity cavity or negative-pressure zone subjects the chimney exit to greater wind velocity, thereby increasing draft from two causes: (1) height and (2) wind aspiration over an open top. As the termination is moved from the center of the building to the sides, its exposure to winds and pressure also varies.

Terminations on pitched roofs may be exposed to either negative or positive static pressure, as well as to variation in wind velocity and direction. On the windward side, pitched roofs vary from complete to partial negative pressure as pitch increases from approximately flat to 30° (Chien et al. 1951). At a 45° pitch, the windward pitched roof surface is strongly positive; beyond this slope, pressures approach those observed on a vertical wall facing the wind. Wind pressure varies with its horizontal direction on a pitched roof, and on the lee (sheltered) side, wind velocity is very low, and static pressures are usually negative. Wind velocities and pressures vary not only with pitch, but with position between ridge and eaves. Reduction of these observed external wind effects to simple rules of termination for a wide variety of chimney and venting systems requires many compromises.

In the wake zone or any higher location exposed to full wind velocity, an open top can create strong venting updrafts. The updraft effect relative to wind dynamic pressure is related to the Reynolds number. Open tops, however, are sensitive to the wind angle as well as to rain (Clarke 1967), and many proprietary tops have been designed to stabilize wind effects and improve the performance. Because of the many compromises made in vent termination design, this stability is usually achieved by sacrificing some of the updraft created by the wind. Further, locating a vent cap in a cavity region frequently removes it from the zone where wind velocity could have a significant effect.

Performance optimization studies of residential vent cap design indicate that the following performance features are important: (1) still-air resistance, (2) updraft ability with no flow, and (3) discharge resistance when vent gases are carried at low velocity in a



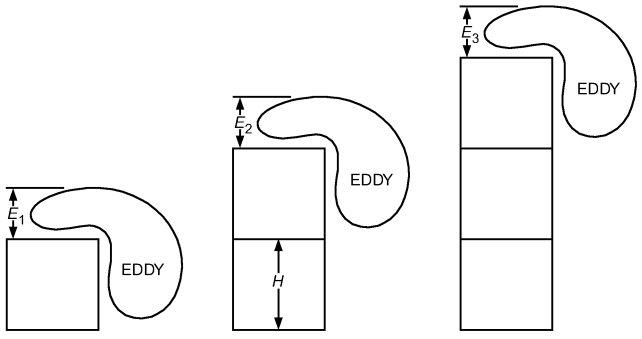
Chimney heights:

A: Discharge into cavity should be avoided because reentry will occur. Dispersion equations do not apply.

B: Discharge above cavity is good. Reentry is avoided, but dispersion may be marginal or poor from standpoint of air pollution. Dispersion equations do not apply.

C: Discharge above wake zone is best; no reentry; maximum dispersion.

Fig. 26 Wind Eddy and Wake Zones for One- or Two-Story Buildings and Their Effect on Chimney Gas Discharge



E = EDDY HEIGHT ABOVE ROOF = $0.5H$

$E_1 = E_2 = E_3$

Studies found for a single cube-shaped building (length equals height) that (1) the height of the eddy above grade is 1.5 times the building height and (2) the height of unaffected air is 2.5 times height above grade. The eddy height above the roof equals $0.5H$, and does not change as building height increases in relation to building width.

Fig. 27 Height of Eddy Currents Around Single High-Rise Buildings

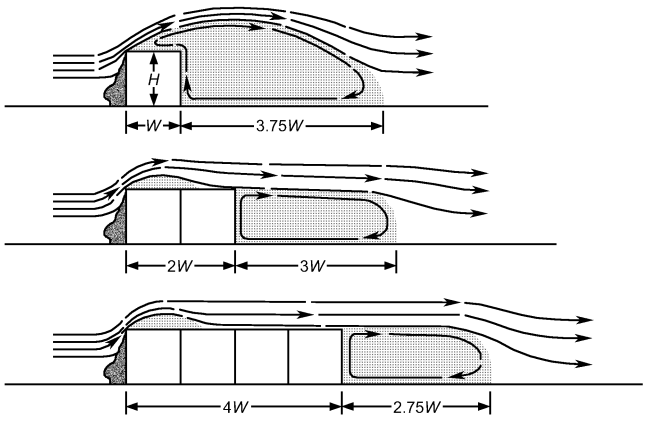


Fig. 28 Eddy and Wake Zones for Low, Wide Buildings

typical wind (3 m/s vent velocity in a 9 m/s wind). Tests in UL *Standard* 441 for proprietary gas vent caps consider these three aspects of performance to ensure adequate vent capacity.

Frequently, air supply to an appliance room is difficult to orient to eliminate wind effects. Therefore, the vent outlet must have a certain updraft capability, which can help balance a possible adverse wind. When wind flows across an inoperative vent termination, a strong updraft develops. Appliance start-up reduces this updraft, and in typical winds, the vent cap may develop greater resistance than it would have in still air. Certain vent caps can be made with very low still-air resistance, yet exhibit excessive wind resistance, which reduces capacity. Finally, because the appliance operates whether there is a wind or not, still-air resistance must be low.

Some proprietary air ventilators have excessive still-air resistance and should be avoided on vent and chimney systems unless a considerably oversized vent is specified. Vertical-slot ventilators, for example, have still-air resistance coefficients of about 4.5. To achieve low still-air resistance on vents and chimneys, the vertical-slot ventilator must be 50% larger than the diameter of the chimney or vent unless it has been specifically listed for such use.

Freestanding chimneys high enough to project above the cavity zone require structurally adequate materials or guying and bracing for prefabricated products. The prefabricated metal building heating appliance chimney places little load on the roof structure, but guying is required at 2.4 to 3.6 m intervals to resist both overturning and oscillating wind forces. Various other expedients, such as spiral baffles on heavy-gage freestanding chimneys, have been used to reduce oscillation.

The chimney height needed to carry the effluent into the undisturbed flow stream above the wake zone can be reduced by increasing the effluent discharge velocity. A 15 m/s discharge velocity avoids downward eddying along the chimney and expels the effluent free of the wake zone. Velocity this high can be achieved only with forced or induced draft.

Rain entry is a problem for open, low-velocity, or inoperative systems. Good results have been obtained with drains that divert the water onto a roof or into a collection system leading to a sump. Figure 29 shows several configurations (Clarke 1967; Hama and Downing 1963). Runoff from stack drains contains acids, soot, and metallic corrosion products, which can cause roof staining. Therefore, these methods are not recommended for residential use. An alternative procedure is to allow all water to drain to the base of the chimney, where it is piped from a capped tee to a sump.

Rain caps prevent vertical discharge of high-velocity flue gases. However, caps are preferred for residential gas-burning equipment because it is easier to exclude rain than to risk rainwater leakage at horizontal joints or to drain it. Also, caps keep out debris and bird nests, which can block the chimney. Satisfactory vent cap performance can be achieved in the wind by using one of a variety of standard configurations, including the A cap and the wind band ventilator, or one of the proprietary designs shown in Figure 29. Where partial rain protection without excessive flow resistance is desired, and either wind characteristics are unimportant or windflow is horizontal, a flat disk or cone cap 1.7 to 2.0 diameters across located 0.5 diameter above the end of the pipe has a still-air resistance loss coefficient of about 0.5.

See Chapter 46 of the 2023 *ASHRAE Handbook—HVAC Applications* for additional information on vent and chimney termination and wind effects.

15. CODES AND STANDARDS

Building and installation codes and standards prescribe the installation and safety requirements of heat-producing appliances and their vents and chimneys. Chapter 52 lists the major national building codes, one of which may be in effect in a given area. Some jurisdictions either adopt a national building code with varying degrees of revisions to suit local custom or, as in many major metropolitan areas, develop a local code that agrees in principle but shares little common text with the national codes. Familiarity with applicable building codes is essential because of the great variation in local codes and adoption of modern chimney design practice.

The national standards listed in Table 11 give greater detail on the mechanical aspects of fuel systems and chimney or vent construction. Although these standards emphasize safety aspects, especially clearances to combustibles for various venting materials, they also recognize the importance of proper flow, draft, and capacity.

16. SYMBOLS

A = area of passage cross section, m^2
A_c = chimney flue cross-sectional area, m^2
A_F = fireplace frontal opening area, m^2
B = existing or local barometric pressure, Pa
B_o = standard pressure, Pa (101 325 Pa)
C_u = temperature multiplier for heat loss, dimensionless
c_p = specific heat of gas at constant pressure, kJ/(kg·K)
d_f = inside diameter, m
d_i = inside diameter, mm
D_a = available draft, Pa
D_b = boost (increase in static pressure by fan), Pa
D_p = depressurization, Pa
D_t = theoretical draft, Pa
F = friction factor for L/d_i
f = Darcy friction factor from Moody diagram (Figure 13, Chapter 3, 2021 *ASHRAE Handbook—Fundamentals*)
H = height of vent or chimney system above grade or system inlet, m
I = operating heat input, MJ/s (MW)
k = system resistance loss coefficient, dimensionless
k_f = fitting friction loss coefficient, dimensionless
k_L = piping friction loss coefficient, dimensionless
L = length of all piping in chimney system from inlet to exit, linear metres
L_m = length of system from inlet to midpoint of vertical or to location of mean gas temperature, m
M = mass flow to input ratio, kg/MJ
Q = volumetric flow rate, m^3/s
q = sensible heat at particular point in vent, MJ/s
q_m = sensible heat at average temperature in vent, MJ/s
T = absolute temperature, K
T_m = mean flue gas temperature at average conditions in system, K
T_o = ambient temperature, K
T_s = standard temperature, K (288.15 K)
U = overall heat transfer coefficient of vent or chimney wall material, referred to inside surface area, $W/(m^2 \cdot K)$
$\overline{U}$ = heat transfer coefficient for Equation (6), $W/(m^2 \cdot K)$
V = velocity of gas flow in passage, m/s
V_F = frontal velocity of ambient air, m/s
w = mass flow of gas, g/s
x = length of one internal side of rectangular chimney cross section, m
y = length of other internal side of rectangular chimney cross section, m
Δp = system flow losses or pressure drop, Pa
Δt = temperature difference, K
Δt_e = temperature difference entering system, K
Δt_m = temperature difference at average temperature location in system, K ($\Delta t_m = T_m - T_o$)
ρ_o = density of air at 288.15 K and 101 325 Pa, kg/m^3 (1.226 kg/m^3)
ρ_m = density of chimney gas at average temperature and local barometric pressure, kg/m^3

CHAPTER 36

HYDRONIC HEAT-DISTRIBUTING UNITS AND RADIATORS

Description 36.1
Ratings of Heat-Distributing Units 36.2
Design 36.3
Applications 36.5

RADIATORS, convectors, and baseboard and finned-tube units are heat-distributing devices used in hot-water and steam heating systems. They supply heat by a **combination of radiation and convection** and maintain the desired air temperature and/or mean radiant temperature in a space without fans. Figures 1 and 2 show sections of typical heat-distributing units. In heating systems, radiant panels are also used. Units are inherently self-adjusting in the sense that heat output is based on temperature differentials; cold spaces receive more heat and warmer spaces receive less heat.

1. DESCRIPTION

Radiators

The term *radiator*, though generally confined to sectional cast-iron column, large-tube, or small-tube units, also includes flat-panel types and fabricated steel sectional types. Small-tube radiators, with a length of only 45 mm per section, occupy less space than column and large-tube units and are particularly suited to installation in recesses (see Table 1). Column, wall-type, and large-tube radiators are no longer manufactured, although many of these units are still in use. See Tables 2, 3, and 4 in Chapter 28 of the 1988 *ASHRAE Handbook—Equipment*, Byrley (1978), or Hydronics Institute (1989) for principal dimensions and average ratings of these units.

The following are the most common types of radiators:

Sectional radiators are fabricated from welded sheet metal sections (generally two, three, or four tubes wide), and resemble free-standing cast-iron radiators.

Panel radiators consist of fabricated flat panels (generally one, two, or three deep), with or without an exposed extended fin surface attached to the rear for increased output. These radiators are most common in Europe.

Tubular steel radiators consist of supply and return headers with interconnecting parallel steel tubes in a wide variety of lengths and heights. They may be specially shaped to coincide with the building structure. Some are used to heat bathroom towel racks.

Specialty radiators are fabricated of welded steel or extruded aluminum and are designed for installation in ceiling grids or floor-mounting. Various unconventional shapes are available.

Pipe Coils

Pipe coils have largely been replaced by finned tubes. See Table 5 in Chapter 28 of the 1988 *ASHRAE Handbook—Equipment* for the heat emission of such pipe coils.

Convectors

A convector is a heat-distributing unit that operates with gravity-circulated air (natural convection). It has a heating element with a large amount of secondary surface and contains two or more tubes with headers at both ends. The heating element is surrounded by an enclosure with an air inlet below and an air outlet above the heating element.

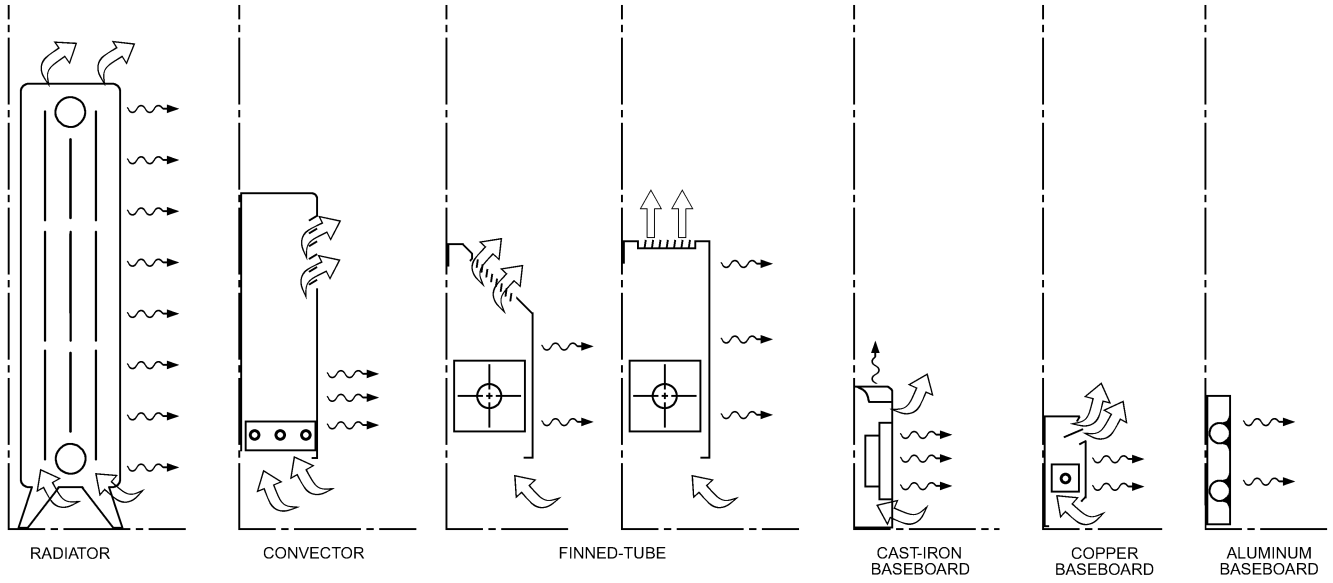

Fig. 1 Terminal Units

The preparation of this chapter is assigned to TC 6.1, Hydronic and Steam Equipment and Systems.

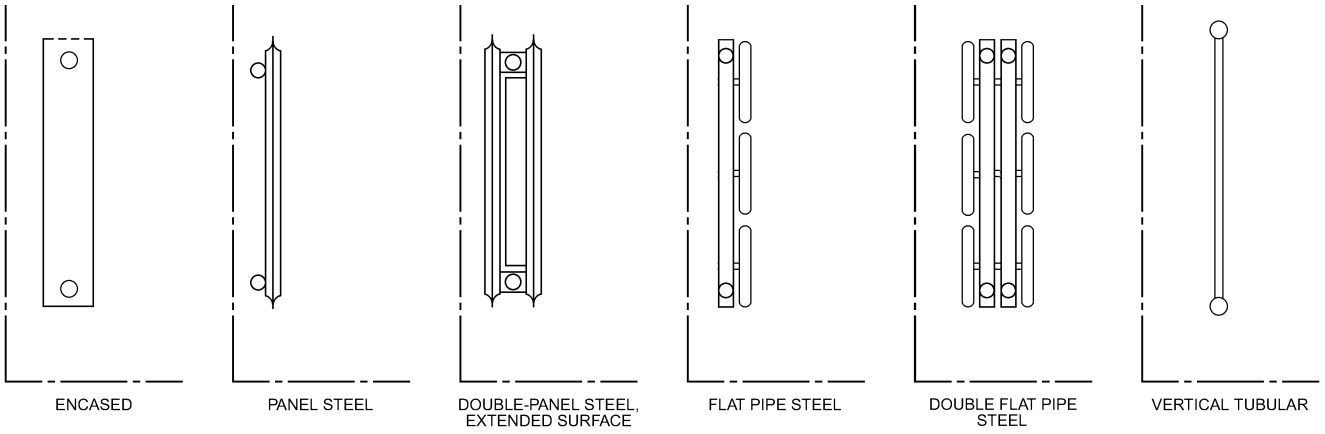

Fig. 2 Typical Radiators

Convectors are made in a variety of depths, sizes, and lengths and in enclosure or cabinet types. The heating elements are available in fabricated ferrous and nonferrous metals. Air enters the enclosure below the heating element, is heated in passing through the element, and leaves the enclosure through the outlet grille located above the heating element. Factory-assembled units comprising a heating element and an enclosure are common, and may be freestanding, wall-hung, or recessed and may have outlet grilles or louvers and arched inlets or inlet grilles or louvers, as desired.

Baseboard Units

Baseboard (or baseboard radiation) units are designed for installation along the bottom of walls in place of conventional baseboard. They may be made of cast iron, with a substantial portion of the front face directly exposed to the room, or with a finned-tube element in a sheet metal enclosure. They use gravity-circulated room air.

Baseboard heat-distributing units are divided into three types: radiant, radiant convector, and finned tube. The **radiant** unit, which is made of aluminum, has no openings for air to pass over the wall side of the unit. Most of this unit's heat output is by radiation.

The **radiant-convector** baseboard is made of cast iron or steel. The units have air openings at the top and bottom to allow circulation of room air over the wall side of the unit, which has extended surface to provide increased heat output. A large portion of the heat emitted is transferred by convection.

The **finned-tube** baseboard has a finned-tube heating element concealed by a long, low sheet metal enclosure or cover. A major portion of the heat is transferred to the room by convection. The output varies over a wide range, depending on the physical dimensions and the materials used. Avoid using a unit with a high relative output per unit length compared to overall heat loss, which would result in a concentration of the heating element over a relatively small area. Optimum comfort for room occupants is obtained when units are installed along as much of the exposed wall as possible.

Finned-Tube Units

Finned-tube (or fin-tube) units are fabricated from metallic tubing, with metallic fins bonded to the tube. They operate with gravity-circulated room air. Finned-tube elements are available in several tube sizes, in either steel or copper (25 to 50 mm nominal steel or 22 to 35 mm nominal copper) with various fin sizes, spacings, and materials. Resistance to steam or water flow is the same as that through standard distribution piping of equal size and type.

Finned-tube elements installed in occupied spaces generally have covers or enclosures in a variety of designs. When human contact is unlikely, they are sometimes installed bare or provided with an expanded metal grille for minimum protection.

A **cover** has a portion of the front skirt made of solid material. The cover can be mounted with clearance between the wall and the cover, and without completely enclosing the rear of the finned-tube element. A cover may have a top, front, or inclined outlet. An **enclosure** is a shield of solid material that completely encloses both the front and rear of the finned-tube element. The enclosure may have an integral back or may be installed tightly against the wall so that the wall forms the back, and it may have a top, front, or inclined outlet.

Heat Emission

These heat-distributing units emit heat by a combination of radiation to the surfaces and occupants in the space and convection to the air in the space.

Chapter 4 of the 2021 *ASHRAE Handbook—Fundamentals* covers the heat transfer processes and the factors that influence them. Those units with a large portion of their heated surface exposed to the space (i.e., radiator and cast-iron baseboard) emit more heat by radiation than do units with completely or partially concealed heating surfaces (i.e., convector, finned-tube, and finned-tube baseboard). Also, finned-tube elements constructed of steel emit a larger portion of heat by radiation than do finned-tube elements constructed of nonferrous materials.

The heat output ratings of heat-distributing units are expressed in watts or in square metres equivalent direct radiation (EDR).

2. RATINGS OF HEAT-DISTRIBUTING UNITS

For convectors, baseboard units, and finned-tube units, an allowance for heating effect may be added to the **test capacity** (the heat extracted from the steam or water under standard test conditions). This **heating effect** reflects the ability of the unit to direct its heat output to the occupied zone of a room. The application of a heating effect factor implies that some units use less steam or hot water than others to produce an equal comfort effect in a room.

Radiators

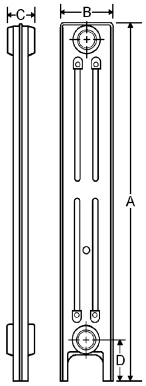
Current methods for rating radiators were established by the U.S. National Bureau of Standards publication, *Simplified Practices Recommendation* R174-65, Cast-Iron Radiators, which has been withdrawn (Table 1).

Convectors

The generally accepted method of testing and rating ferrous and nonferrous convectors in the United States was given in *Commercial Standard* CS 140-47, Testing and Rating Convectors (Dept. of

Table 1 Small-Tube Cast-Iron Radiators

Number of Tubes per Section	Catalog Rating per Section,[a] W	Section Dimensions				
		A Height, mm[b]	B Width, mm		C Spacing, mm[c]	D Leg Height, mm[b]
			Min.	Max.		
3	113	635	83	89	45	65
4	113	483	113	122	45	65
	127	559	113	122	45	65
	141	635	113	122	45	65
5	148	559	143	160	45	65
	169	635	143	160	45	65
6	162	483	173	203	45	65
	211	635	173	203	45	65
	260	813	173	203	45	65



[a] Ratings based on steam at 101.7°C and air at 21.1°C. They apply only to installed radiators exposed in a normal manner, not to radiators installed behind enclosures, behind grilles, or under shelves. For ratings at other temperatures, multiply table values by factors found in Table 2.

[b] Overall height and leg height, as produced by some manufacturers, are 25 mm greater than shown in columns A and D. Radiators may be furnished without legs. Where greater than standard leg heights are required, leg height should be 115 mm.

[c] Length equals number of sections multiplied by 45 mm.

Commerce 1947), but it has been withdrawn. This standard contained details covering construction and instrumentation of the test booth or room and procedures for determining steam and water ratings.

Under the provisions of *Commercial Standard* CS 140-47, the rating of a top outlet convector was established at a value not in excess of the test capacity. For convectors with other types of enclosures or cabinets, a percentage that varies up to a maximum of 15% (depending on the height and type of enclosure or cabinet) was added for heating effect (Brabbee 1926; Willard et al. 1929). The addition made for heating effect must be shown in the manufacturer's literature.

The testing and rating procedure set forth by *Commercial Standard* CS 140-47 does not apply to finned-tube or baseboard radiation.

Baseboard Units

The generally accepted method of testing and rating baseboards in the United States is covered in the *Testing and Rating Standard for Baseboard Radiation* (AHRI 2005). This standard contains details covering construction and instrumentation of the test booth or room, procedures for determining steam and hot-water ratings, and licensing provisions for obtaining approval of these ratings. Baseboard ratings include an allowance for heating effect of 15% in addition to the test capacity. The addition made for heating effect must be shown in the manufacturer's literature.

Finned-Tube Units

The generally accepted method of testing and rating finned-tube units in the United States is covered in AHRI *Standard* 1410. This standard contains details covering construction and instrumentation of the test booth or room, procedures for determining steam and water ratings, and licensing provisions for obtaining approval of these ratings.

The rating of a finned-tube unit in an enclosure that has a top outlet is no greater than the test capacity. For finned-tube units with other types of enclosures or covers, a percentage is added for heating effect that varies up to a maximum of 15%, depending on the height and type of enclosure or cover. The addition made for heating effect must be shown in the manufacturer's literature (Pierce 1963).

Other Heat-Distributing Units

Unique radiators and radiators from other countries generally are tested and rated for heat emission in accordance with prevailing standards. These other testing and rating methods have basically the same procedures as the Hydronics Institute and AHRI standards, which are used in the United States. See Chapter 6 for information on the design and sizing of radiant panels.

Corrections for Nonstandard Conditions

The heating capacity of a radiator, convector, baseboard, finned-tube heat-distributing unit, or radiant panel is a power function of the temperature difference between the air in the room and the heating medium in the unit, shown as

$$q = c(t_s - t_a)^n \quad (1)$$

where

q = heating capacity, W
c = constant determined by test
t_s = average temperature of heating medium, °C. For hot water, use arithmetic average of entering and leaving water temperatures.
t_a = room air temperature, °C. Air temperature 1.5 m above floor is generally used for radiators, whereas entering air temperature is used for convectors, baseboard units, and finned-tube units.
n = exponent that equals 1.2 for cast-iron radiators, 1.31 for baseboard radiation, 1.42 for convectors, 1.0 for ceiling heating and floor cooling panels, and 1.1 for floor heating and ceiling cooling panels. For finned-tube units, n varies with air and heating medium temperatures. Correction factors to convert heating capacities at standard rating conditions to heating capacities at other conditions are given in Table 2.

Equation (1) may also be used to calculate heating capacity at nonstandard conditions.

3. DESIGN

Effect of Water Velocity

Designing for high temperature drops through the system (as much as 35 to 45 K in low-temperature water (LTW) systems and as much as 110 K in high-temperature systems) can result in low water velocities in the finned-tube or baseboard element. Applying very short runs designed for conventional temperature drops (i.e., 10 K) can also result in low velocities.

Figure 3 shows the effect of water velocity on the heat output of typical sizes of finned-tube elements. The figure is based on work done by Harris (1957) and Pierce (1963) and tests at the Hydronics Institute. The velocity correction factor F_v is

Table 2 Correction Factors *c* for Various Types of Heating Units

Steam Pressure (Approx.), kPa (absolute)	Steam or Water Temp., °C	Radiator			Convector			Finned-Tube			Baseboard		
		Room Temp., °C			Air Temp., °C			Air Temp., °C			Air Temp., °C		
		25	20	15	25	20	15	25	20	15	25	20	15
9.5	45	—	—	—	—	—	—	0.15	0.21	0.26	0.14	0.19	0.24
15.8	55	—	—	0.40	—	—	0.33	0.26	0.32	0.37	0.24	0.30	0.36
25.0	65	0.40	0.47	0.54	0.33	0.40	0.47	0.37	0.44	0.50	0.36	0.43	0.49
38.6	75	0.54	0.61	0.68	0.47	0.54	0.61	0.50	0.57	0.64	0.49	0.56	0.63
57.9	85	0.68	0.76	0.83	0.61	0.69	0.77	0.64	0.71	0.78	0.63	0.70	0.78
84.6	95	0.83	0.91	0.99	0.77	0.85	0.93	0.78	0.86	0.94	0.78	0.86	0.94
120.9	105	0.99	1.07	1.15	0.93	1.02	1.11	0.94	1.01	1.09	0.94	1.02	1.11
169.2	115	1.15	1.24	1.32	1.11	1.20	1.30	1.09	1.18	1.26	1.11	1.20	1.29
232.3	125	1.32	1.41	1.50	1.30	1.40	1.50	1.26	1.34	1.42	1.29	1.38	1.47
313.4	135	1.50	1.59	1.68	1.50	1.60	1.70	1.42	1.51	1.60	1.47	1.57	1.66
415.8	145	1.68	1.77	1.86	1.70	1.81	1.92	1.60	1.69	1.78	1.66	1.76	1.86

Note: Use these correction factors to determine output ratings for radiators, convectors, and finned-tube and baseboard units at operating conditions other than standard. Standard conditions in the United States for a radiator are 102°C heating medium temperature and 21°C room temperature (at center of space and at 1.5 m level).

Standard conditions for convectors and finned-tube and baseboard units are 102°C heating medium temperature and 18°C inlet air temperature at 101.3 kPa atmospheric pressure. Water flow is 0.9 m/s for finned-tube units. Inlet air at 18°C for convectors and finned-tube or baseboard units represents the same room comfort conditions as 21°C room air temperature for a radiator. Standard conditions for radiant panels are 50°C heating medium temperature and 20°C for room air temperature; *c* depends on panel construction.

To determine output of a heating unit under nonstandard conditions, multiply standard heating capacity by appropriate factor for actual operating heating medium and room or inlet air temperatures.

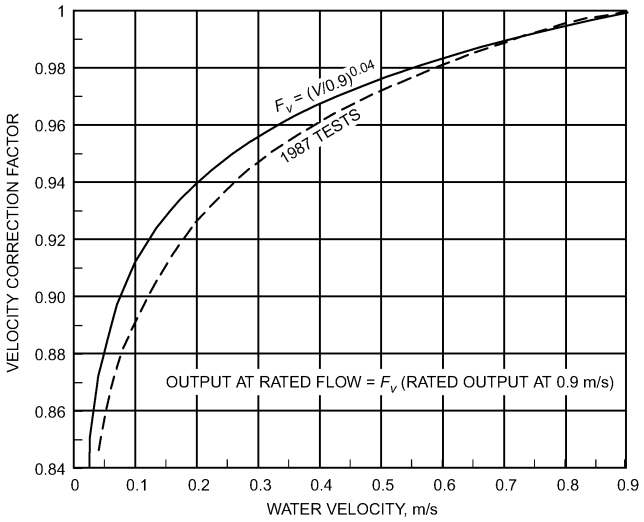


Fig. 3 Water Velocity Correction Factor for Baseboard and Finned-Tube Radiators

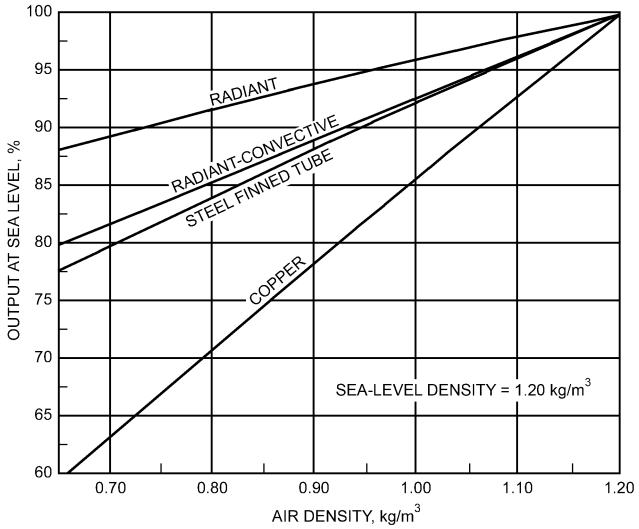

Fig. 4 Effect of Air Density on Radiator Output

$$F_v = (V/0.9)^{0.0} \quad (2)$$

where V = water velocity, m/s.

Heat output varies little over the range from 0.15 to 0.9 m/s, where F_v ranges from 0.93 to 1.00. The factor drops rapidly below 0.15 m/s because flow changes from turbulent to laminar at around 0.03 m/s. Avoid such a low velocity because the output is difficult to predict accurately when designing a system. In addition, the curve is so steep in this region that small changes in actual flow have a significant effect on output. Not only does the heat transfer rate change, but the temperature drop and, therefore, the average water temperature change (assuming a constant inlet temperature).

The designer should check water velocity throughout the system and select finned-tube or baseboard elements on the basis of velocity as well as average temperature. Manufacturers of finned-tube and baseboard elements offer a variety of tube sizes, ranging from 15 mm copper tubes for small baseboard elements to 50 mm for large finned-tube units, to aid in maintenance of turbulent flow conditions over a wide range of flow.

Effect of Altitude

The effect of altitude on heat output varies depending on the material used and the portion of the unit's output that is radiant rather than convective. The reduced air density affects the convective portion. Figure 4 shows the reduction in heat output with air density (Sward and Decker 1965). The approximate correction factor F_A for determining the reduced output of typical units is

$$F_A = (p/p_o)^n \quad (3)$$

where

p = local station atmospheric pressure
p_o = standard atmospheric pressure
n = 0.9 for copper baseboard or finned tube
= 0.5 for steel finned-tube or cast-iron baseboard

= 0.2 for radiant baseboard and radiant panels

The value of p/p_o at various altitudes may be calculated as follows:

$$p/p_o = e^{-1.22\times10^{-4}h} \quad (4)$$

where h = altitude, m. The following are typical values of p/p_o:

Altitude h, m	p/p_o
600	0.93
1200	0.86
1500	0.83
1800	0.80

Sward and Harris (1970) showed that some components of heat loss are affected in the same manner.

Effect of Mass

Mass of the terminal unit (typically cast-iron versus copper-aluminum finned element) affects the heat-up and cooldown rates of equipment. It is important that high- and low-mass radiation not be mixed in the same zone. High-mass systems have historically been favored for best comfort and economy, but tests by Harris (1970) showed no measurable difference. The thermostat or control can compensate by changing the burner's cycle rate. The effect of mass is further reduced by constantly circulating modulated temperature water to the unit. The only time that mass can have a significant effect is in response to a giant shift in load. In that situation, the low-mass unit will respond faster.

Performance at Low Water Temperatures

Table 2 summarizes the performance of baseboard and finned-tube units with an average water temperature down to 38°C. Solar-heated water, industrial waste heat in a low- to medium-temperature district heating system, condensing boilers, heat pump system cooling water, and ground-source heat pumps are typical applications in this range. To compensate for heating capacity loss, either heat-distributing equipment should be oversized, or additional heat-distributing units should be installed. Minimize capital and operating costs (Kilkis 1998).

Effect of Enclosure and Paint

An enclosure placed around a direct radiator restricts airflow and diminishes the proportion of output resulting from radiation. However, enclosures of proper design may improve heat distribution in the room compared to that obtained with an unenclosed radiator (Allcut 1933; Willard et al. 1929).

For a radiator or cast-iron baseboard, the finish coat of paint affects the heat output. Oil paints of any color give about the same results as unpainted black or rusty surfaces, but an aluminum or a bronze paint reduces the heat emitted by radiation. The net effect may reduce the total heat output of the radiator by 10% or more (Allen 1920; Rubert 1937; Severns 1927).

4. APPLICATIONS

Radiators

Radiators can be used with steam or hot water. They are installed in areas of greatest heat loss: under windows, along cold walls, or at doorways. They can be freestanding, semirecessed, or with decorative enclosures or shields (although these affect output) (Willard et al. 1929).

Unique and imported radiators are generally not suitable for steam applications, although they have been used extensively in low-temperature water systems with valves and connecting piping left exposed. Various combinations of supply and return locations are possible, and may alter heat output. Although long lengths may be ordered for linear applications, lengths may not be reduced or increased by field modification. The small cross-sectional areas often inherent in unique radiators require careful evaluation of flow requirements, water temperature drop, and pressure drops.

Convectors

Convectors can be used with steam or hot water. Like radiators, they should be installed in areas of greatest heat loss. They are particularly applicable where wall space is limited, such as in entryways and kitchens.

Baseboard Radiation

Baseboard units are used almost exclusively with hot water. When used with one-pipe steam systems, tube sizes of 32 mm nominal diameter must be used to allow drainage of condensate counterflow to the steam flow.

The basic advantage of the baseboard unit is that its normal placement is along the cold walls and under areas where the greatest heat loss occurs. Other advantages are that it (1) is inconspicuous, (2) offers minimal interference with furniture placement, and (3) distributes the heat near the floor. This last characteristic reduces the floor-to-ceiling temperature gradient to about 1 to 2 K and tends to produce uniform temperature throughout the room. It also makes baseboard heat-distributing units adaptable to homes without basements, where cold floors are common (Kratz and Harris 1945).

Heat loss calculations for baseboard heating are the same as those used for other types of heat-distributing units. Hydronics Institute (1989) describes a procedure for designing baseboard heating systems.

Finned-Tube Radiation

The finned-tube unit can be used with either steam or hot water. It is advantageous for heat distribution along the entire outside wall, thereby preventing downdrafts along the walls in buildings such as schools, churches, hospitals, offices, airports, and factories. It may be the principal source of heat in a building or a supplementary heater to combat downdrafts along the exposed walls in conjunction with a central conditioned air system. Its placement under or next to windows or glass panels helps to prevent fogging or condensation on the glass.

Normal placement of a finned tube is along the walls where the heat loss is greatest. If necessary, the units can be installed in two or three tiers along the wall. Hot-water installations requiring two or three tiers may run a serpentine water flow if the energy loss is not excessive. A header connection with parallel flow may be used, but the design must not (1) allow water to short circuit along the path of least resistance, (2) reduce capacity because of low water velocity in each tier, or (3) cause one or more tiers to become air-bound.

Many enclosures have been developed to meet building design requirements. The wide variety of finned-tube elements (tube size and material, fin size, spacing, fin material, and multiple-tier installation), along with the various heights and designs of enclosures, give great flexibility of selection for finned-tube units that meet the needs of load, space, and appearance.

In areas where zone control rather than individual room control can be applied, all finned-tube units in the zone should be in series. In such a series loop installation, however, temperature drop must be considered in selecting the element for each separate room in the loop.

Radiant Panels

Hydronic radiant heating panels are controlled-temperature surfaces on the floor, walls, or ceiling; a heated fluid circulates through a circuit embedded in or attached to the panel. More than 50% of the total heating capacity is transmitted by radiant heat transfer. Usually, 50°C mean fluid temperature delivers enough heat to indoor

surfaces. With such low temperature ratings, hydronic radiant panels are suitable for low-temperature heating. See Chapter 6 for more information.

SOLAR energy use is becoming more economical, primarily due to technological maturity, economies of scale, and governmental policies with immediate interest in low-carbon and sustainable construction (Kavlak et al. 2018). In addition, many countries consider solar and renewable energy a security measure, to ensure the availability of power under adverse conditions. While the United States continues to grow its solar industry, China, Europe, Asia, and the Mediterranean basin are leading development of advanced manufacturing techniques and applications. However, equipment and systems are still very similar in all markets; therefore, this chapter primarily discusses the basic equipment used, with particular attention to collectors. More detailed descriptions of systems and designs can be found in Chapter 36 of the 2023 *ASHRAE Handbook—HVAC Applications.*

Commercial and industrial solar thermal energy systems are generally classified according to the heat transfer medium used in the collector loop (i.e., air or liquid). Although both systems share basic fundamentals of conversion for solar radiant energy, the equipment used in each is entirely different. Air systems are primarily limited to forced-air space heating and industrial and agricultural drying processes. Liquid systems are suitable for a broader range of applications, such as hydronic space heating, service water heating, industrial process water heating, energizing heat-driven air conditioning, and pool heating, and as a heat source for series-coupled heat pumps. Because of this wide range in capability, liquid systems are more common than air systems in commercial and industrial applications.

As shown in Table 1, global installed thermal capacity of solar collectors at the end of 2017 reached 473.8 gigawatts (GW_{th}), which corresponds to an annual solar thermal energy yield of at least 390 TWh (Weiss and Spork-Dur 2018). Unglazed water collectors are used mainly for low-temperature (e.g., swimming pool) heating; their main markets are in North America (i.e., the United States and Canada) with an installed capacity of 16.1 GW_{th}, followed by Australia and Brazil (3.7 GW_{th} each). Glazed flat-plate and evacuated-tube collectors, which are mainly used to generate domestic hot water and space heating, dominate the market in China (334.5 GW_{th}), Turkey (16.3 GW_{th}), and Germany (13.3 GW_{th}).

By the end of 2017, the total thermal capacity in operation in the European Union exceeded 36.5 GW_{th}, corresponding to 52.1 million m^2 of collector area. Germany is the leader in terms of market volume, with about 38% of the European market, whereas Austria, Greece, Italy, Spain, France, and Poland together account for about 45%. Solar hot-water systems are now mandatory in new buildings according to solar ordinances in Cyprus, Greece, Italy, Portugal, Slovenia, Spain, and elsewhere in Europe.

China is the leader in the global solar heating industry, producing an estimated 334.5 GW_{th} or 477.8 million m^2 of collectors in 2017. Most installations in China use evacuated-tube collectors for domestic hot water only. The trend in Europe is towards larger **solar-combi systems** that provide both domestic hot water and space heating, accounting for half of the annual market in Austria and Germany (Balaras et al. 2010), as well as multipurpose heat-pump-assisted solar systems (Todorovic et al. 2010). The U.S. market for solar hot-water collectors (excluding unglazed swimming pool heating) is still relatively small but is gaining ground (especially in California): some states have set solar thermal carve-outs in their renewable portfolio standards (RPS), or allow electric utilities to meet RPS requirements with solar water heating systems (REN21 2018). Other markets that are growing quickly include Denmark, India, Mexico, Australia, and South Africa, although some of these markets are challenged by a lack of standards, leading to use of inferior products and poor installations, which have undermined the systems' reputation.

Table 1 Worldwide Solar Capacity in Operation by Type

	Capacity, GW_{th}	Equiv. Glazed Collector Area, 1 000 000 m^2
Glazed flat-plate collectors	107.2	153.1
Evacuated-tube collectors	336.6	480.9
Unglazed collectors	28.6	41.0
Glazed and unglazed air collectors	1.4	1.8
Total	**473.8**	**676.8**

Photovoltaic (PV) systems convert light from the sun directly into electricity for a wide variety of applications. The cost of PV systems has dropped significantly worldwide. At the end of 2017, the average price in the United States for installed systems varied from $2.88/W for grid-connected commercial systems to $0.98/W for grid-connected, ground-mounted ones (IEA 2018). This cost reduction has made PV systems considerably more economical, particularly when combined with federal tax credits and local incentives, and the amount of installed capacity has thus increased dramatically.

In 2018, the global cumulative installed photovoltaic capacity crossed the 500 GW_p mark and produced at least 660 TWh annually (IEA 2019a). China is the leader in terms of cumulative installed capacity (176.1GW_p), followed by the European Union (115 GW_p), United States (62.2 GW_p), and Japan (56 GW_p). Germany is also a leader, with about 39% of the cumulative European installed capacity, whereas Italy, the United Kingdom, France, Spain, Belgium, the Netherlands, and Austria together account for about 50%. Other markets that are also growing quickly include India, Australia, Mexico, Korea, and Turkey.

PV systems with thermal heat recovery (PVT) are a hybrid solar technology that integrates photovoltaic and thermal solar energy conversion within a single system. In PVT systems, the fraction of incident solar radiation that is absorbed is converted partially into electricity and partially into thermal energy that is recovered by a heat recovery fluid (air, water, or a refrigerant), reaching combined (electrical and thermal) efficiencies of up to 70%. By the end of

The preparation of this chapter is assigned to TC 6.7, Solar Energy Utilization.

2018, a total of 524.2 MW_{th} thermal capacity of PVT modules and 178.2 MW_p of PV power was installed globally, corresponding to 1 million m² of PVT modules. Early adopters of this hybrid solar technology are France (215.6 MW_{th} and 70.1 MW_p), Korea (137.6 MW_{th} and 47.8 MW_p), China (65.6 MW_{th} and 22.8 MW_p), and Germany (53.6 MW_{th} and 18.6 MW_p). More information on PVT systems and designs can be found in Chapter 36 of the 2023 *ASHRAE Handbook—HVAC Applications*.

1. SOLAR HEATING SYSTEMS

Solar energy system design requires careful attention to detail because solar radiation is a low-intensity form of energy, and the equipment to collect and use it can be expensive. A brief overview of air and liquid systems is presented here to show how the equipment fits into each type of system. Chapter 36 of the 2023 *ASHRAE Handbook—HVAC Applications* covers solar energy use, and books on design, installation, operation, and maintenance are also available (ASHRAE 1988, 1990, 1991).

Solar energy and HVAC systems often use the same components and equipment. This chapter covers only the following elements, which are either exclusive to or have specific uses in solar energy applications:

- Collectors and collector arrays
- Thermal energy storage
- Heat exchangers
- Controls

Thermal energy storage is covered in Chapter 50, heat exchangers in Chapter 47, pumps in Chapter 44, and fans in Chapter 21.

1.1 AIR-HEATING SYSTEMS

Air-heating systems circulate air through ducts to and from an air heating collector (Figure 1). Air systems are effective for space heating because a heat exchanger is not required, and the collector inlet temperature is low throughout the day (approximately room temperature). Air systems do not need protection from freezing, overheat, or corrosion. Furthermore, air costs nothing and does not cause disposal problems or structural damage. However, air ducts and air-handling equipment require more space than pipes and pumps, ductwork is hard to seal, and leaks are difficult to detect. Fans consume more power than the pumps of a liquid system, but if the unit is installed in a facility that uses air distribution, only a slight power cost is chargeable against the solar space-heating system. Thermal storage for hot-air systems has been problematic as well because of the difficulty in controlling humidity and mold growth in pebble beds and other such devices, particularly in humid climates.

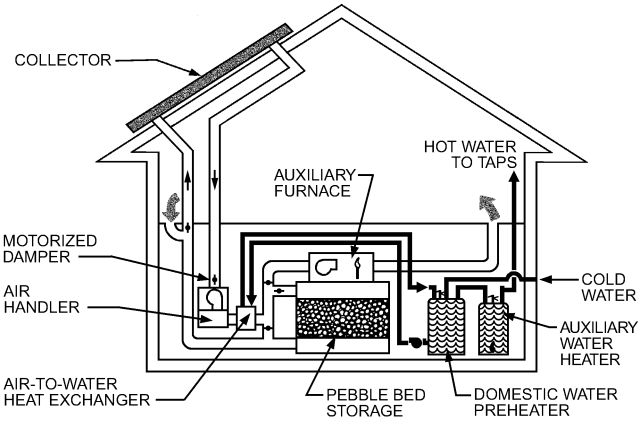

Fig. 1 Air-Heating Space and Domestic Water Heater System

Most air space-heating systems also preheat domestic hot water through an air-to-liquid heat exchanger. In this case, tightly fitting dampers are required to prevent reverse thermosiphoning at night, which could freeze water in the heat exchanger coil. If this system heats only water in the summer, the parasitic power consumption must be charged against the solar energy system because no space heating is involved and there are no comparable energy costs associated with conventional water heating. In some situations, solar water-heating systems could be more expensive than conventional water heaters, particularly if electrical energy costs are high. To reduce parasitic power consumption, some systems use the low speed of a two-speed fan.

1.2 LIQUID-HEATING SYSTEMS

Liquid-heating systems circulate a liquid, often a water-based fluid, through a solar collector (Figures 2 and 3). The liquid in solar collectors must be protected against freezing, which could damage the system.

Freezing is the principal cause of liquid system failure. For this reason, freeze tolerance is an important factor in selecting the heat transfer fluid and equipment in the collector loop. A solar collector radiates heat to the cold sky and freezes at air temperatures well above 0 °C. Where freezing conditions are rare, small solar heating systems are often equipped with low-cost protection devices that depend on simple manual, electrical, and/or mechanical components (e.g., electronic controllers and automatic valves) for freeze protection. Because of the large investment associated with most commercial and industrial installations, solar designers and installers must consider designs providing reliable freeze protection, even in the warmest climates.

Thermosiphon solar domestic hot-water heating systems operate at low, self-regulated collector flow rates. Their performance is generally better in temperate climates than active (using a pump to circulate the fluid) systems operating at conventional flow rates and is comparable to pump systems operating at low collector flow rates. Thermosiphon systems dominate the market in residential

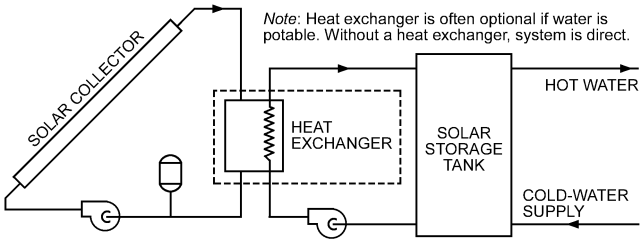

Fig. 2 Simplified Schematic of Indirect Nonfreezing System

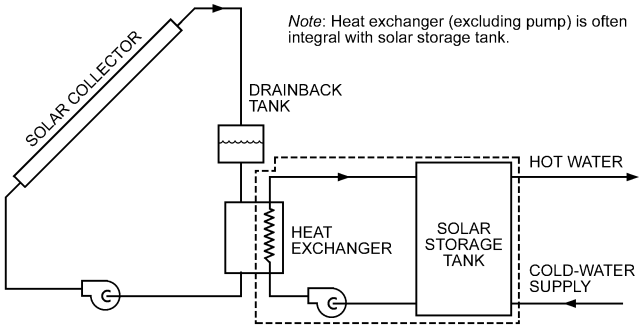

Fig. 3 Simplified Schematic of Indirect Drainback Freeze Protection System

and low-rise building applications in southern Europe and China, and Australia. The collector fluid is circulated by natural convection, eliminating the need for the pump and controller of an active system. The hot-water storage tank is placed above the collector area. The flow rate varies depending on the absorbed solar radiation, fluid temperatures, system geometry, etc.

Direct and Indirect Systems

In a direct liquid system, city water circulates through the collector. In an indirect system, the collector loop is separated from the high-pressure city water supply by a heat exchanger. In areas of poor water quality, isolation protects the collectors from fouling by minerals in the water. Indirect systems also offer greater freeze protection, so they are used almost exclusively in commercial and industrial applications.

Freeze Protection

Direct systems, used where freezing is infrequent and not severe, can avoid freeze damage by (1) recirculating warm storage water through the collectors, (2) continually flushing the collectors with cold water, or (3) isolating collectors from the water and draining them. Systems that can be drained to avoid freeze damage are called **drain-down** systems. Although all of these methods can be effective, none of them are generally approved by sanctioning bodies or recommended by manufacturers. Use caution when designing direct systems in freezing climates with any of these freeze protection schemes.

Indirect systems use two methods of freeze protection: (1) nonfreezing fluids and (2) drainback.

Nonfreezing Fluid Freeze Protection. The most popular solar energy system for commercial use is the indirect system with a nonfreezing heat transfer fluid to transmit heat from the solar collectors to storage (Figure 2). The most common heat transfer fluid is water/propylene glycol, although other heat transfer fluids such as silicone oils, hydrocarbon oils, or refrigerants can be used. Because the collector loop is closed and sealed, the only contribution to pump pressure is friction loss; therefore, the location of solar collectors relative to the heat exchanger and storage tank is not critical. Traditional hydronic sizing methods can be used for selecting pumps, expansion tanks, heat exchangers, and air removal devices, as long as the heat transfer liquid's thermal properties are considered.

When the control system senses an increase in solar panel temperature, the pump circulates the heat transfer liquid, and energy is collected. The same control also activates a pump on the domestic water side that circulates water through the heat exchanger, where it is heated by the heat transfer fluid. This mode continues until the temperature differential between the collector and the tank is too slight for meaningful energy to be collected. At this point, the control system shuts the pumps off. At low temperatures, the nonfreezing fluid protects the solar collectors and related piping from bursting. Because the heat transfer fluid can affect system performance, reliability, and maintenance requirements, fluid selection should be carefully considered.

Because the collector loop of the nonfreezing system remains filled with fluid, it allows flexibility in routing pipes and locating components. However, a double-separation (double-wall) heat exchanger is generally required (by local building codes) to prevent contamination of domestic water in the event of a leak. The double-wall heat exchanger also protects the collectors from freeze damage if water leaks into the collector loop. However, the double-wall heat exchanger reduces efficiency by forcing the collector to operate at a higher temperature. The heat exchanger can be placed inside the tank, or an external heat exchanger can be used, as shown in Figure 2. The collector loop is closed and, therefore, requires an expansion tank and pressure-relief valve. Air purge is also necessary to expel air during filling and to remove air that has been absorbed into the heat transfer fluid.

Overtemperature protection is necessary to ensure that the system operates within safe limits and to prevent collector fluid from corroding the absorber or heat exchanger. For maximum reliability, glycol should be replaced every few years.

In some cases, systems have failed because the collector fluid in the loop thermosiphoned and froze the water in the heat exchanger. If the water side is exposed to the city water system, this disastrous situation must be avoided by design.

Drainback Freeze Protection. A drainback solar water-heating system (see Figure 3) uses ordinary water as the heat transport medium between the collectors and thermal energy storage. Reverse-draining (or back-siphoning) the water into a drainback tank located in a nonfreezing environment protects the system from freezing whenever the controls turn off the circulator pump or a power outage occurs.

For drainback systems with a large amount of working fluid in the collector loop, heat loss can be significantly decreased and overall efficiency increased by including a tank for storing the heat transfer fluid at night. Using a night storage tank in large systems is an appropriate strategy even for regions with favorable meteorological conditions.

The drainback tank can be a sump with a volume slightly greater than the collector loop, or it can be the thermal energy storage tank. The collector loop may or may not be vented to the atmosphere. Many designers prefer the nonvented drainback loop because makeup water is not required and the corrosive effects of air that would otherwise be ingested into the collector loop are eliminated.

The drainback system is virtually fail-safe because it automatically reverts to a safe condition whenever the circulator pump stops. Furthermore, a 20 to 30% glycol solution can be added to drainback loops for added freeze protection in case of controller or sensor failure. Because the glycol is not exposed to stagnation temperatures, it does not decompose.

A drainback system requires space for the necessary pitching of collectors and pipes for proper drainage. Also, a nearby heated area must have a room for the pumps and the drainback tank. Plumbing exposed to freezing conditions drains to the drainback tank, making the drainback design unsuitable for sites where the collector cannot be elevated above the storage tank.

Both dynamic and static pressure losses must be considered in drainback system design. Dynamic pressure loss is due to friction in the pipes, and static pressure loss is associated with the distance the water must be lifted above the level of the drainback tank to the top of the collector. There are two distinct designs of drainback systems: the oversized downcomer (or open-drop) and the siphon return. The static pressure requirement remains constant in the open-drop system and decreases in the siphon return.

Drainback performs better than other systems in areas with low temperatures or high irradiance. Drainback has the advantage that time and energy are not lost in reheating a fluid mass left in the collector and associated piping (as in the case of antifreeze systems). Also, water has a higher heat transfer capacity and is less viscous than other heat transfer fluids, resulting in smaller parasitic energy use and higher overall system efficiency. In closed-return (indirect) designs, there is also less parasitic energy consumption for pumping because water is the heat transfer fluid. Drainback systems can be worked on safely under stagnation conditions, but should not be restarted during peak solar conditions to avoid unnecessary thermal stress on the collector.

1.3 SOLAR THERMAL ENERGY COLLECTORS

Collector Types

Solar collectors depend on air heating, liquid heating, or liquid-vapor phase change to transfer heat. The most common type for

commercial, residential, and low-temperature (<95°C) industrial applications is the flat-plate collector.

Liquid-Heating Collectors. Figure 4A shows a cross section of a flat-plate liquid collector. A flat-plate collector contains an absorber plate covered with a black coating and one or more transparent covers. The covers are transparent to incoming solar radiation and relatively opaque to outgoing (long-wave) radiation, but their principal purpose is to reduce convection heat loss. The collector box is insulated to prevent conduction heat loss from the back and edge of the absorber plate. This type of collector can supply hot water or air at temperatures up to 95°C, although efficiency diminishes rapidly above 70°C. The advantages of flat-plate collectors are simple construction, low relative cost, no moving parts, relative ease of repair, and durability. They also absorb diffuse radiation, which is a distinct advantage in cloudy climates.

Another type of collector is the integral collector storage (ICS) system. These collectors incorporate thermal storage within the collector itself. The storage tank surface serves as the absorber surface. Most ICS systems use only one tank, but some use several tanks in series. As with flat-plate collectors, insulated boxes enclose the tanks with transparent coverings on the side facing the sun. Although the simplicity of ICS systems is attractive, they are generally suitable only for applications in mild climates with small thermal storage requirements. Freeze protection by manually draining the unit is necessary in colder climates.

Still another type of collector is the evacuated tube, where the absorber mechanism is encased in a glass vacuum tube (Figure 5). Absorbers may be a simple copper fin tube on a copper sheet, a large copper cylinder in ICS applications, or a heat pipe. The latter uses a phase-change fluid to transfer heat to a common manifold where the working fluid circulates. The vacuum envelope reduces convection and conduction losses, so the tubes can operate at higher temperatures than flat-plate collectors. Like flat-plate collectors, they collect both direct and diffuse radiation. Because of its high-temperature capability, the evacuated-tube collector is favored for energizing heat-driven air-conditioning equipment, particularly when combined with concentrating reflectors behind the tubes.

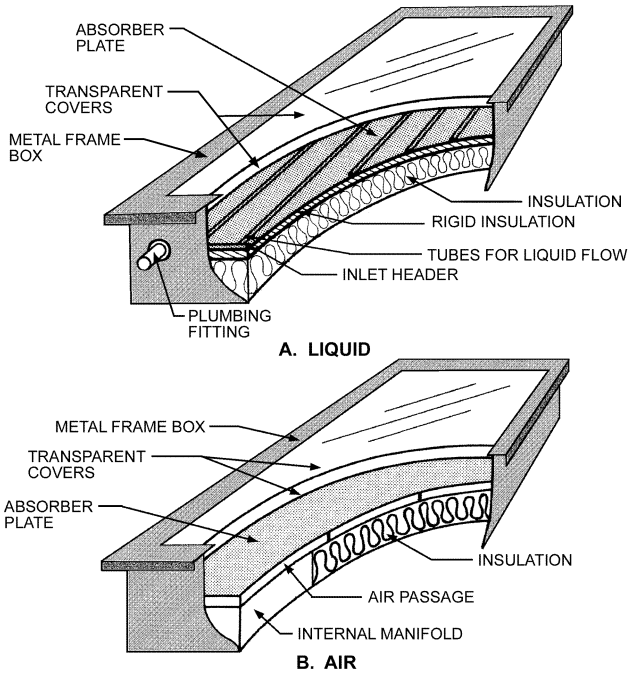

Fig. 4 Solar Flat-Plate Collectors

Flat-plate and evacuated-tube collectors are usually mounted in a fixed position. Concentrating collectors are available that must be arranged to track the movement of the sun. These are mainly used for high-temperature industrial applications above 115°C. For more information on concentrating collectors, see Chapter 36 of the 2023 *ASHRAE Handbook—HVAC Applications*.

Finally, unglazed flat-plate absorbers are often used for low-temperature applications such as pool water heating. The most popular configurations are made of plastic structured to create an almost fully wetted surface or uses very small fins on extruded tubes. Metal absorber plates from glazed collectors are also used, but generally with a heat exchanger to avoid contact with the pool water chemicals.

Air-Heating Collectors. Air-heating collectors are also contained in a box, covered with one or more glazings, and insulated on the sides and back. Figure 4B shows a cross section of a flat-plate air collector. The primary differences from liquid-heating collectors are in the design of the absorber plate and flow passages. Because the working fluid (air) has poor heat transfer characteristics, it flows over the entire absorber plate, and sometimes on both the front and back of the plate, to make use of a larger heat transfer surface. In spite of the larger surface area, air collectors generally have poorer overall heat transfer than liquid collectors. However, they are usually operated at a lower temperature for space heating applications because they require no intervening heat exchangers.

Transpired air collectors can be attached to the roof or side of a building to create a plenum for the preheated air. The collector is simply the siding material with many small holes through which the air is drawn, thus warming the air for space-heating or drying applications.

Liquid-Vapor Collectors. A third class of collectors uses liquid-vapor phase change to transfer heat at high efficiency. These collectors feature a heat pipe (a highly efficient thermal conductor) placed inside a vacuum-sealed tube (Figure 5B). The heat pipe contains a small amount of fluid (e.g., methanol) that undergoes an evaporating/condensing cycle. In this cycle, solar heat evaporates the liquid, and the vapor travels to a heat sink region, where it condenses and releases its latent heat. This process is repeated by a return feed of the condensed fluid back to the solar absorber.

Most phase-change fluids have low freezing temperatures, so the heat pipe offers inherent protection to the tubes from freezing and overheating, but not to the fluid being heated. This self-limiting temperature control is a unique feature of the evacuated heat pipe collector.

Collector Construction

Absorber Plates. The key component of a flat-plate collector is the absorber plate. It contains the heat transfer fluid and serves as a heat exchanger by converting radiant energy into thermal energy. It

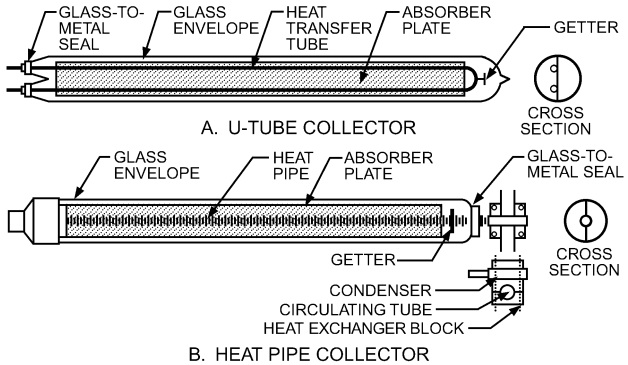

Fig. 5 Evacuated-Tube Collector

must maintain structural integrity at temperatures ranging from below freezing to well above 150°C. Chapter 36 of the 2023 *ASHRAE Handbook—HVAC Applications* illustrates typical liquid collectors and shows the wide variety of absorber plate designs in use.

Materials for absorber plates and tubes are usually highly conductive metals such as copper, aluminum, and steel, although low-temperature collectors for swimming pools are usually made from extruded elastomeric material such as ethylene-propylene terpolymer (EPDM) and polypropylene. Flow passages and fins are usually copper, but aluminum fins are sometimes inductively welded to copper tubing. Occasionally, fins are mechanically attached, but there is potential for corrosion with this design. A few manufacturers produce all-aluminum collectors, but they must be checked carefully to determine whether they incorporate corrosion protection in the collector loop.

Figure 6 shows a plan view of typical absorber plates. The serpentine design (Figure 6A) is used less frequently because it is difficult to drain and imposes a high pressure drop, but it can produce higher temperatures at lower flow rates. Most manufacturers use absorber plates similar to those shown in Figures 6D and 6E.

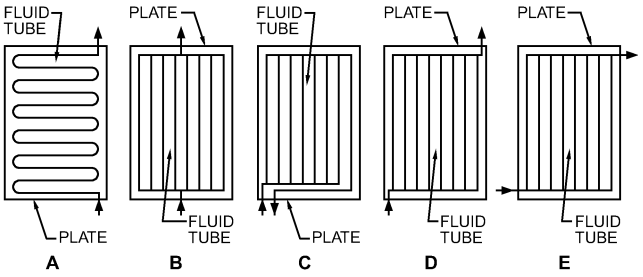

Fig. 6 Plan View of Liquid Collector Absorber Plates

In liquid collectors, manifold selection is important because the design can restrict the array piping configuration. The manifold must be drainable and free-floating, with generous allowance for thermal expansion. Some manufacturers provide a choice of manifold connections to give designers flexibility in designing arrays.

In air collectors, most manufacturers increase the heat transfer area by using fins, matrices, or corrugated surfaces (Figure 7). Many of these designs increase air turbulence, which improves collector efficiency (at the expense of increased fan power).

Figure 7 also shows cross sections of typical solar water collectors. Water passages can be integrated with the absorber plate to ensure good thermal contact (Figure 7E), or they can be soldered, brazed, or otherwise fastened to the absorber plate (Figure 7F). Manufactured collectors are made in modular sizes, typically 910 by 2130 mm, and these are connected to form a bank or row. Because most commercial-scale systems involve more than 100 m^2 of collectors, there can be numerous piping connections, depending on design.

Absorber plates may be coated with spectrally selective or nonselective materials. Selective coatings are more efficient, but cost more than nonselective, or flat black, coatings. However, their higher efficiencies may reduce the overall size of the array, resulting in lower total cost.

Solar collectors with colored absorbers (e.g., blue, red-brown, green) may be aesthetically attractive for building integration. Although colored collectors have lower efficiency than the typical black collectors, the difference in energy output depends on the

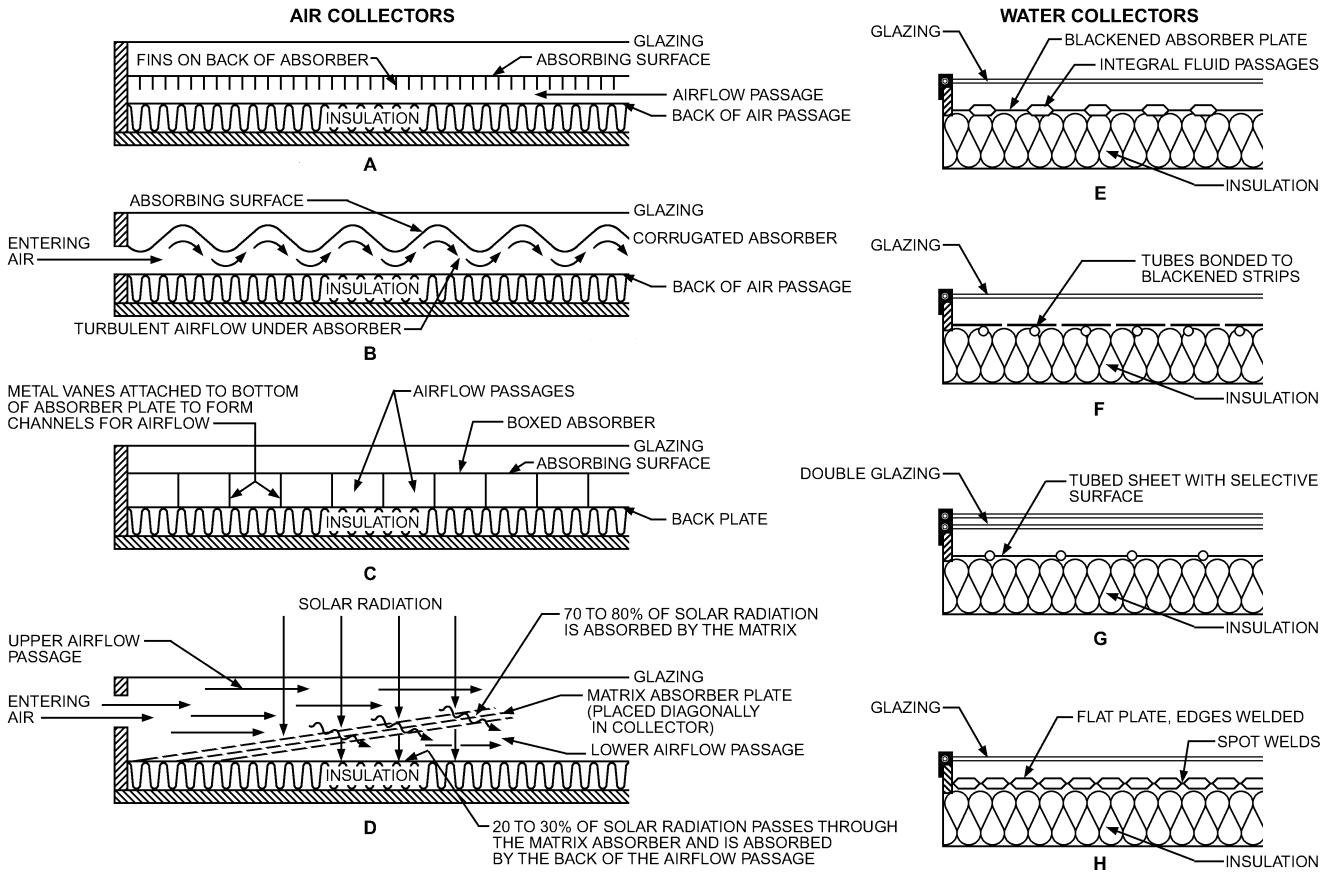

Fig. 7 Cross Sections of Various Solar Air and Water Heater

absorber darkness. For a medium value of the coefficient of absorptance ($\alpha = 0.85$), the drop in amount of energy from colored collectors (about 7 to 18%, depending on location) is satisfactory compared to the performance of collectors with black absorbers ($\alpha = 0.95$). Colored collectors require a proportionately larger collector aperture area to have the same energy output as that of typical black collectors (Kalogirou et al. 2005). Selective colored absorbers are efficient in a wider range of operating temperatures than absorbers with high-emissivity paints, and selective absorbers stable to weather conditions are needed for unglazed collectors to avoid degradation by environmental effects.

Housing. The collector housing is the container that provides structural integrity for the collector assembly. The housing must be structurally sound, weathertight, fire resistant, and mechanically connectable to a substructure to form an array. Collector housing materials include the following:

- Galvanized or painted steel
- Aluminum folded sheet stock or extruded wall materials
- Various plastics, either molded or extruded
- Composite wood products
- Standard elements of the building

Extruded anodized aluminum, including extruded channels, offers durability and ease of fabrication. Grooves are sometimes included in the extruded channels to accommodate proprietary mounting fixtures. The high temperatures of a solar collector deteriorate wood housings; consequently, wood is often forbidden by fire codes.

Glazing. Solar collectors for domestic hot water are usually single-glazed to reduce absorber plate convective and radiative losses. Some collectors have double glazing to further reduce these losses; however, double glazing should be restricted to applications where the value of $(t_i - t_a)/I_t$ exceeds that of domestic hot-water applications (e.g., space heating or activating absorption refrigeration); the parameters for this ratio are defined in Equations (4) and (5). Glazing materials are plastic, plastic film, or glass. Glass can absorb the long-wave thermal radiation emitted by the absorber coating, but it is not affected by ultraviolet (UV) radiation. Because of their impact tolerance, only tempered, low-iron glass covers should be considered. These covers have a solar transmission rating of 84 to 91%.

If the probability of vandalism is high, polycarbonate, which has high impact resistance, should be considered. Unfortunately, its transmittance is not as high as that of low-iron glass, and it is susceptible to long-term UV degradation.

Insulation. Collector enclosures must be well insulated to minimize heat losses. Insulation adjacent to the absorber plate must withstand temperatures up to 200°C and, most importantly, must not outgas volatile products within this range. Many insulation materials designed for construction applications are not suitable for solar collectors because the binders outgas volatiles at normal collector operating temperatures.

Solar collector insulation is typically made of mineral fiber, ceramic fiber, glass foam, plastic foam, or fiberglass. Fiberglass is the least expensive insulation and is widely used in solar collectors. For high-temperature applications, rigid fiberglass board with a minimum of binder is recommended. Also, a layer of polyisocyanurate foam in collectors is often used because of its superior R-value. Because it can outgas at high temperatures, the foam must not be allowed to contact the collector plate.

Figure 8 illustrates the preferred method of combining fiberglass and foam insulation to obtain both high efficiency and durability. Note that the absorber plate should be free-floating to avoid thermal stresses. Despite attempts to make collectors watertight, moisture is always present in the interior. This moisture can physically degrade mineral wool and reduce the R-value of fiberglass, so drainage and venting are crucial.

1.4 ROW DESIGN

Piping Configuration

Most commercial and industrial systems require a large number of collectors. Connecting the collectors with one set of manifolds makes it difficult to ensure drainability, balanced flow, and low pressure drop. An array usually includes many individual groups of collectors, called rows, to provide the necessary flow characteristics. Rows can be grouped into (1) parallel flow or (2) combined series-parallel flow. Parallel flow is the most frequently used because it is inherently balanced, has low pressure drop, and is drainable. Figure 9 illustrates

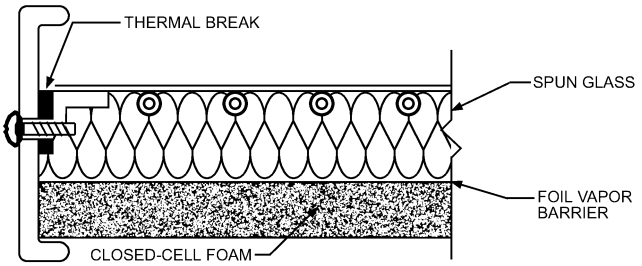

Fig. 8 Cross Section of Suggested Insulation to Reduce Heat Loss from Back Surface of Absorber

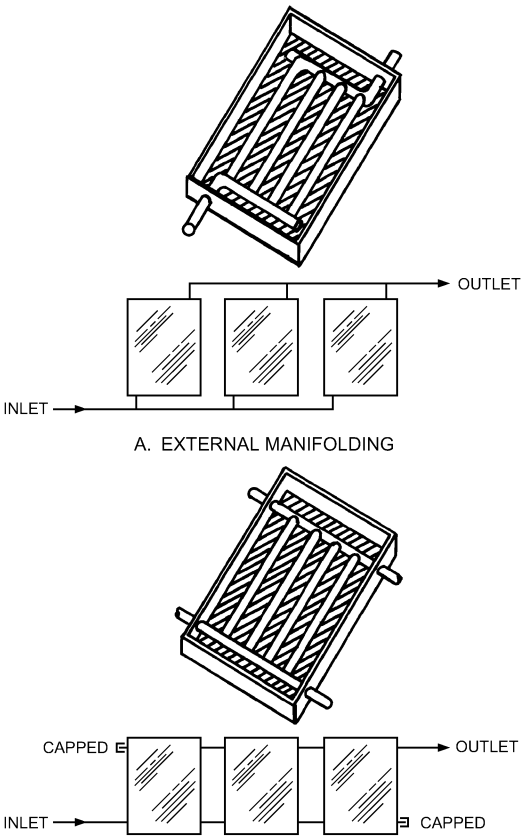

Fig. 9 Collector Manifolding Arrangements for Parallel-Flow Row

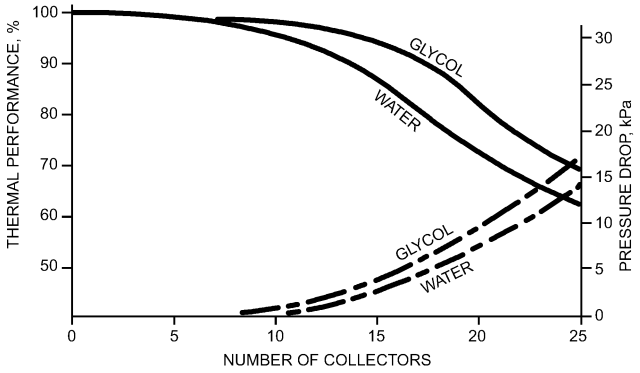

Fig. 10 Pressure Drop and Thermal Performance of Collectors with Internal Manifolds Numbers

various collector header designs for forming a parallel-flow row (the flow is parallel but the collectors are connected in series).

Generally, flat-plate collectors connect to the main piping in one of the methods shown in Figure 9. The **external manifold** collector has a small-diameter connection meant to carry only the flow for one collector. It must be connected individually to the manifold piping, which is not part of the collector panel, as depicted in Figure 9A.

Internal manifold collectors incorporate the manifold piping integral with each collector (Figure 9B). Headers at either end of the collector distribute flow to the risers. Several collectors with large headers can be placed side by side to form a continuous supply and return manifold. With 25 mm headers, four to eight 3.7 m^2 collectors can be placed side by side. Collectors with 25 mm headers can be mounted in a row without producing unbalanced flow. Most collectors have four plumbing connections, some of which may be capped if the collector is located on the end of the array. Internally manifolded collectors have the following advantages:

- Piping costs are lower because fewer fittings and less insulation are required.
- Heat loss is less because less piping is exposed.
- Installation is more attractive.

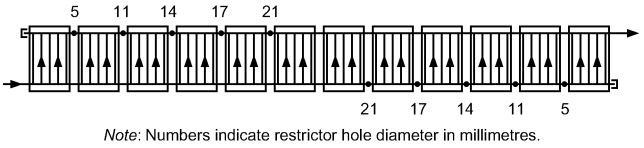
Some of their disadvantages are as follows:

- For drainback systems, the entire row must be pitched, thus complicating mounting.
- Flow may be imbalanced if too many collectors are connected in parallel.
- Removing the collector for servicing may be difficult.
- Stringent thermal expansion requirements must be met if too many collectors are combined in a row.

Velocity Limitations

Fluid velocity limits the number of internally manifolded collectors that can be contained in a row. For 25 mm headers, up to eight 3.7 m^2 collectors can usually be connected for satisfactory performance. If too many are connected in parallel, the middle collectors will not receive enough flow, and performance will decrease. Connecting too many collectors also increases pressure drop. Figure 10 shows the effect of collector number on performance and pressure drop for one particular design. Newton and Gilman (1983) describe a general method to determine the number of internally manifolded collectors that can be connected.

Flow restrictors can be used to accommodate a large number of collectors in a row. The flow distribution in the 12 collectors of Figure 11 would not be satisfactory without the flow restrictors shown at the interconnections. The flow restrictors are barriers with a drilled hole of the diameter indicated. Some manufacturers calculate the required hole diameters and provide predrilled restrictors.



Note: Numbers indicate restrictor hole diameter in millimetres.

Fig. 11 Flow Pattern in Long Collector Row with Restrictions

Chapter 22 of the 2021 *ASHRAE Handbook—Fundamentals* gives information on sizing piping. Knowles (1981) provides the following expression for the minimum acceptable header diameter:

$$D = 50.4(Q/\Delta p)^{0.45}N^{0.64} \quad (1)$$

where

D = header diameter, mm
N = number of collectors in module
Q = recommended flow rate for collector, L/s
Δp = pressure drop across collector at recommended flow rate, kPa

Because pipe is available in a limited number of diameters, selection of the next larger size ensures balanced flow. Usually, the sizes of supply and return piping are graduated to maintain the same pressure drop while minimizing piping cost. Complicated configurations may require a hydraulic static regain calculation.

Thermal Expansion

Thermal expansion will affect the row shown in Figure 11. Thermal expansion (or contraction) of a module of collectors in parallel may be estimated by the following equation:

$$\Delta = 0.0153n(t_c - t_i) \quad (2)$$

where

Δ = expansion or contraction of collector array, mm
n = number of collectors in array
t_c = collector temperature, °C (generally the maximum stagnation temperature)
t_i = installation temperature of collector array, °C (generally the lowest possible air temperature)

Because absorbers are rigidly connected, the absorber must have sufficient clearance from the side frame to allow the expansion indicated in Equation (2).

1.5 ARRAY DESIGN

Piping Configuration

Liquid Systems. To maintain balanced flow, an array or field of collectors should be built from identical rows configured as described in previous sections. Whenever possible, rows must be connected in reverse-return fashion (Figure 12), which ensures that the array is self balanced. With proper care, an array can drain, which is an essential requirement for drainback freeze protection.

Piping to and from the collectors must be sloped properly in a drainback system. Typically, piping and collectors must slope to drain at 20 mm per linear metre. Elevations throughout the array, especially the highest and lowest point of the piping, should be noted on the drawings.

When freezing is not of a concern, another option is to connect the rows in series (Figure 13). There is some loss in efficiency on each row, but this configuration allows for lower overall flow rates, thus reducing the size of the main supply and return pipes, as well as the size of the pump required. This technique has been used in Europe for large central heating systems to generate the higher temperatures required for absorption air conditioning. Generally, it is

recommended that no more than three rows be put in series, to maintain adequate array performance.

The external manifold collector has different mounting and plumbing considerations from the internal manifold collector (Figure 14). A row of externally manifolded collectors can be mounted horizontally, as shown in Figure 14A. The lower header must be pitched as shown. The pitch of the upper header can be either horizontal or pitched toward the collectors so it can drain back through the collectors.

Arrays with internal manifolds pose a greater challenge in designing and installing the collector mounting system. For these collectors to drain, the entire bank must be tilted, as shown in Figure 14B.

Reverse return always implies an extra pipe run. Sometimes, it is more convenient to use direct return (Figure 15). In this case, balancing valves are needed to ensure uniform flow through the rows. The balancing valves *must* be connected at the row outlet to provide the flow resistance necessary to ensure filling of all rows on pump start-up.

It is often impossible to configure parallel arrays because of the presence of rooftop equipment, roof penetrations, or other building-imposed constraints. Although the list is not complete, the following requirements should be considered when developing the array configuration:

- Strive for a self-balancing configuration.
- For drainback, design rows, subarrays, and arrays to be individually and collectively drainable.
- Always locate collectors or rows with high flow resistance at the outlet to improve flow balance and ensure the drainback system fills.
- Minimize flow and heat transfer losses.

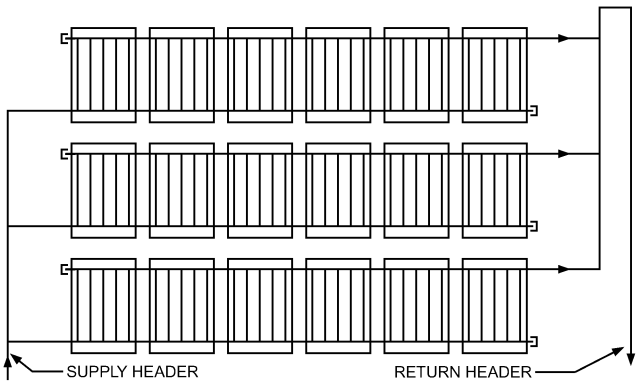


Fig. 12 Reverse-Return Array Piping

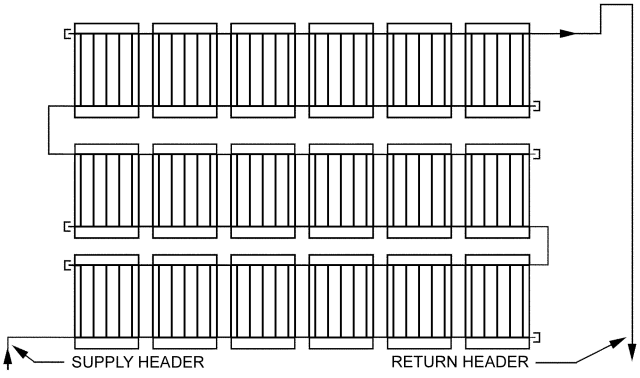

Fig. 13 In-Series Array Piping

In general, it is easier to configure complex array designs for nonfreezing fluid systems. Newton and Gilman (1983) provide some typical examples. However, with careful attention to these criteria, it is also possible to design successful large drainback arrays.

Air Systems. Air distribution within the collector array is the most critical feature of an air system for effective operation. Proper airflow must take into account the overall pressure drop to allow efficient fan motor sizing. Balancing, automatic, backdraft, and fire dampers are usually needed. Air leaks (both into and out of the ducts and from component to component) must be minimized.

For example, some air collector systems contain a water coil for preheating water. Despite the inclusion of automatic and backdraft dampers, leakage within the system can freeze coils. One possible solution is to position the coil near the warm end of the storage bin. Another is to circulate an antifreeze solution in the coil. Whatever the solution, the designer must remember that even the lowest-leakage dampers will leak if improperly installed or adjusted.

As with liquid systems, the main supply and return ducts should be connected in a reverse-return configuration, with balancing dampers on each supply branch to the collector modules. If reverse return is not feasible, the main ducts should include balancing dampers at strategic locations. Here too, having fewer branch ducts reduces balancing needs and costs.

Unlike liquid systems, air collectors can be built on site. Although material and cost savings can be substantial with site-built collectors, extreme care is necessary to ensure long life, low leak-

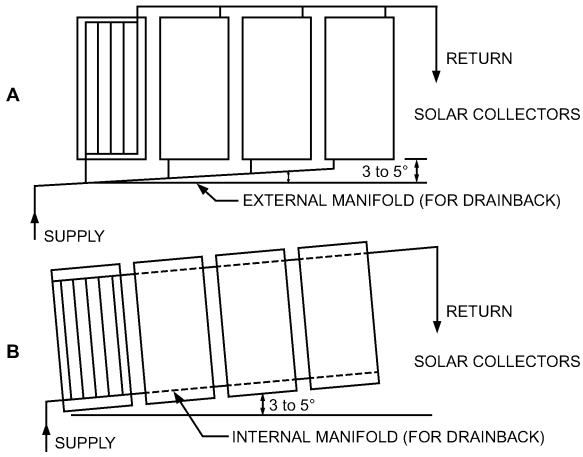

Fig. 14 Mounting for Drainback Collector Modules

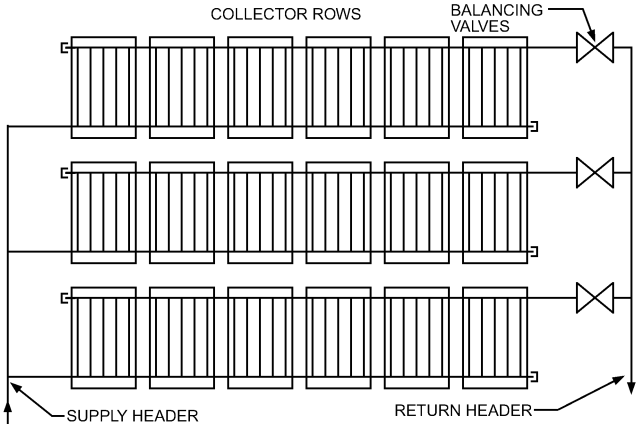

Fig. 15 Direct-Return Array Piping

age, and proper air distribution. Quality control in the field can be a problem, so well-trained designers and installers are critical to the success of these systems.

Performance. The effect of array and air distribution system designs on the overall system performance must be considered. Duffie and Beckman (2013) give standard procedures for estimating the impact of series connection and duct thermal losses. The effect on fan operation and fan power is more difficult to determine. For unique system designs and more detailed performance estimates, including fan power, performance simulation tools can be used.

Shading

When large collector arrays are mounted on flat roofs or level ground, multiple rows of collectors are usually installed in a sawtooth fashion. These multiple rows should be spaced so that they do not shade each other at low sun angles. However, it is usually not desirable to avoid mutual shading altogether. Additional rows can sometimes be added to a roof or other constrained area; this increases the solar fraction but sacrifices efficiency. Kutscher et al. (1982) presents a method of estimating the energy delivered annually when there is some row-to-row shading in the array. The most common practice is to base row spacing on the lowest sun angle during the most important time of the year. For example, water and pool heating systems that operate mostly in the summer can use the higher sun angles of summer or spring and fall. Space-heating systems may want to maximize exposure in the winter, so they should use the lowest sun angle at the winter solstice. A system that operates year round may use the spring equinox sun angle as a reasonable compromise to allow more rows.

1.6 THERMAL COLLECTOR PERFORMANCE

Under steady-state flow conditions, the useful heat delivered by a solar collector is equal to the energy absorbed in the heat transfer fluid minus the direct and indirect heat losses from the surface to the surroundings. This principle can be stated in the following relationship:

$$q_u = A_c[I_t\tau\alpha - U_L(\bar{t}_p - t_a)] \tag{3}$$

where

q_u = useful energy delivered by collector, W
A_c = total aperture collector area, m^2
I_t = irradiance, total (direct plus diffuse) solar energy incident on upper surface of sloping collector structure, W/m^2
τ = transmittance (fraction of incoming solar radiation that reaches absorbing surface), dimensionless
α = absorptance (fraction of solar energy reaching surface that is absorbed), dimensionless
U_L = overall heat loss coefficient, $W/(m^2 \cdot K)$
$\bar{t}_p$ = average temperature of absorbing surface of absorber plate, °C
t_a = atmospheric temperature, °C

Except for average plate temperature $\bar{t}_p$, these terms can be readily determined. For convenience, Equation (3) can be modified by substituting inlet fluid temperature for the average plate temperature, if a suitable correction factor is included. The resulting equation is

$$q_u = F_R A_c[I_t\tau\alpha - U_L(t_i - t_a)] \tag{4}$$

where

F_R = correction factor, or collector heat removal efficiency factor; <1.0
t_i = temperature of fluid entering collector, °C

The heat removal factor F_R can be considered the ratio of the heat actually delivered to that delivered if the collector plate were at a uniform temperature equal to that of the entering fluid. An F_R of 1.0 is theoretically possible if (1) the fluid is circulated at such a high rate that its temperature rise is negligible, and (2) the heat transfer coefficient and fin efficiency are so high that the temperature difference between the absorber surface and the fluid is negligible.

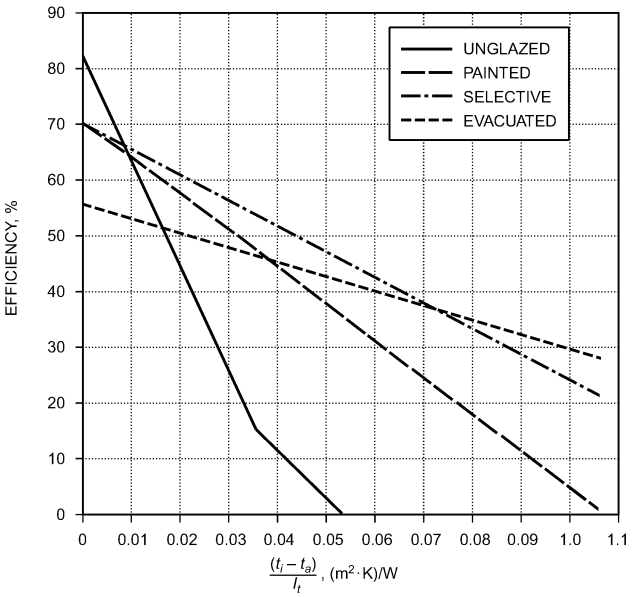

Fig. 16 Solar Collector Type Efficiencies

In Equation (4), the temperature t_i of the inlet fluid depends on the characteristics of the complete solar heating system and the building's heat demand. However, F_R is affected only by the solar collector characteristics, fluid type, and fluid flow rate through the collector.

Solar air heaters remove substantially less heat than liquid collectors. However, their lower collector inlet temperature makes their system efficiency comparable to that of liquid systems for space-heating applications.

Equation (4) may be rewritten in terms of the instantaneous efficiency of total solar radiation collection by dividing both sides of the equation by $I_t A_c$. The result is

$$\eta = F_R\tau\alpha - F_R U_L \frac{(t_i - t_a)}{I_t} \tag{5}$$

where η = collector efficiency, dimensionless.

Equation (5) plots as a straight line on a graph of efficiency versus the heat loss parameter $(t_i - t_a)/I_t$. Plots of Equation (5) for various liquid collectors are shown in Figure 16. The intercept (intersection of the line with the vertical efficiency axis) equals $F_R\tau\alpha$. The slope of the line (i.e., any efficiency difference divided by the corresponding horizontal scale difference) equals $-F_R U_L$. If experimental data on collector heat delivery at various temperatures and solar conditions are plotted, with efficiency as the vertical axis and $(t_i - t_a)/I_t$ as the horizontal axis, the best straight line through the data points correlates collector performance with solar and temperature conditions. The intersection of the line with the vertical axis is where the temperature of the fluid entering the collector equals the ambient temperature, and collector efficiency is at its maximum. At the intersection of the line with the horizontal axis, collection efficiency is zero. This condition corresponds to such a low radiation level, or to such a high temperature of the fluid into the collector, that heat losses equal solar absorption, and the collector delivers no useful heat. This condition, normally called **stagnation**, usually occurs when no coolant flows to a collector. Solving Equation (5)

for t_i under the hottest conditions yields the stagnation temperature for the collectors at that site.

Equation (5) includes all important design and operational factors affecting steady-state performance except collector flow rate and solar incidence angle. Flow rate indirectly affects performance through the average plate temperature. If the heat removal rate is reduced, the average plate temperature increases, and more heat is lost. If the flow is increased, collector plate temperature and heat loss decrease.

Solar Incidence Angle. These relationships assume that the sun is perpendicular to the plane of the collector, which rarely occurs. For glass cover plates, specular reflection of radiation occurs, thereby reducing the $\tau\alpha$ product. The incident angle modifier $K_{\tau\alpha}$, defined as the ratio of $\tau\alpha$ at some incidence angle θ to $\tau\alpha$ at normal radiation $(\tau\alpha)_n$, is described by the following simple expression for specular reflection:

$$K_{\tau\alpha} = \frac{\tau\alpha}{(\tau\alpha)_n} = 1 + b_o\left(\frac{1}{\cos\theta} - 1\right) \tag{6}$$

For a single glass cover, b_o is approximately –0.10. Many flat-plate collectors, particularly evacuated tubes, have some limited focusing capability. The incident angle modifiers for these collectors are not modeled well by Equation (6), which is a linear function of $(1/\cos\theta) - 1$.

Cellular Flow Rate. Equation (5) is not convenient for air collectors when it is desirable to present data based on collector outlet temperature t_{out} rather than inlet temperature, which is the commonly measured variable for liquid systems. The relationship between the heat removal factors for these two cases is

$$F_R\tau\alpha = \frac{(F_R\tau\alpha)'}{1 + (F_R U_L)'/mc_p} \tag{7a}$$

$$F_R U_L = \frac{(F_R U_L)'}{1 + (F_R U_L)'/mc_p} \tag{7b}$$

where mc_p is mass flow times specific heat of air, $F_R U_L$ and $F_R\tau\alpha$ apply to $t_i - t_a$ in Equation (5), and $(F_R U_L)'$ and $(F_R\tau\alpha)'$ apply to $t_{out} - t_a$.

Testing Methods

In the late 1970s, ASHRAE adopted *Standard* 93, Methods of Testing to Determine the Thermal Performance of Solar Collectors, which was a modified version of the procedure published by the National Bureau of Standards (NBS). *Standard* 93 went through regular revisions and updates until 2018, when it was replaced by ISO *Standard* 9806, Solar Thermal Collectors—Test Methods.

ISO *Standard* 9806 gives information on testing solar energy collectors using single-phase fluids (the thermal energy collection process can be separated from the storage one). The data can be used to predict performance in any location and under any conditions where load, weather, and insolation are known.

The standard presents efficiency in a modified form of Equation (5). It specifies that the efficiency be reported in terms of gross collector area A_g rather than aperture collector area A_c. The reported efficiency is lower than the efficiency based on net area, but the total energy collected does not change from this simplification. Therefore, gross collector area must be used when analyzing performance of collectors based on experiments that determine $F_R\tau\alpha$ and $F_R U_L$ according to ISO *Standard* 9806.

Unless otherwise specified, ISO *Standard* 9806 suggests that testing be done at 0.02 kg/s per square metre of gross collector area for liquid systems. For air systems, testing should be done at three values equally distributed between the flow rates of 0.008 and 0.083 kg/s of gross collector area.

For hybrid collectors (e.g. photovoltaic collector with thermal energy recovery [PVT]) generating thermal and electric energy, the mode of electric operation of the PVT collector has a major impact on thermal performance. Thus, ISO *Standard* 9806 suggests that testing be done with the PVT collector maintained within 15% of its maximum power point (MPP).

Annual compilations of collector test data for glazed and unglazed solar collectors may be obtained from Solar Rating and Certification Corporation (www.solar-rating.org). Another source for this information is the collector manufacturer. However, a manufacturer sometimes publishes efficiency data at a much higher flow rate than the recommended design value. In such cases, collector data should be obtained from an independent laboratory.

Collector Test Results and Initial Screening Methods

Final collector selection should be made only after energy analysis of the complete system, including realistic weather conditions and loads, has been completed. Also, a preliminary screening of collectors with various performance parameters should be conducted to identify those that best match the load. One way to accomplish this is to identify the expected range of heat loss parameter $(t_i - t_a)/I_t$ for the load and climate on a plot of efficiency η as a function of heat loss parameter, as indicated in Figure 16.

Ambient temperature during the swimming season may vary by 10 K above or below pool temperature. The corresponding parameter values range from 0.026 W/(m$^2\cdot$K) on cool overcast days (low I_t) to as low as –0.026 W/(m$^2\cdot$K) on hot overcast days. For most swimming pool heating, unglazed collectors offer the highest performance and are the least expensive.

The heat loss parameter for service water heating can range from 0.009 to 0.062 W/(m$^2\cdot$K), depending on the climate at the site and the desired hot-water delivery temperature. Convective space heating requires an even greater collector inlet temperature than water heating, and the primary load coincides with lower ambient temperature. In many areas of the United States, space heating coincides with low radiation values, which further increases the heat loss parameter. However, many space-heating systems are accompanied by water heating, and some space-heating systems (e.g., radiant panels) are available at a lower $(t_i - t_a)/I_t$ value.

Air conditioning with solar-activated absorption equipment is economical only when the cooling season is long and solar radiation levels are high. These devices require at least 80°C water. Thus, on a 27°C day with radiation at 950 W/m^2, the heat loss parameter is 0.05. Higher operating temperatures are desirable to prevent excessive derating of the air conditioner. Only the most efficient (low $F_R U_L$) collector is suitable. Derating may also be minimized by using convective-radiant hybrid air-conditioning systems.

Collector efficiency curves may be used as an initial screening device. However, efficiency curves illustrate only instantaneous performance of a collector. They do not include incidence angle effects (which vary throughout the year); heat exchanger effects; probabilities of occurrence of t_i, t_a, and I_t; system heat loss; or control strategies. Final selection requires determining a collector's long-term energy output and performing cost-effectiveness studies. Estimating a particular collector's and system's annual performance requires appropriate methods such as *f*-Chart (Duffie and Beckman 2013) or performance simulation tools that allow the study of the behavior of transient systems. The Solar Rating and Certification Corporation (SRCC), International Organization for Standardization (ISO), European Committee for Standardization (CEN), and other rating agencies provide day-long collector outputs under various solar and operating conditions. These ratings can greatly simplify selection of the proper collector type, including cost

Table 2 Average Performance* Parameters for Generic Types of Liquid Flat-Plate Collectors

Collector Type	Vertical Intercept	Slope, W/(m²·K)	Clear-Day Category C Output, MJ/m²·day
Unglazed	0.807	–18.68	4.77

considerations. Table 2 shows a comparison of generic types of liquid flat-plate collectors.

Generic Test Results

The generic types of liquid flat-plate collectors are **unglazed**, **single-glazed painted-** and **selective-surface absorbers**, and **evacuated tubes**. Table 2 shows the average output, intercept, and slope for these. The normalized day-long energy output for a clear day in category C points out the difficulties in using only the instantaneous efficiency data. Category C holds the temperature difference constant at 20 K all day, and a clear day is defined as 22.7 MJ/m²·day, which is high for most of the United States. Note that evacuated-tube collectors do not perform very well under these circumstances. SRCC and other rating agencies publish a matrix of collector outputs for various temperature differences and solar days. Table 3 shows the SRCC matrix for each generic collector type. Further explanation of the categories is available on the SRCC website, www.solar-rating.org, or in their standards.

The daily outputs in Table 3 show a clear advantage for each type of collector starting from the upper left corner and proceeding diagonally down and across. At low temperature differences, for categories A and B under clear and mildly cloudy conditions, unglazed collectors provide a clear advantage. The middle of the matrix is a bit less definitive, but painted and selective-surface collectors tend to perform best in the range. At the lower right corner, evacuated tubes perform best under high temperature differences and low solar inputs. Determining where a project falls in this rating matrix is very important in selecting the proper collector; the designer should be familiar with the location's average daily solar input and the desired operating temperature. For example, selective-surface collectors might work well for a high-temperature application in Phoenix in the summer because the daytime temperature difference is low and the solar input is high, whereas evacuated tubes are a better choice in Atlanta.

1.7 THERMAL ENERGY STORAGE

Design and selection of thermal storage equipment is one of the most neglected elements of solar energy systems. In fact, the energy storage system has an enormous influence on overall system cost, performance, and reliability, and its design is highly interactive with that of other system elements (e.g., collector loop, thermal distribution system). Thus, it should be considered within the context of the total system.

Energy can be stored in liquids, solids, or phase-change materials (PCMs). Water is the most frequently used liquid storage medium, although the collector loop may use water, oils, or aqueous glycol as a collection fluid. For service water heating and most building space heating, water is normally contained in some type of tank. Air systems typically store heat in rocks or pebbles, but sometimes use the building's structural mass. Chapter 36 of the 2023 *ASHRAE Handbook—HVAC Applications* and ASHRAE (1991) cover this topic in more detail.

Air System Thermal Storage

The most common storage media for air collectors have been rocks or a regenerator matrix made from concrete masonry units (CMUs). Gravel was widely used as a storage medium because it is plentiful and relatively inexpensive; however, the inherent cost and likelihood of mold growth in humid climates put an end to its use. Other possible media include PCMs, water, and the inherent building mass.

Where large interior temperature swings are tolerable, the building's inherent mass may be sufficient for thermal storage. Designated storage may also be eliminated where the array output seldom exceeds the concurrent demand. Loads requiring no storage are usually the most cost-effective applications of air collectors, and heated air from the collectors can be distributed directly to the space.

Water can be used as a storage medium for air collectors by using a conventional heating coil to transfer heat from the air to the water in the storage tank. Advantages of water storage include compatibility with hydronic heating systems and relative compactness (roughly one-third the volume of pebble beds).

Liquid System Thermal Storage

For units large enough for commercial liquid systems, the following factors should be considered:

- Pressurized versus unpressurized storage
- External versus internal heat exchanger

- Single versus multiple tanks
- Steel versus nonmetallic tank(s)
- Type of service (i.e., service hot water [SHW], building space heating [BSH], or a combination of the two)
- Location, space, and accessibility constraints imposed by architectural limitations
- Interconnect constraints imposed by existing mechanical systems
- Limitations imposed by equipment availability

The following sections present examples of the more common configurations.

Pressurized Storage. Defined here as storage that is open to the city water supply, pressurized storage is preferred for small service water heating systems because it is convenient and provides an economical way of meeting ASME *Boiler and Pressure Vessel Code* requirements with off-the-shelf equipment. Typical storage size is about 40 to 80 L per square metre of collector area. The largest off-the-shelf water heater is 450 L; however, no more than three or four of these should be connected in parallel. Hence, the largest storage that can be considered with off-the-shelf water heater tanks is about 1350 to 1800 L, and must be compared to a single tank with the additional labor and material to connect them, plus the amount of floor space required. For larger solar hot-water and combined systems, the following concerns are important when selecting storage:

- Higher cost per unit volume of ASME rated tanks in sizes greater than 450 L
- Handling difficulties because of large mass
- Accessibility to locations suitable for storage
- Interfacing with existing SHW and BSH systems
- Corrosion protection for steel tanks

The choice of pressurized storage for medium-sized systems is based on the availability of suitable low-cost tanks near the site. Identifying a suitable supplier of low-cost tanks can extend the advantages of pressurized storage to larger SHW installations.

Storage pressurized at city water supply pressure is not practical for building space heating, except for small applications such as residences, apartments, and small commercial buildings.

With pressurized storage, the heat exchanger is always located on the collector side of the tank. Either the internal or external heat exchanger configuration can be used. Figure 17 illustrates the three main types of internal heat exchanger concepts: immersed coil, wraparound jacket, and tube bundle. Small tanks (less than 450 L) are available with either of the first two heat exchangers already installed. For larger tanks, a large assortment of tube bundle heat exchangers are available that can be incorporated into the tank design by the manufacturer.

Sometimes, more than one tank is needed to meet design requirements. Additional tanks offer the following benefits:

- Added storage volume
- Increased heat exchanger surface
- Reduced pressure drop in the collection loop
- Increased stratification for larger volumes

Disadvantages compared to a single tank of the same volume include the following:

- Higher installation costs
- Greater space requirements
- Higher heat losses (reduced performance)

Figure 18 illustrates the multiple-tank configuration for pressurized storage. The exchangers are connected in reverse-return fashion to minimize flow imbalance. A third tank may be added.

An external heat exchanger provides greater flexibility because the tank and heat exchanger can be selected independently of each other (Figure 19). A drawback to this method is that an additional pump, with its parasitic energy consumption, is required.

When selecting an external heat exchanger for a system protected by a nonfreezing liquid, consider the following factors related to start-up after at least one extremely cold night:

- Freeze-up of the water side of the heat exchanger
- Performance loss due to extraction of heat from storage

For small systems, an internal heat exchanger/tank arrangement prevents the water side of the heat exchanger from freezing. However, the energy required to maintain the water above freezing must be extracted from storage, thereby decreasing overall performance.

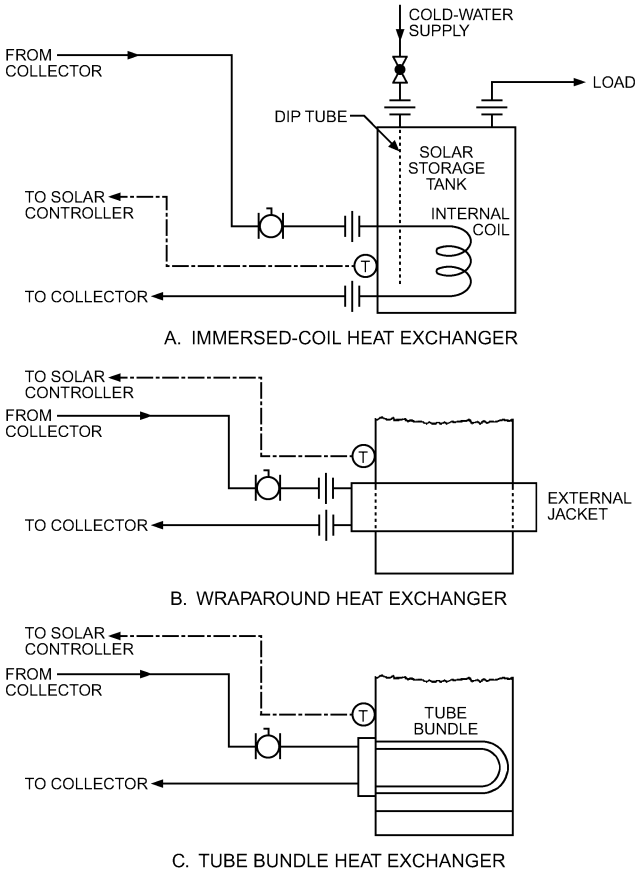

Fig. 17 Pressurized Storage with Internal Heat Exchanger

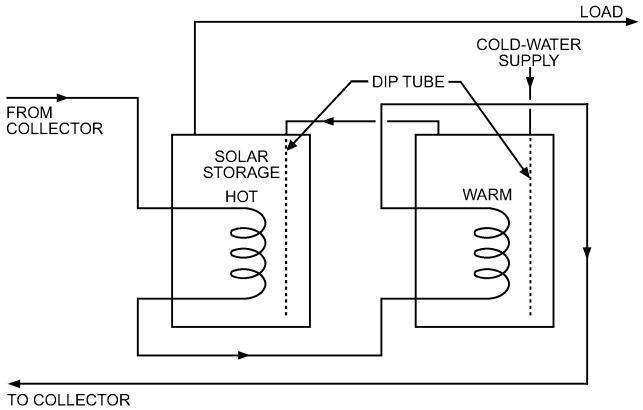

Fig. 18 Multiple Storage Tank Arrangement with Internal Heat Exchangers

With the external heat exchanger/tank combination, a bypass can be arranged to divert cold fluid around the heat exchanger until it has been heated to an acceptable level, such as 27°C. When the heat transfer fluid has warmed to this level, it can enter the heat exchanger without freezing or extracting heat from storage. If necessary, this arrangement can also be used with internal heat exchangers to improve performance. In mild climates where freezing is not an issue, the heat exchanger can be eliminated, thus reducing system cost and complexity.

Unpressurized Storage. For systems greater than about 30 m^3 (5.7 m^3 storage volume minimum), unpressurized storage is usually more cost-effective than pressurized. In this chapter, the term *unpressurized* means tanks at or below the pressure expected in an unvented drainback loop.

Unpressurized storage for water and space heating implies a heat exchanger on the load side of the tank to isolate the high-pressure (potable water) loop from the low-pressure collector loop. Figure 20 illustrates unpressurized storage with an external heat exchanger. In this configuration, heat is extracted from the top of the solar storage tank, and cooled water is returned to the bottom. On the load side of the heat exchanger, water to be heated flows from the bottom of the backup storage tank, and heated water returns to the top. The heat exchanger may have a double wall to protect a potable water supply. A differential temperature controller controls the two pumps on either side of the heat exchanger. If the pumps are small, both may be controlled by the same controller without overloading it.

The external heat exchanger in Figure 20 provides good system flexibility and freedom in component selection. In some cases, system cost and parasitic power consumption may be reduced by an internal heat exchanger. Some field-fabricated heat exchangers use coiled soft copper tube. For larger systems, where custom fabrication is more feasible, a specified heat exchanger can be installed at the top of the tanks.

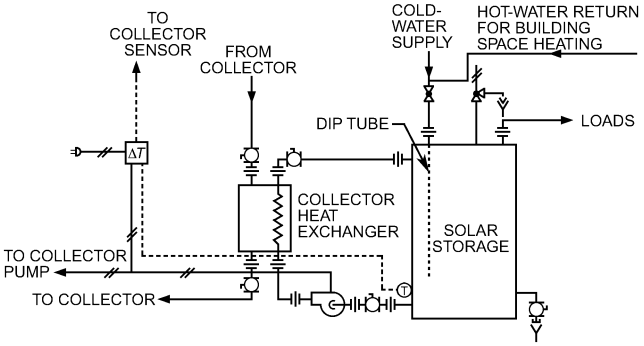

Fig. 19 Pressurized Storage System with External Heat Exchanger

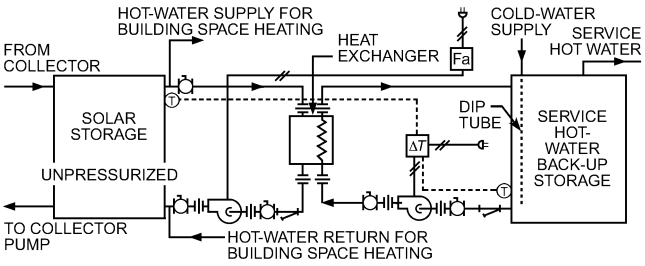

Fig. 20 Unpressurized Storage System with External Heat Exchanger

Storage Tank Construction

Steel. For most liquid solar energy systems, steel is the preferred material for storage tank construction. Steel tanks are relatively easy to fabricate to ASME *Pressure Vessel Code* requirements, readily available, and easily attached to pipes and fittings.

Steel tanks used for pressures of 200 kPa and above must be ASME rated. Because water main pressure is usually above this level, open systems must use ASME code tanks. These pressure-rated storage tanks are more expensive than unpressurized types. Costs can usually be significantly reduced if a unpressurized tank can be used.

Steel tanks are subject to corrosion, however. Because corrosion rates increase with temperature, the designer must be particularly aware of corrosion protection methods for solar energy applications. A steel tank must be protected against (1) electrochemical corrosion, (2) oxidation (rusting), and (3) galvanic corrosion (Cole et al. 1980).

The pH of the liquid and the electric potential of the metal are the primary governing factors of electrochemical corrosion. A sacrificial anode made from a metal more reactive than steel can provide protection. Magnesium is recommended for solar applications. Because protection ends when the anode has dissolved, the anode must be inspected annually.

Oxygen can enter the tank through air dissolved in the water entering the tank or through an air vent. In pressurized storage, oxygen is continually replenished by the incoming water. Besides causing rust, oxygen catalyzes other types of corrosion. Unpressurized storage systems are less susceptible to corrosion caused by oxygen because they can be designed as unvented systems, so corrosion is limited to the small amount of oxygen contained in the initial fill water.

Coatings on the tank interior protect it from oxidation. Some of the most common coatings include the following:

- **Phenolic epoxy** should be applied in four coats.
- **Baked-on epoxy** is preferred over painted-on epoxy.
- **Glass lining** offers more protection than the epoxies and can be used under severe water conditions.
- **Hydraulic stone** provides the best protection against corrosion and increases the tank's heat retention capabilities. Its mass may cause handling problems in some installations.

The coating should either be flexible enough to withstand extreme thermal cycling or have the same coefficient of expansion as the steel tank. In the United States, all linings used for potable water tanks should be approved by the Food and Drug Administration (FDA) for the maximum temperature expected in the tank.

Dissimilar materials in an electrolyte (water) are in electrical contact with each other and corrode by galvanic action. Copper fittings screwed into a steel tank corrode the steel, for example. Galvanic corrosion can be minimized by using dielectric bushings to connect pipes to tanks.

Plastic. Fiberglass-reinforced plastic (FRP) tanks offer the advantages of low mass, high corrosion resistance, and low cost. Premium-quality resins allow operating temperatures as high as 99°C, well above the temperature imposed by flat-plate solar collectors. Before delivery of an FRP tank is accepted, inspect the tank for damage that may have occurred during shipment. The gel coat on the inside must be intact, and no glass fibers should be exposed.

Concrete. Concrete vessels lined with a waterproofing membrane may also be used (in vented systems only) to contain a liquid thermal storage medium. Concrete storage tanks are inexpensive, and can be shaped to fit almost any retrofit application. Also, they have excellent resistance to the loading that occurs when they are placed below grade. Concrete tanks must have smooth corners and edges.

Concrete storage vessels have some disadvantages. Seepage often occurs unless a proper waterproofing surface is applied.

Waterproofing paints are generally unsatisfactory because the concrete often cracks after settling. Other problems may occur because of poor workmanship, poor location, or poor design. Usually, tanks should stand alone and not be integrated with a building or other structure. Pay careful attention to expansion joints and seams because they are particularly difficult to seal. Sealing at pipe taps can be a problem. Penetrations should be above liquid level, if possible.

Finally, concrete tanks are heavy and may be more difficult to support in a proper location. Their mass may make insulating the tank bottom more expensive and difficult.

Storage Tank Insulation

Heat loss from storage tanks and piping is one of the major causes of poor system performance. The average R-value of storage tanks in solar applications is about half the insulation design value because of poorly insulated supports. Different standards recommend various design criteria for tank insulation. Performance requirements for unfired storage tanks are included in the service-water-heating sections of ASHRAE *Standards* 90.1 and 90.2. A 12 h maximum capacity loss of 1 to 2% should be feasible. The following equation can be used to calculate the insulation R-value for this requirement:

$$\frac{1}{R} = \frac{fQ}{A\theta} \frac{1}{(t_{avg} - t_a)} \tag{8}$$

where

R = thermal resistivity of insulation, $(m^2 \cdot K)/W$
f = specified fraction of stored energy that can be lost in time θ
Q = stored energy, J
A = exposed surface area of storage unit, m^2
θ = given time period, s
t_{avg} = average temperature in storage unit, °C
t_a = ambient temperature surrounding storage unit during heating season, °C

The insulation factor $fQ/A\theta$ is found from Table 4 for various tank shapes (Cole et al. 1980).

Most solar water-heating systems use large steel pressure vessels, which are usually shipped uninsulated. Materials suitable for field insulation include fiberglass, rigid foam, and flexible foam blankets. Fiberglass is easy to transport and make fire retardant, but it requires significant labor to apply and seal.

Another widely used insulation consists of rigid sheets of polyisocyanurate foam cut and taped around the tank. Material that is 75 to 100 mm thick can provide 3.5 to 5.3 $(m^2 \cdot K)/W$ insulation value. Rigid foam insulation is sprayed directly onto the tank from a foaming truck or in a shop. It bonds well to the tank surface (no air space between tank and insulation) and insulates better than an equivalent thickness of fiberglass. When most foams are exposed to flames, they ignite and/or produce toxic gases. When located in or adjacent to a living space, they often must be protected by a fire barrier and/or sprinkler system.

Some tank manufacturers and suppliers offer custom tank jackets of flexible foam with zipper-like connections that provide quick installation and neat appearance. Some of the fire considerations for rigid foam apply to these foam blankets.

Tank supports are a major source of heat loss. To provide suitable load-bearing capability, the supports must be in direct contact with the tank wall or attached to it. Thermal breaks must be provided between the supports and the tank (Figure 21). If insulating the tank from the support is impractical, the external surface of the supports must be insulated, and the supports must be placed on insulating material that can support the compressive load. Wood, foam glass, and closed-cell foam can be used, depending on the compressive load.

Table 4 Insulation Factor $fQ/A\theta$ for Cylindrical Water Tanks

Size, m^3	Horizontal Tank Insulation Factor, W/m^2

Stratification and Short Circuiting

Because hot water rises and cold water sinks in a vessel, the pipe to the collector inlet should always be connected to the bottom of the tank. The collector then operates at its best efficiency because it is always at the lowest possible temperature. The return from the collector should always run near the bottom of the tank to encourage stratification and avoid introducing cooler fluid to the top of the tank after a draw occurs. Techniques such as using diffusers and lower flow rates have been developed to reduce destratification of flow returning from the collector. Generally, the better the tank stratification, the better the solar system performs overall. Similarly, the load should be extracted from the top of the tank, and cold makeup water should be introduced at the bottom. Because of increased static pressure, vertical storage tanks enhance stratification better than horizontal tanks.

If a system has a rapid tank turnover or if the buffer tank of the system is closely matched to the load, thermal stratification does not offer any advantages. However, in most solar energy systems, thermal stratification increases performance because temperature differences are relatively small. Thus, any enhancement of temperature differentials improves heat transfer efficiency.

Thermal stratification can be enhanced by the following:

- Using a tall vertical tank
- Situating the inlet and outlet piping of a horizontal tank to minimize vertical fluid mixing
- Sizing the inlets and outlets such that exhaust flow velocity is less than 0.6 m/s
- Using flow diffusers (Figure 22)
- Plumbing multiple tanks in series

Multiple tanks generally yield the greatest temperature difference between cold water inlet and hot water outlet. With the piping/tank configuration shown in Figure 18, the difference can approach

17 K. In addition to the cost of the second tank, the cost of extra footings, insulation, and sensors must be considered. However, multiple tanks may save labor at the site because of their small diameter and shorter length. Smaller tanks require less demolition to install in retrofit (e.g., access through doorways, hallways, and windows).

For additional information on stratification and thermal storage, see Chapter 50.

Storage Sizing

The following specific site factors are related to system performance or cost.

Solar Fraction. Most solar energy systems are designed to produce anywhere from 50 to 90% of the energy required to satisfy the load. If a system is sized to produce less than this, there must be greater coincidence between load and available solar energy. Therefore, smaller, lower-cost storage can be used with low-solar-fraction systems without impairing system performance.

Load Matching. A commercial application's load profile may allow using less storage without incurring performance penalties. For example, a company cafeteria or a restaurant serving large luncheon crowds has its greatest hot-water usage during, and just after midday. Because the load coincides with the availability of solar radiation, less storage is required for carryover. For loads that peak during the morning, collectors can be rotated toward the southeast (in the northern hemisphere), sometimes improving output for a given array.

Storage Cost. If a solar storage tank is insulated adequately, performance generally improves with increased storage volume, but the savings must justify the investment. The cost of storage can be minimized by using multiple low-cost water heaters and unpressurized storage tanks made from materials such as fiberglass or concrete.

Performance and cost relationships between solar availability, collector design, storage design, and load are highly interactive. Furthermore, the designer should maximize investment benefits on an annual basis, rather than for one or two months. Thus, solar energy system performance models combined with economic analysis should optimize storage size for a specific site. Several commercially available pieces of software offer such performance modeling capabilities, including NREL's System Advisor Model (SAM; NREL 2019).

SAM's simplified model represents a one-tank solar water (or glycol) heating system with an auxiliary electric heater. The model allows the user to define a specific site; hot-water load profiles; mains and set temperature profiles; and characteristics of the collector, heat exchanger, and solar tank. A financial model is also incorporated for cost-benefit analysis on residential or commercial applications.

Many hydronic solar energy systems are used with a series-coupled heat pump or an absorption air-conditioning system. In the case of a heat pump, lower storage temperatures, which create higher collector efficiencies, are desirable. In this case, the collector size may be greater than recommended for conventional SHW or hydronic building space heating (BSH) systems. In contrast, absorption air conditioners require much higher temperatures (>80°C) than BSH or hydronic BSH systems to activate the generator (Balaras et al. 2006). Therefore, the storage-to-collector ratio can be much less than recommended for BSH. For absorption air conditioning, thermal energy storage may act as a buffer between the collector and generator, which prevents cycling caused by frequent changes in insolation level.

Seasonal Storage. Installations with large solar collector areas and heat storage capacity could cover 50 to 80% of the total heat demand, or even 100% of the load when coupled with seasonal thermal energy storage (Balaras et al. 2010). A central solar heating plant with seasonal storage (CSHPSS) has three main components (Figure 23): solar collector array, seasonal storage tank, and piping network (Argiriou 1997). Heat produced by the collectors throughout the year is stored in the storage tank. This heat is then used to provide domestic hot water and space heating to the buildings when required. A CSHPSS aims for high solar fractions (50 to 80%). The heat is distributed through a hydraulic pipe network. Although solar radiation has a low power density, which requires a large collector area with small heat losses, the output from a stratified storage has a high power density. CSHPSS is easily combined with existing district heating installations and is three to four times more cost effective compared to common small solar systems.

CSHPSS is suitable for heating loads greater than 500 MWh/year; lower loads have high relative storage costs and large relative storage heat losses. The area to be covered should have a relatively high heat density for district heating to be economical. Low-temperature space heating is preferable for operation at low temperatures, especially of return water in the distribution system. On average, 0.20 to 0.30 m^2 collector area per unit heated floor area and

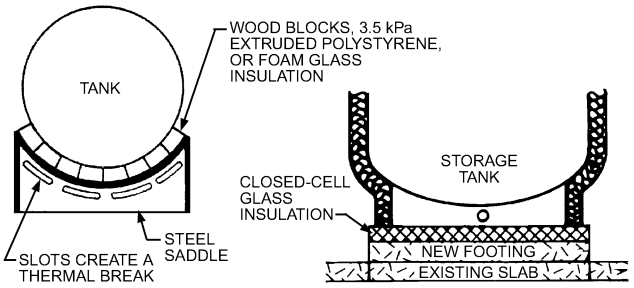

Fig. 21 Typical Tank Support Detail

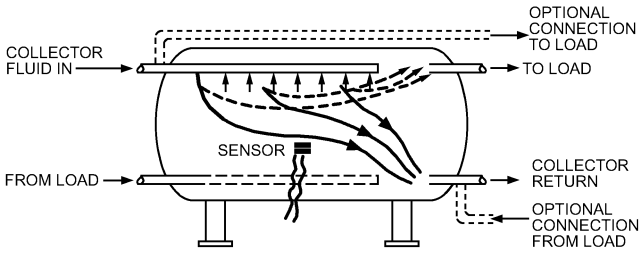

Fig. 22 Tank Plumbing Arrangements to Minimize Short Circuiting and Mixing

(Adapted from Kreider 1982)

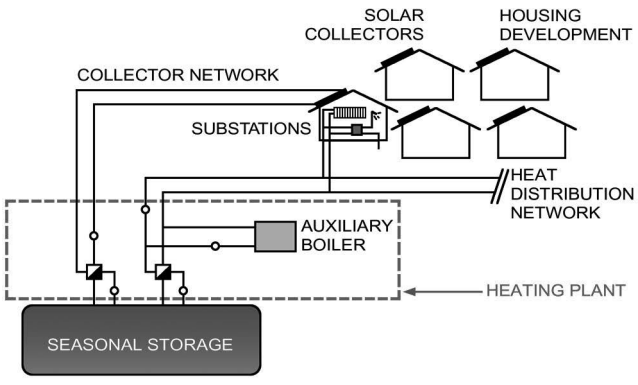

Fig. 23 Schematic of CSHPSS

2 m^3 of storage (water equivalents) per unit collector area are needed to cover 50 to 80% of the total heating load in new buildings.

1.8 HEAT EXCHANGERS

Requirements

The heat exchanger transfers heat from one fluid to another. In closed solar energy systems, it also isolates circuits operating at different pressures and separates fluids that must not be mixed. Heat exchangers are used in solar applications to separate the heat transfer fluid in the collector loop from the domestic water supply in the storage tank (pressurized storage) or the domestic water supply from the storage (unpressurized storage). Heat exchangers for solar applications may be placed either inside or outside the storage or drainback tank.

Selecting a heat exchanger involves the following considerations:

Performance. Heat exchangers always degrade the performance of a solar system; therefore, selecting an adequate size is important. When in doubt, select an oversized heat exchanger.

Guaranteed separation of fluids. Many code authorities require a vented, double-wall heat exchanger to ensure fluid isolation. System protection requirements may also dictate the need for guaranteed fluid separation.

Thermal expansion. The temperature in a heat exchanger may vary from below freezing to the boiling temperature of water. The design must withstand these thermal cycles without failing.

Materials. Galvanic corrosion is always a concern in liquid solar energy systems. Consequently, the piping, collectors, and other hydronic component materials must be compatible.

Space constraints. Often, space for mounting and servicing the heat exchanger is limited. Physical size and configuration must be considered during selection.

Serviceability. The water side of a heat exchanger is exposed to the scaling effects of dissolved minerals, so design must provide access for cleaning and scale removal.

Pressure loss. Energy consumed in pumping fluids reduces system performance. Pressure drop through the heat exchanger should be limited to 7 to 14 kPa to minimize energy consumption.

Pressure capability. Because the heat exchanger is exposed to cold-water supply pressure, it should be rated for pressures above 520 kPa (gage).

Internal Heat Exchanger

The internal heat exchanger can be a coil inside the tank or a jacket wrapped around the pressure vessel (see Figure 17). Several manufacturers supply tanks with either type of internal heat exchanger. However, the maximum size of pressurized tanks with internal heat exchangers is usually about 450 L. Heat exchangers may be installed with relative ease inside unpressurized tanks that open from the top. Figures 24 and 25 illustrate methods of achieving double-wall protection with either type of internal heat exchanger.

For installations with larger tanks or heat exchangers, a tube bundle is required. However, it is not always possible to find a heat exchanger of the desired area that will fit within the tank. Instead, a horizontal tank with the tube bundle inserted from the tank end can be used. A second option is to place a shroud around the tube bundle and to pump fluid around it (Figure 26). This approach combines the performance of an external heat exchanger with the compactness of an internal heat exchanger, but unfortunately it causes tank mixing and loss of stratification.

External Heat Exchanger

Because an external heat exchanger is detached from the tank, it offers greater design flexibility than internal heat exchangers and is preferred for most commercial applications. Shell-and-tube, tube-and-tube, and plate-and-frame heat exchangers are used in solar applications. Shell-and-tube heat exchangers are found in many solar designs because they are economical, easy to obtain, and constructed with suitable material; however, they normally do not have double-wall protection, which is often required for potable-water-heating applications. Several manufacturers produce tube-and-tube heat exchangers that offer high performance and the double-wall safety required by many code authorities, but they are usually limited in size. The plate-and-frame heat exchanger is more cost effective for large potable-water applications where positive separation of heat transfer fluids is required. These heat exchangers are compact and offer excellent heat transfer performance.

Shell-and-Tube. Shell-and-tube heat exchangers accommodate large heat exchanger areas in a compact volume. The number of shell-side and tube-side passes (i.e., the number of times the fluid changes direction from one end of the heat exchanger to the other) is a major variable in selection. Because the exchanger must compensate for thermal expansion, flows in and out of the tube side are generally at the same end of the exchanger. Therefore, the number of tube-side passes is even. By appropriate baffling, two, four, or more tube passes may be created. However, as the number of passes increases, the path length grows, resulting in greater pressure drop

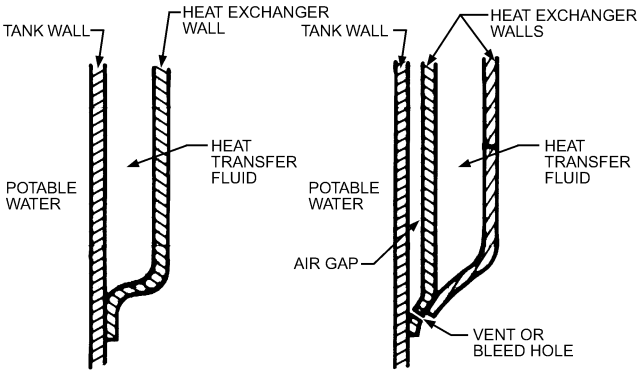

Fig. 24 Cross Section of Wraparound Shell Heat Exchangers

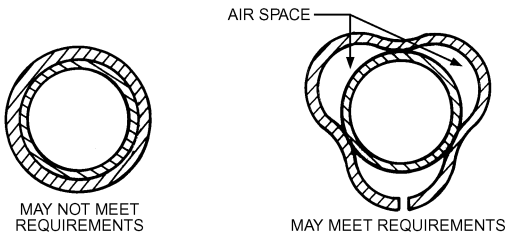

Fig. 25 Double-Wall Tubing

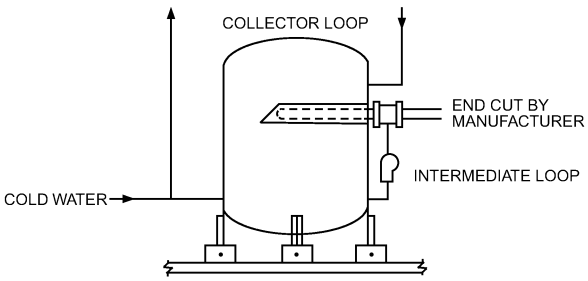

Fig. 26 Tube Bundle Heat Exchanger with Intermediate Loop

of the tube-side fluid. Unfortunately, double-wall shell-and-tube heat exchangers are hard to find.

Tube-and-Tube. Fluids in the tube-and-tube heat exchanger run counterflow, which gives closer approach temperatures. The exchanger is also compact and only limited by system size. Several may be piped in parallel for higher flow, or in series to provide approach temperatures as close as 8 K. Many manufacturers offer the tube-and-tube with double-wall protection.

The counterflow configuration operates at high efficiency. For two heat exchangers in series, effectiveness may reach 0.80. For single heat exchangers or multiple ones in parallel, effectiveness may reach 0.67. Tube-and-tube heat exchangers are cost effective for smaller residential systems.

Plate-and-Frame. These heat exchangers are suitable for pressures up to 2 MPa and temperatures to 200°C. They are economically attractive when a high-quality, heavy-duty construction material is required or if a double-wall heat exchanger is needed for leak protection. Typical applications include food industries or domestic water heating when any possibility of product contamination must be eliminated. This exchanger also gives added protection to the collector loop.

Contamination is not possible when an intermediate loop is used (Figure 27) and the integrity of the plates is maintained. A colored fluid in the intermediate loop gives a visual means of detecting a leak through changes in color. The sealing mechanism of the plate-and-frame heat exchanger prevents cross-contamination of heat transfer fluids. Plate-and-frame heat exchangers cost the same as or less than equivalent shell-and-tube heat exchangers constructed of stainless steel.

Brazed Plate. Brazed-plate exchangers are designed for pressures up to 3 MPa and temperatures up to 260°C. These are similar to plate-and-frame, but without the frame. The edges of the plates are brazed together, creating a compact unit. Brazed plates tend to be on the smaller end of the flow rate spectrum and can be economical for residential and small commercial systems.

Heat Exchanger Performance

Solar collectors perform less efficiently at high fluid inlet temperatures. Heat exchangers require a temperature difference between the two streams to transfer heat. The smaller the heat transfer surface area, the greater the temperature difference must be to transfer the same amount of heat and the higher the collector inlet temperature must be for a given tank temperature. As the solar collector is forced to operate at the progressively higher temperature associated with a smaller heat exchanger, its efficiency is reduced.

In addition to size and surface area, the heat exchanger's configuration is important for achieving maximum performance. The performance of a heat exchanger is characterized by its effectiveness (a type of efficiency), which is defined as follows:

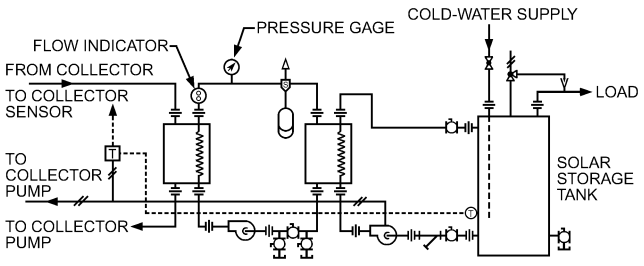

Fig. 27 Double-Wall Protection Using Two Heat Exchangers in Series

$$E = \frac{q}{(mc_p)_{min}(t_{hi} - t_{ci})} \quad (9)$$

where

E = effectiveness
q = heat transfer rate, kW
mc_p = minimum mass flow rate times fluid specific heat, kW/K
t_{hi} = hot (collector-loop) stream inlet temperature, °C
t_{ci} = cold (storage) stream inlet temperature, °C

For heat exchangers located in the collector loop, minimum flow usually occurs on the collector side rather than the tank side.

The effectiveness E is the ratio between the heat actually transferred and the maximum heat that could be transferred for given flow and fluid inlet temperature conditions. E is relatively insensitive to temperature, but it is a strong function of heat exchanger design.

A designer must decide what heat exchanger effectiveness is required for the specific application. A method that incorporates heat exchanger performance into a collector efficiency equation (Equation [5]) uses storage tank temperature t_s as the collector inlet temperature with an adjusted heat removal factor F_R. Equation (10) relates F_R and heat exchanger effectiveness:

$$\frac{F_R'}{F_R} = \frac{1}{1 + (F_R U_L / mc_p)[Amc_p / E(mc_p)_{min} - 1]} \quad (10)$$

The heat exchanger effectiveness must be converted into heat transfer surface area. Franta (1981) provides details of shell-and-tube heat exchangers and heat transfer fluids.

For more information on heat exchangers, see Chapter 47.

1.9 CONTROLS

The brain of an active solar energy system is the automatic temperature control. Numerous studies and reports of operational systems show that faulty controls, usually the sensors, are often the cause of poor performance. Reliable controllers are available, and with a full understanding of each system function, proper control systems can be designed. In general, control systems should be simple; additional controls are not a good solution to a problem that can be solved by better mechanical design. Key considerations for control system design include the following:

- Collector sensor location/selection
- Storage sensor location
- Overtemperature sensor location
- On/off controller characteristics
- Selection of reliable solid-state devices, sensors, controllers, etc.
- Control panel location in heated space
- Connection of controller according to manufacturer's instructions
- Design of control system for all possible system operating modes, including heat collection, heat rejection, power outage, freeze protection, auxiliary heating, etc.
- Selection of alarm indicators for pump failure, low and high temperatures, loss of pressure, controller failure, nighttime operation, etc.

Control categories to consider when designing automatic controls for solar energy systems are as follows:

- Collection to storage
- Storage to load
- Auxiliary energy to load
- Alarms
- Miscellaneous (e.g., for heat rejection, freeze protection, draining, and overtemperature protection)

Types of controllers include snap switches, timers, photovoltaic (PV) modules, and differential temperature controllers. The latter is the most common, with PV popular for residential systems.

Differential Temperature Controllers

Most controls used in solar energy systems are similar to those for HVAC systems. The major exception is the differential temperature controller (DTC), which is the basis of solar energy system control. The DTC is a comparing controller with at least two temperature sensors (typically at the solar collectors and storage tank) that controls one or several devices (Figure 28). On unpressurized systems, other DTCs may control extraction of heat from the storage tank.

The DTC monitors the temperature difference, and when the temperature of the panel exceeds that of the storage by the predetermined amount (generally 4.5 to 11 K), the DTC switches on the actuating devices. When the temperature of the panel drops to 1.5 to 5.5 K above the storage temperature, the DTC, either directly or indirectly, stops the pump. Indirect control through a control relay may operate one or more pumps and possibly perform other control functions, such as actuation of control valves.

The manufacturer's predetermined set point of the DTC may be adjustable or fixed. If the controller set point is a fixed temperature differential, the controller should correspond to the requirements of the system. An adjustable differential set point makes the controller more flexible and allows it to be adjusted to the specific system. The optimum *off* temperature differential should be the minimum possible; the minimum depends on whether there is a heat exchanger between the collectors and storage.

If the system requires a heat exchanger, the energy transferred between two fluids raises the differential temperature set point. The minimum, or *off*, temperature differential is the point at which pumping the energy costs as much as the value of the energy being pumped. For systems with heat exchangers, the *off* set point is generally between 3 and 5.5 K. If the system does not have a heat exchanger, a range of 1.5 to 3.5 K is acceptable for the *off* set point. Heat lost in piping and power required to operate the pump should also be considered.

The optimum differential *on* set point is difficult to calculate because of the changing variables and conditions. Typically, the *on* set point is 5.5 to 8.5 K above the *off* set point. The optimum *on* set point is a balance between optimum energy collection and avoiding short-cycling the pump. ASHRAE's *Active Solar Heating System Design Manual* (1988) describes techniques for minimizing short cycling.

Photovoltaically Powered Pumps

The ability to drive a pump in direct proportion to the available irradiance without an external electric power makes PV pumps very popular in residential applications. Brush pumps powered by DC require additional maintenance, but have proven to be as reliable as their AC counterparts. The lack of larger DC brushless motors has limited adoption of this technology in commercial solar systems. Using PV pumps offers the security of having hot water during power outages. The primary disadvantage is the higher first cost.

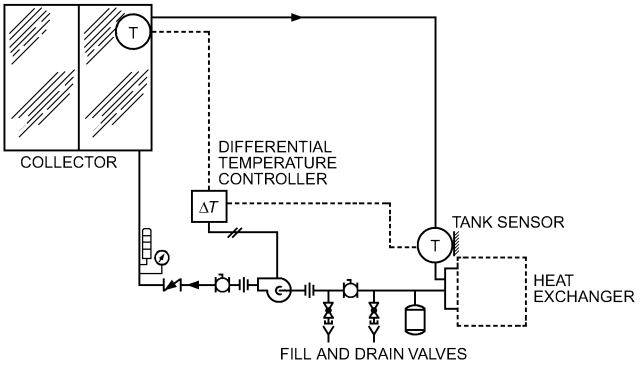

Fig. 28 Basic Nonfreezing Collector Loop for Building Service Hot-Water Heating (Nonglycol Heat Transfer Fluid)

Overtemperature Protection

Overheating may occur during periods of high insolation and low load; thus, all portions of the solar energy system require protection against overheating. Liquid expansion or excessive pressure may burst piping or storage tanks, and steam or other gases in a system may restrict liquid flow, making the system inoperable. Glycols break down and become corrosive if subjected to temperatures greater than 115°C. The system can be protected from overheating by (1) stopping circulation in the collection loop until storage temperature decreases, (2) discharging overheated water from the system and replacing it with cold makeup water, or (3) using a heat exchanger coil as a means of heat rejection to ambient air.

The following questions should be answered to determine whether overtemperature protection is necessary:

- Is the load ever expected to be off, such that the solar input will be much higher than the load? The designer must determine possibilities based on the owner's needs and a computer analysis of system performance.
- Do individual components, pumps, valves, circulating fluids, piping, tanks, and liners need protection? The designer must examine all components and base the overtemperature protection set point on the component that has the lowest specified maximum operating temperature. This may be a valve or pump with an 80 to 150°C maximum operating temperature. Sometimes, this criterion may be met by selecting components that can operate at higher temperatures.
- Is steam formation or discharging boiling water at the tap possible? If the system has no mixing valve that mixes cold water with the solar-heated water before it enters the tap, the water must be maintained below boiling temperature. Otherwise, the water will flash to steam as it exits the tap and, most likely, scald the user. Some city codes require a mixing valve to be placed in the system for safety.

Differential temperature controllers are available that sense overtemperature. Depending on the controller used, the sensor may be mounted at the bottom or the top of the storage tank. If it is mounted at the bottom, the collector-to-storage differential temperature sensor can be used to sense overtemperature. Input to a DTC mounted at the top of the tank is independent of the bottom-mounted sensor, and the sensor monitors the true high temperature.

The normal action taken when the DTC senses an overtemperature is to turn off the pump to stop heat collection. After the panels in a drainback system are drained, they attain stagnation temperatures. Although drainback is not desirable, the panels used for these systems should be designed and tested to withstand overtemperature as well as the thermal shock of start-up when relatively cool water enters the stagnation-temperature panels. The temperature difference can range from 40 to 170 K. Such a difference could warp panels made with two or more materials of different thermal expansion coefficients. If the solar panels cannot withstand the thermal shock, an interlock should be incorporated into the control logic to prevent this situation. One method uses a high-temperature sensor mounted on the collector absorber that prevents the pump from operating until the collector temperature drops below the sensor set point.

If circulation stops in a closed-loop antifreeze system that has a heat exchanger, high stagnation temperatures will occur. These temperatures could break down the glycol heat transfer fluid. To prevent damage or injury caused by excessive pressure, a pressure relief

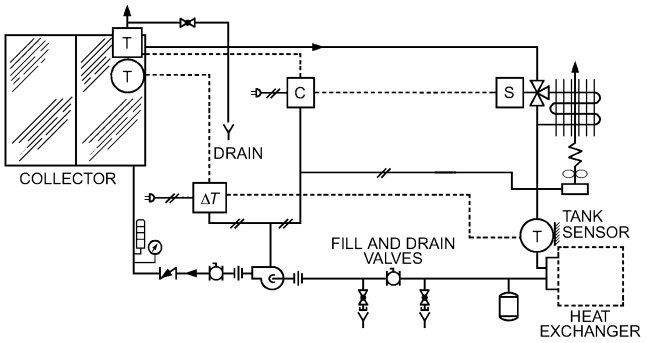

Fig. 29 Heat Rejection from Nonfreezing System Using Liquid-to-Air Heat Exchanger

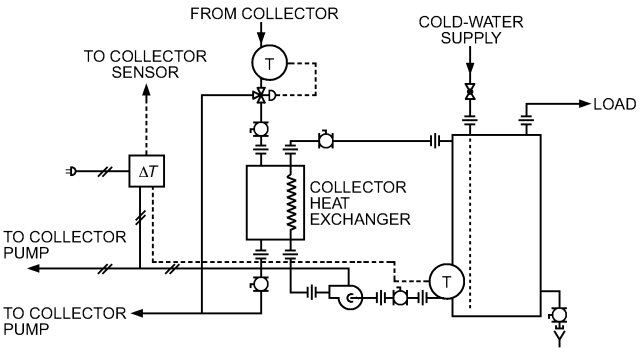

Fig. 30 Nonfreezing System with Heat Exchanger Bypass

valve must be installed in the loop, and a means of rejecting heat from the collector loop must be provided. The section on Hot-Water Dump describes a common way to relieve pressure. Pressure increases because of thermal expansion of any fluid; when water-based absorber fluids are used, pressure builds from boiling.

The pressure-relief valve should be set to relieve at or below the maximum operating pressure of any component in the closed-loop system. Typical settings are around 350 kPa (gage), corresponding to a temperature of approximately 150°C. However, these settings should be checked. When the pressure-relief valve does open, it discharges expensive antifreeze solution. Glycol antifreeze solutions damage many types of roof membranes. The discharge can be piped to large containers to save the antifreeze, but this design can create dangerous conditions because of the high pressures and temperatures involved.

If a collector loop containing glycol stagnates, chemical decomposition raises the liquid's fusion point, and freezing becomes possible. An alternative method continues fluid circulation but diverts flow from storage to a heat exchanger that dumps heat to the ambient air or other sink (Figure 29). This wastes energy, but protects the system. A sensor on the solar collector absorber plate that turns on the heat rejection equipment can provide control. The temperature sensor set point is usually 95 to 120°C and depends on the system components. When the sensor reaches the high-temperature set point, it turns on pumps, fans, alarms, or whatever is necessary to reject the heat and warn of the overtemperature. The dump continues to operate until the overtemperature control in the collector loop DTC senses an acceptable drop in tank temperature and is reset to its normal state.

Hot-Water Dump

If water temperatures above 95°C are allowed, the standard temperature-pressure [99°C, 1034 kPa (gage)] safety relief valve may operate occasionally. If these temperatures are reached, the valve opens, and some of the hot water vents out. However, these valves are designed for safety purposes, and after a few openings, they leak hot water. Thus, they should not be relied on as the only control device. An aquastat that controls a solenoid, pneumatic, or electrically actuated valve should be used instead.

Heat Exchanger Freeze Protection

When selecting an external heat exchanger for a system protected by a nonfreezing fluid and started after an overnight (or longer) exposure to extreme cold, consider the following factors:

- Freeze-up of the water side of the heat exchanger
- Performance loss due to extraction of heat from storage

In small systems, an internal heat exchanger/tank can be placed on the water side of the heat exchanger to prevent freezing. However, the energy required to keep the water above freezing must be extracted from storage, which decreases overall performance. With the external heat exchanger/tank combination, a bypass can be installed (Figure 30). The controller positions the valve to bypass the heat exchanger until the fluid in the collector loop attains a reasonable level (e.g., 27°C). When the heat transfer fluid has warmed to this level, it can enter the heat exchanger without freezing or extracting heat from storage. The arrangement in Figure 30 can also be used with an internal heat exchanger, if necessary, to improve performance.

2. PHOTOVOLTAIC SYSTEMS

Photovoltaic (PV) devices, or cells, convert light directly into electricity. The cells are connected in a combination of series and parallel strings and laminated into modules to produce a nominal maximum voltage and current output when exposed to solar radiation. PV modules can be connected in series, in parallel, or a combination to form arrays that produce larger voltages and/or currents. PV systems rely on sunlight, have no moving parts (unless a solar tracking system is used), are modular to match various power requirements, are reliable, and require minimal maintenance. Photovoltaic systems can be used independently or in conjunction with other electrical power sources.

A typical PV system consists of (1) PV modules, (2) power conversion equipment (e.g., inverters, microinverters, charge controllers, optimizers), (3) balance-of-system (BoS) equipment (e.g., wires, switches, fuses, mounting system), and occasionally (4) a battery bank. In many instances, BoS also refers to all PV system components except the PV modules. PV modules connected in series form a **PV string.** Multiple PV strings connected in series and parallel configurations form a **PV array**. All components are described in the following sections.

Most early PV installations were **stand-alone** systems (i.e., located at sites where utility power was unavailable); applications include communications, remote power, remote monitoring, lighting, water pumping, battery charging, and cathodic protection. These systems may have a battery bank to provide power when the sun is not available. Excess power generated during the day is stored in the battery bank through a charge controller, for later use.

More recently, **grid-connected** (or **grid-tied**) systems have predominated. These systems use string inverters or micro-inverters that convert direct current from the PV array to alternating current. The AC output from the inverters is fed to the AC load circuit. The inverters are designed to synchronize their AC output (phase, frequency, and voltage) with the electric utility. If the grid is down, these systems automatically shut down to prevent backfeeding power into the lines, to protect utility personnel.

Some advanced systems are **grid-interactive** and can function in an isolated mode (when the grid is down) or in a parallel-to-the-grid mode of operation by using grid-interactive inverters. Where energy resiliency and emergency operation are of importance, using these systems is recommended. A typical grid-interactive system incor-

porates battery storage and aims to reduce end-use utility energy consumption, reduce peak power demand, and enhance energy resilience.

Other, less common system configurations connect PV modules directly to an **AC/DC hybrid heat pump**. In this case, no inverter is required: the AC/DC hybrid heat pump can be connected directly to the DC-generating PV array. During the daytime, if the (DC) power generated from the PV is not sufficient, the AC/DC hybrid heat pump draws the additional (AC) power from the electric utility. When the sun is not available, the heat pump is powered only by the utility. Such a configuration can reduce electricity consumption and peak demand for heating and cooling. A drawback is that excess solar electricity is wasted when PV energy production is greater than heat pump energy consumption.

There are also PV systems with thermal energy recovery (PVT). The primary objective of PVT systems is to generate both electricity and thermal energy using the same surface area by recovering part of the heat generated by the PV modules through a heat recovery mechanism. These systems can be either air or water based (or, less frequently, refrigerant based). The main benefit of these systems is that space PVT systems use less surface area than side-by-side thermal and PV systems. More information on the design and performance of PVT systems can be found in Chapter 36 of the 2023 *ASHRAE Handbook—HVAC Applications*.

Fundamentals of Photovoltaics

Photovoltaic Effect. In simple terms, when a photon strikes a PV cell or film, it can be reflected, transmitted through, or absorbed and thus transfer its energy to an electron. This excited electron can reach an established layer of junctions within the cell that was created during the manufacturing process. As electrons reach the junction layer, an electric charge is established between the front and back of the solar cell. Electric contacts placed on the front and back of the cell provide a conduction path for these electrons to flow, creating an electric current.

PV Cells. A PV cell consists of the active PV material, metal grids, antireflection coatings, and supporting material. The complete cell is optimized to maximize both the amount of light entering the cell and the power output of the cell. The photovoltaic material can be one of a number of compounds. Metal grids enhance current collection from the front and back of the solar cell. Grid design varies among manufacturers. The antireflective coating is applied to the top of the cell to maximize the light going into the cell; typically, this coating is a single layer optimized for sunlight. As a result, PV cells range in color from black to blue. In some, the top of the cell is covered with a semitransparent conductor that functions as both the current collector and the antireflection coating. A completed PV cell is a two-terminal device with positive and negative leads, and its output is DC.

In general, all PV cells perform similarly. However, the choice of PV material can have important effects on system design and performance. Both the composition of the material and its atomic structure are influential. PV materials include silicon, gallium arsenide, copper indium diselenide, cadmium telluride, indium phosphide, and many others. The atomic structure of a silicon PV cell can be monocrystalline, polycrystalline, or amorphous (i.e., having no crystalline structure). The most commonly produced PV modules are made of crystalline silicon, either mono- or polycrystalline. The industry distinguishes between cells made with junctions or thin film, made by laminating layers to produce the junctions.

Because of quantum effects, electrons designated to leave their atoms in a PV cell only absorb photon energy of a certain band of wavelengths; the other light energy is not absorbed. Multijunction cells (thin-film with two or more layers of junctions laid on top of one another) can have higher efficiency because each junction layer can be designed to respond to different wavelengths of incoming radiation.

PV Modules. A module is a collection of PV cells that protects the cells and provides a usable operating voltage. Crystalline silicon PV cells can be fragile and susceptible to corrosion by humidity or fingerprints and can have delicate wire leads. Also, the operating voltage of a single PV cell is less than 1 V, making it unusable by itself for many applications. For example, a typical 152 × 152 mm cell operates around 0.5 V and produces approximately 8 A; if 128 cells were wired together in series as one module, then the module would produce approximately 64 V at 8 A, and generate 512 W.

Depending on the manufacturer and type of PV material, modules have different appearances and performance characteristics. Also, modules may be designed for specific conditions, such as hot or marine environments.

Mono and polycrystalline silicon cells are produced individually. Some amorphous silicon cells, although manufactured in large rolls, are later processed as individual cells. These cells are connected in series and parallel to produce the desired operating voltage and wattage. These arrays of cells are then encapsulated with a polymer, a transparent frontsheet (commonly solar, low-iron glass), and a backsheet (glass or polymer). Polymer-encapsulated PV modules can be constructed in a lightweight, flexible (nonrigid) package for building integrated applications.

Cells made of amorphous silicon, cadmium telluride, or copper indium diselenide are manufactured on large rolls of material that become either the frontsheet or the backsheet of the module. A large area of PV material is divided into smaller cells by scribing or cutting the material into electrically isolated cells. Later processing steps automatically interconnect the cells in series and parallel. All modules also include a robust junction box attached to the module for wiring to other modules or other electrical equipment.

Current-Voltage (I-V) Curves. The current from a PV module depends on the external voltage applied and the incident irradiance on the surface of the module. When the module is short-circuited, current is at maximum (short-circuit current I_{sc}), and voltage across the module is zero. When the PV module circuit is open, voltage is at a maximum (open-circuit voltage V_{oc}), and current is zero. In either case, at open or short circuit, the power (current times voltage, $I \times V$) is zero. Between open and short circuit, the power output is greater than zero. A current-voltage (I-V) curve represents the range of combinations of current and voltage (Figure 31).

The power-voltage (P-V) curve can be plotted on the same graph. There exists an operating point at which output power is maximized (P_{mp}), also known as maximum power point (V_{mp}, I_{mp}). Given P_{mp}, an additional parameter, **fill factor (FF)**, can be calculated as

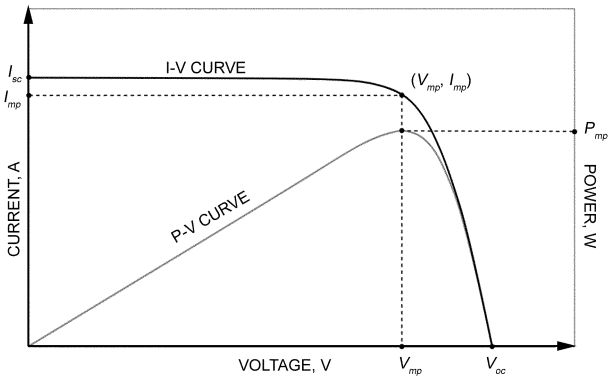

Fig. 31 Representative Current-Voltage and Power-Voltage Curves for Typical Photovoltaic Module

$$P_{mp} = I_{sc}V_{oc}\text{FF} \quad (11)$$

Fill factor is thus defined as the ratio of maximum obtainable power under the I-V curve, to the product of the open-circuit voltage and short-circuit current.

Efficiency and Power. Efficiency is the electrical power output of the module divided by the incident irradiance. It is commonly reported under **standard test conditions (STC)**. These conditions, established by international standard, are defined as 1000 W/m^2 incident irradiation at a spectrum of 1.5 atmospheres equivalent spectral absorption, with a cell temperature of 25°C. PV modules generally convert 5 to 22% of the incident solar radiation into electricity, although the exact percentage varies depending on the photovoltaic technology used and its operating conditions. More information on PV technologies and performance efficiencies can be found in Chapter 36 of the 2023 *ASHRAE Handbook—HVAC Applications*.

Module Reliability and Durability. PV modules are reliable and durable when properly made. As with any electrical equipment, the designer must verify that the product is tested or rated for the intended application. A PV module is a large-area semiconductor with no internal moving parts. Even a concentrator module has no internal moving parts, although there are external parts that keep the module aimed at the sun.

PV modules are designed for outdoor use in harsh surroundings such as marine, tropic, arctic, and desert environments. There are many international standards that test the suitability of PV modules for outdoor use in different climates. A buyer or user should check the suitability of the module for a given climate.

Modules are also tested for electrical safety. All modules have a maximum voltage rating supplied by the manufacturer or labeled on the module. This becomes important when interconnecting several modules into an array and connecting arrays to other electrical equipment. Most modules are tested for ground isolation to prevent personal injury or property damage. To meet the *National Electrical Code*®, modules must be listed by Underwriters Laboratories (UL) or other equivalent testing body.

Module Performance. The performance output of a module is provided by the manufacturer and shown on a label on each module. The value provided is in watts per square metre (W/m^2), and represents the expected nominal power output of the module in watts at STC. Modules are typically marketed and sold by this nominal watt value ($/W). Designers are cautioned that the actual performance of a module under real operating conditions may vary significantly, depending on climatic conditions, air mass, solar spectrum, and solar angle of incidence.

Figure 32 shows that the maximum power P_{mp} occurs only at a single point on the I-V curve, which is the product of the maximum power current I_{mp} and the maximum power voltage V_{mp}. This point is referred to as the **maximum power point (MPP)**.

Off-the-shelf inverters and charge controllers available today use maximum peak-power tracking (MPPT) algorithms to optimize PV power output. Typically, the PV array output wattage is sampled and the voltage is adjusted automatically many times per second for maximum power production. Peak power tracking consumes some of the energy generated by the PV array, though this is typically far less than the extra power gained when compared to a non-power tracking system.

PV modules experience daily variations in light intensity, with the incident solar irradiance varying between 0 W/m^2 (at night) and 1200 W/m^2. The upper limit of daily irradiance varies significantly between different geographic locations, seasons, local climate and PV orientation. Figure 33 shows that current, and therefore power, is proportional to the incident irradiance. The point on the I-V curves indicates the MPP under different irradiance levels.

Solar PV module performance decreases with increasing temperature (Figure 34), in an almost linear manner. The high cell operating temperatures have an effect on the operating voltage and consequently the power output. The operating current is not very sensitive to cell operating temperatures, so it remains relatively constant.

The California Energy Commission requires all modules to be tested for utility scale applications test conditions (PTC), in addition to STC (California Public Utilities Commission 2017). PTC specify 1000 W/m^2 incident irradiation at a spectrum of 1.5 atmospheres equivalent spectral absorption, with an ambient temperature of 20°C. The cell is allowed to reach nominal operating cell temperature (NOCT), which may be 17 to 28 K higher than when tested

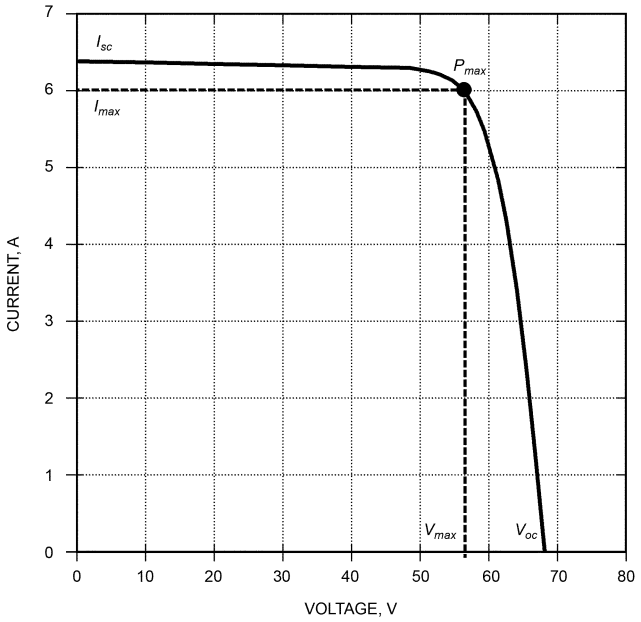

Fig. 32 Module *IV* Curve at STC

(Courtesy SunPower and Khalid Nagidi)

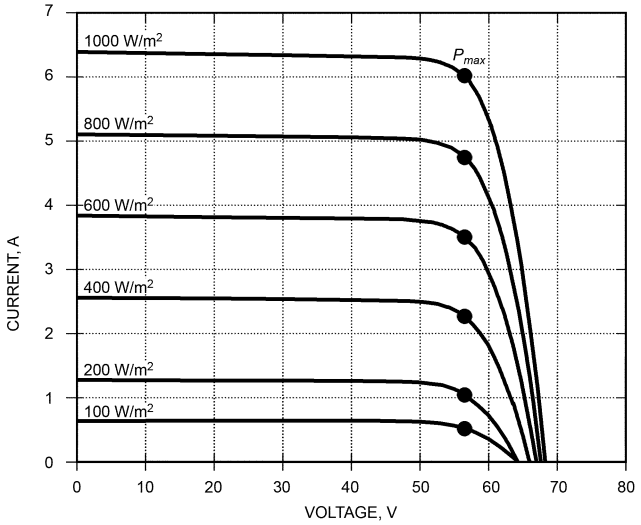

Fig. 33 Effect of Insolation on Module Performance

(Courtesy SunPower and Khalid Nagidi)

under PTC. The lower the NOCT value, the lower the cell temperature, therefore, the higher the PV module performance. PTC give a better indication of actual operating performance; the difference in STC and PTC values indicates the specific module's temperature dependence. The closer the PTC to STC rating, the higher the module output is under more common and realistic operating conditions. The PTC-to-STC ratio is usually between 0.85 and 0.95. Thin-film modules generally have PTC values closer to STC.

All photovoltaic modules experience light-induced degradation (LID). The performance output is provided for new modules with only brief exposure. Modules with crystalline silicon cells experience minimal LID, but thin-film cells can take up to 1000 h of exposure for the initial LID to stabilize. Most thin-film manufacturers rate the modules at the stabilized power output, allowing for an initial period of excess performance. Over 150°C, amorphous silicon modules can undergo thermal annealing, which can reverse the effects of LID (Radue and van Dyk 2010). Improving the stability of thin-film modules over exposure time is an active area of research in the PV industry.

Mono or polycrystalline silicon modules generally exhibit the least power output degradation from exposure, followed by multijunction and single-junction thin-film modules; amorphous cells display the most degradation. Also, note that the performance STC test temperature is 25°C. As cells heat up, their performance declines in a linear manner, about 0.5% per K (for silicon). When selecting equipment for PV systems, it is important to recognize the difference between published cell efficiencies of various types from laboratories and tested module efficiencies. Cell efficiencies may be developed by a lab on small test cells and use short exposure times and may not transfer to the efficiencies of manufactured modules.

Power tolerance indicates how close the PV module actual output would be to its rated output under STC. For example, if a 300 W module has a power tolerance of ±5%, its actual output under STC can fluctuate from 285 W to 315 W. Some PV modules have a positive only power tolerance such as "+5/–0," which means that these modules should be able to produce at least rated power under STC, and possibly 5% more.

Most PV manufacturers provide 25 year power output warranties under STC with an average power output decrease of 0.5% per year. Almost all of them guarantee 90% power output for the first 10 years and 80% thereafter for the remaining 15 years. Few of them now provide 25 year linear power output warranties under STC.

Related Equipment

Inverters. An inverter converts DC from the PV arrays to AC. The inverter's output can be single or multiphase, with a voltage of 120, 220, 440, etc., and a frequency of 50 or 60 Hz. Inverters are rated by total power capacity, which ranges from hundreds of watts to megawatts. Some inverters have good surge capacity for starting motors; others have limited surge capacity. The designer should specify both the type and the size of the load the inverter is intended to service.

The output waveform of the inverter, though still AC, can be square, modified square (also called modified sine wave), or sine. For some small applications, modified sine wave inverters are available. Inverters should be selected with care, because equipment that contains silicon-controlled rectifiers (SCRs) or variable-speed motors, such as some vacuum cleaners and laser printers, can be damaged by square- and modified-square-wave inverter outputs. Electric utilities supply sine wave output, and most manufacturers produce inverters with sine wave outputs that avoid unexpected equipment damage. Sine wave inverters generate a waveform very close to that provided by the utility grid. Some can supply AC power that is better regulated and even has lower total harmonic distortion (THD) than utility power.

Inverters can be categorized relative to their interaction with the utility grid. A **stand-alone** inverter is used on off-grid PV systems, and can supply the AC waveform. Commonly, it also provides charge controller capabilities to allow the connection and charge/discharge of a battery bank. A **grid-connected** inverter synchronizes the waveform frequency to the electric utility. All grid-connected inverters must have anti-islanding protection built in so they can be turned off automatically if the utility grid loses power, to protect utility workers from electrical shocks. **Grid-interactive** inverters are grid-connected inverters with advanced capabilities. They can regulate or form their own local grid, thus allowing the PV system to supply the AC load circuit with power for emergency loads, even when the grid is down. They may also provide grid ancillary services at the request of the utility, such as improving voltage or reactive power characteristics.

In addition, inverters can be categorized relative to PV connection configuration (Figure 35). In the case of a **string inverter**, several modules are connected in the form of PV strings or arrays. The current (and power) output of the each PV string is dictated by the current output of the worst performing module. For **microinverters**, each individual PV module has its own microinverter that acts as maximum power point tracker. One benefit of the microinverter is that, because each PV module is individually optimized, modules with different orientations and/or shading may in some cases perform better than an array of modules connected to one inverter.

In addition, microinverters allow both system- and module-level monitoring, whereas string inverters allow only monitoring at the system level. Currently, the capital cost for a microinverter configuration is higher than a string inverter. Another less common configuration is using a string inverter with power optimizers. **Power optimizers** are DC-to-DC converters connected to individual modules, able to optimize the power output of each module. However, a string inverter is still required to convert DC to AC.

Take care to ensure that any PV system complies with local codes and the equipment is certified to the appropriate test and standards, such as those by Institute of Electrical and Electronics Engineers (IEEE), Underwriters Laboratories (UL), or California *Rule* 21 (California Public Utilities Commission 2017).

Battery Charge Controllers. Charge controllers regulate the rate at which current is added or drawn from the PV system to the battery bank, thus preventing overcharging. Charge controllers

can be categorized as shunt or series type and can also function as a low-battery-voltage disconnect to prevent battery overdischarge. When the battery bank is full, a shunt charge controller redirects the excess current to a shunt load (e.g., auxiliary electric element) while a series charge controller disconnects the PV system. Often, stand-alone and grid-interactive inverters tend to integrate charge controller circuitry, eliminating the need for a separate charge controller.

Some stand-alone charge controllers use pulse-width modulation (PWM), which allows battery voltage to determine the operating voltage of the PV system. However, battery voltage may not be the optimum PV operating voltage. On the other hand, stand-alone MPPT charge controllers optimize the operating voltage of the PV modules independent of battery voltage so that the PV operates at its MPP. Because the MPP tracker also consumes some of the PV energy to operate, this approach may not always increase the annual generation, especially if the battery and PV arrays are carefully balanced.

A stand-alone charge controller should be selected based on battery voltage (typically 12, 24, or 48 V), V_{oc} and I_{sc} of the PV array, and desired features.

There are four common phases of operating a charge controller:

- **Bulk phase:** the charge controller fills the battery bank from the PV array to approximately 85% of its capacity.
- **Absorption phase:** voltage is maintained at the bulk set point and current is regulated to maintain that voltage.
- **Float phase:** once the battery bank is fully charged, the charging voltage is reduced to the float voltage setting.
- **Equalization:** intentional overcharge of a fully charged battery, which stirs up the electrolyte and evens out its chemical state of charge to keep the battery healthy.

Batteries. Batteries are used in some PV systems to supply power at night or when the PV system cannot meet the demand and to reduce peak power demand and/or enhance energy resilience. The selection of battery type and size depends primarily on load and availability requirements. In all cases, batteries must be located in an area without extreme temperatures and with some ventilation. Designers should be aware that all lead-acid batteries lose their effective energy capacity as the surrounding ambient temperature decreases. For optimal battery performance, battery banks should be kept between 10 and 24°C.

Battery types include lead-acid, nickel cadmium, nickel hydride, lithium, and many others. For a PV system, the main requirement is that the battery be capable of repeated deep discharges without damage. Starting-lighting-ignition batteries (car batteries) are not designed for this and should not be used.

Deep-cycle lead-acid batteries are commonly used. These batteries can be flooded or valve regulated (sealed) and are commercially available in a variety of sizes. Flooded, or wet, batteries require greater maintenance than valve-regulated batteries but can last longer with proper care. For more capacity, batteries can be arranged in parallel, but using more than three strings leads to uneven performance, premature failure of some batteries, and potentially early replacement of the entire battery bank. The rapidly decreasing cost of lithium-nickel-cobalt and lithium-ferrous-phosphate batteries and their ability to operate at higher voltages, as well as charge and discharge rapidly, has made them more common in off-grid PV systems. Utility-sized systems also use them for maintaining output.

Balance-of-System (BOS) Components. These components (e.g., mounting systems, DC and AC wiring, relays, fuses, transformers) are just as important as the other major PV system components. PV systems should be designed and installed with the intent of safety and minimal maintenance, and their installation should not compromise any building envelope warranties. In the United States, wire sizing, insulation, and use of fuses, circuit breakers, and other protective devices are covered by the *National Electrical Code*® (NFPA *Standard* 70).

Photovoltaic modules can be mounted on the ground or on the roof of a building, or can be integrated as part of the building envelope (e.g., facades, windows, overhangs). The latter is usually called **building-integrated photovoltaics (BIPV)**. Numerous state-of-the-art BIPV modules and system solutions are available in the market. The International Energy Agency's Photovoltaic Power Systems Programme (IEA PVPS) Task 15 provides extensive technical information related to BIPV design, testing, certification, and installation (IEA 2019b), and the Solar Energy Application Centre's (SEAC) biennial BIPV status report (SUPSI 2017). Cerón et al. (2013), Jelle et al. (2012), and Norton et al. (2011) review research on enhancing conversion efficiency and economic viability of BIPV systems, along with advances in system design, installation, and operation. Installation of a PV or BIPV system must comply with local electrical, fire, and building codes. More information on the design and performance, operation and maintenance of PV and BIPV systems can be found in Chapter 36 of the 2023 *ASHRAE Handbook—HVAC Applications*.

Solar Tracking Systems. There are three types of solar tracking systems. A **single-axis tracker** follows the sun from east to west with the PV array tilted at a fixed angle. Such a tracker can be a practical and economical solution when used in utility-sized PV systems (>100 MW) and can facilitate snow removal.

A **dual-axis system** tracks the sun from east to west and adjusts the PV array's north/south tilt angle to account for the sun's solar elevation change. An **azimuth tracker** has a fixed slope and rotates around a vertical axis. Proper use of these systems can increase annual solar energy harvest by approximately 30% or more if the site has adequate solar resources. Due to the higher capital and maintenance cost associated with tracking systems and the declin-

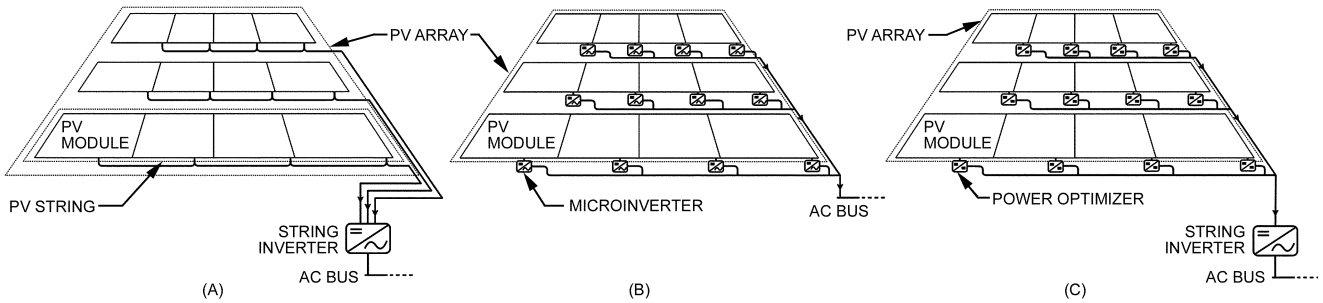

Fig. 35 PV System Configurations Using (A) String Inverter, (B) Microinverters, and (C) String Inverter with Power Optimizers

Source: Natural Resources Canada 2019

ing cost per watt of solar modules, tracking systems are typically used in off-grid and/or mission-critical solar power systems.

Operation and Maintenance 38.42
Symbols 38.43

A COMPRESSOR is one of the four essential components of the basic vapor compression refrigeration system; the others are the condenser, evaporator, and expansion device. The compressor circulates refrigerant through the system and increases refrigerant vapor pressure to create the pressure differential between the condenser and evaporator. This chapter describes the design features of several categories of commercially available refrigerant compressors.

There are two broad categories of compressors: positive displacement and dynamic. **Positive-displacement compressors** increase refrigerant vapor pressure by reducing the volume of the compression chamber through work applied to the compressor's mechanism. Positive-displacement compressors include many styles of compressors currently in use, such as reciprocating, rotary (rolling piston, rotary vane, single screw, twin screw, tri screw), and orbital (scroll, trochoidal).

Dynamic compressors increase refrigerant vapor pressure by continuous transfer of kinetic energy from the rotating member to the vapor, followed by conversion of this energy into a pressure rise. Centrifugal compressors function based on these principles.

There are many reasons to consider each compressor style. Some compressors have physical size limitations that may limit their application to smaller capacity equipment; some have associated higher noise; and some have efficiency levels that make them more or less attractive. Each piece of equipment using a compressor has a certain set of design parameters (refrigerant, cost, performance, sound, capacity, etc.) that requires the designer to evaluate various compressor characteristics and choose the best compressor type for the application.

Figure 1 demonstrates the volumetric flow rate of the compressor as a function of the differential pressure (discharge pressure minus suction pressure) against which the compressor is required to work. Three common compressor styles are represented on the chart. Positive-displacement compressors tend to maintain a relatively constant volumetric flow rate over a wide range of differential pressures, given this compressor type draws a predetermined volume of vapor into its chamber and compresses it to a reduced volume mechanically, thereby increasing the pressure. This helps to keep the equipment operating near its design capacity regardless of the conditions. Centrifugal compressors dynamically compress the suction gas by converting velocity energy to pressure energy. Therefore, they do not have a fixed volumetric flow rate, and the capacity can vary over a range of pressure ratios. This tends to make centrifugal-based equipment much more application specific.

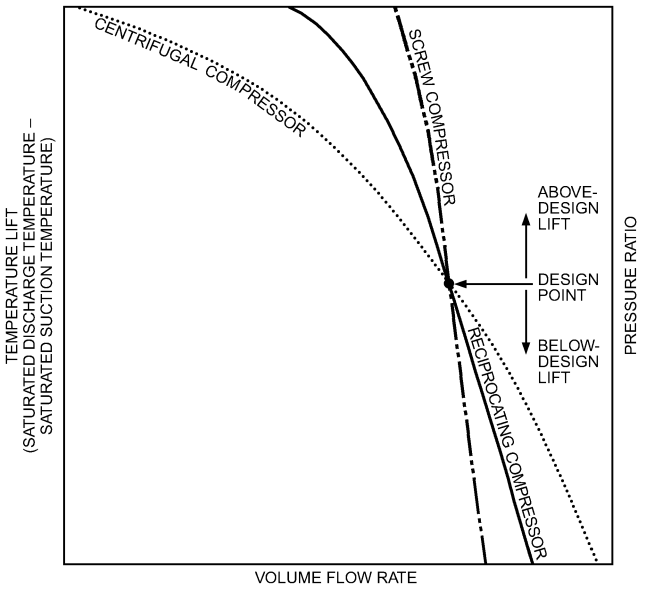

Fig. 1 Comparison of Single-Stage Centrifugal, Orbiting, Reciprocating, and Screw Compressor Performance

1. POSITIVE-DISPLACEMENT COMPRESSORS

Major types of positive-displacement compressors classified by compression mechanism design are shown in Figure 2.

Compressors also can be further classified as single-stage or multistage, and by type of motor drive (electrical or mechanical), capacity control (single speed, variable speed, single speed with adjustable compression chamber volume), and drive enclosure (hermetic, semihermetic, open).

Open-drive compressors are those in which the shaft or other moving part extends through a seal in the crankcase for an external driver. Ammonia compressors are predominantly manufactured only in the open design because of the incompatibility of the refrigerant and common hermetic motor materials. Most automotive compressors are also open-drive type.

The preparation of this chapter is assigned to TC 8.1, Positive Displacement Compressors, and TC 8.2, Centrifugal Machines.

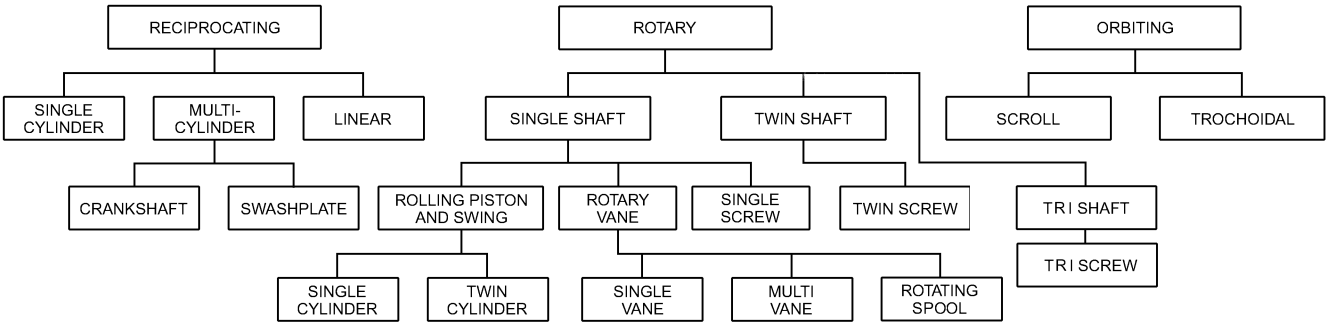

Fig. 2 Types of Positive-Displacement Compressors (Classified by Compression Mechanism Design)

Hermetic compressors contain the motor and compressor in the same refrigerant-tight housing. Hermetic compressors are permanently sealed with no access for servicing internal parts in the field, with the motor shaft integral with the compressor crankshaft and the motor in contact with the refrigerant. Hermetic compressors normally have the motor-compressor pump assembly mounted inside a steel shell, which is sealed by welding.

A **semi-hermetic compressor** (also called bolted, accessible, or serviceable) is a compressor of bolted construction that is amenable to field repair. The seal in the bolted joints is provided by O rings or gaskets. Open-drive compressors are of semi-hermetic construction.

1.1 PERFORMANCE

Compressor performance depends on an array of design compromises involving characteristics of the refrigerant, compression mechanism, and motor. The goal is to provide the following:

- Greatest trouble-free life expectancy
- Most refrigeration effect for least power input
- Lowest applied cost
- Wide range of operating conditions
- Acceptable vibration and sound level

The useful measure of compressor performance is the coefficient of performance (COP). The COP is the ratio of the compressor's refrigerating capacity to the input power. For a hermetic or semi-hermetic compressor, the COP includes the combined operating efficiencies of the motor and the compressor:

$$\text{COP (hermetic or semi-hermetic)} = \frac{\text{Capacity, W}}{\text{Input power to motor, W}}$$

The COP for an open compressor does not include motor efficiency:

$$\text{COP (open)} = \frac{\text{Capacity, W}}{\text{Input power to shaft, W}}$$

Because capacity and motor/shaft power vary with operating conditions, COP also varies with operating conditions.

Power input per unit of refrigerating capacity (W/W) is used to compare different compressors at the same operating conditions, primarily with open-drive industrial equipment.

$$\frac{W_{in}}{W_{out}} = \frac{\text{Power input to shaft, W}}{\text{Compressor capacity, W}}$$

Ideal Compressor

During operation, pressure and volume in the compression chamber vary as shown in Figure 3. There are four sequential processes: first, gas is drawn into the compression chamber during the suction process (1-2); next is compression (2-3); and then higher-pressure gas is pushed out during the discharge process (3-4), followed by the next cycle.

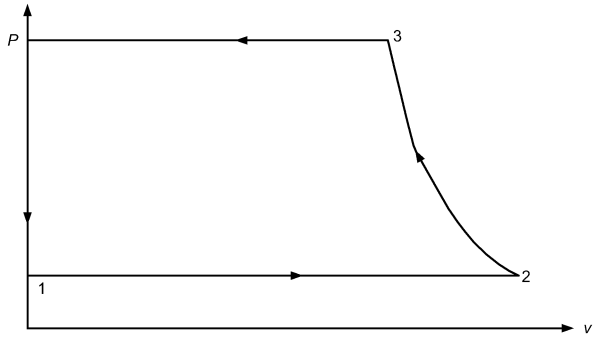

Fig. 3 Ideal Compressor Cycle

The capacity of a compressor at a given operating condition is a function of the mass of gas compressed per unit time. Ideally, mass flow is equal to the product of the compressor displacement per unit time and the gas density, as shown in Equation (1):

$$m = \rho_s V_d \tag{1}$$

where

m = ideal mass flow of compressed gas, kg/s
ρ_s = density of gas entering compressor (at suction port), kg/m^3
V_d = geometric displacement of compressor, m^3/s

The ideal refrigeration cycle, discussed in detail in Chapter 2 of the 2021 *ASHRAE Handbook—Fundamentals*, consists of four processes, as shown in Figure 4:

1–2: isentropic (reversible and adiabatic) compression
2–3: desuperheating, condensing, and subcooling at constant pressure
3–4: adiabatic expansion
4–1: boiling and superheating at constant pressure

The following quantities can be determined from the pressure-enthalpy diagram in Figure 4 using m, the mass flow of gas from Equation (1),

$$Q_o = mQ_{refrigeration\ effect} = m(h_1 - h_4) \tag{2}$$

$$P_{oi} = mQ_{work\ of\ compression} = m(h_2 - h_1) = mw_{oi} \tag{3}$$

where

w_{oi} = specific work of isentropic compression, J/kg
Q_o = ideal capacity, W
P_{oi} = ideal power input, W

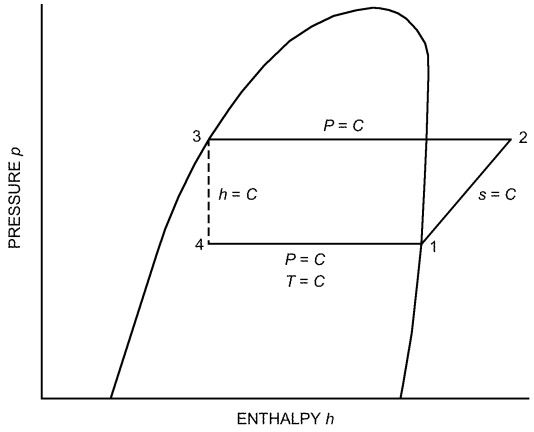

Fig. 4 Pressure-Enthalpy Diagram for an Ideal Refrigeration Cycle

Actual Compressor

Ideal conditions never occur, so actual compressor performance differs from ideal performance. Various factors contribute to decreased capacity and increased power input. Depending on compressor type, some or all of the following factors can have a major effect on compressor performance.

- **Pressure drops in compressor**
  - Through shutoff valves
  - Through suction accumulator
  - Across suction strainer/filter
  - Across motor (hermetic compressor)
  - In manifolds (suction and discharge)
  - Through valves and valve ports (suction and discharge)
  - In internal muffler
  - Through internal lubricant separator
  - Across check valves
- **Heat gain by refrigerant from**
  - Cooling the hermetic motor
  - Internal heat exchange between compressor and suction gas
- **Power losses because of**
  - Friction
  - Lubricant pump power consumption
  - Motor losses
- **Valve inefficiencies** caused by imperfect mechanical action
- **Internal gas leakage**
- **Oil circulation**
- **Reexpansion** (clearance losses)**.** The gas remaining in the compression chamber after discharge reexpands into the compression chamber during the suction cycle and limits the mass of fresh gas that can be brought into the compression chamber.
- **Over- and undercompression.** Overcompression occurs when pressure in the compression chamber reaches discharge pressure before finishing the compression process. Undercompression occurs when the compression chamber reaches the discharge pressure after finishing the compression process.
- **Deviation from isentropic compression.** In the actual compressor, the compression process deviates from isentropic compression primarily because of fluid and mechanical friction and heat transfer in the compression chamber. The actual compression process and work of compression must be determined from measurements.

Compressor Efficiency, Subcooling, and Superheating

Deviations from ideal performance are difficult to evaluate individually. They can, however, be grouped together and considered by category. Their effect on ideal compressor performance is characterized by the following efficiencies:

Volumetric efficiency η_v is the ratio of actual volumetric flow to ideal volumetric flow (i.e., the geometric compressor displacement).

Compression isentropic efficiency η_{oi} considers only what occurs within the compression volume and is a measure of the deviation of actual compression from isentropic compression. It is defined as the ratio of work required for isentropic compression of the gas w_{io} to work delivered to the gas within the compression volume w_a.

$$\eta_{oi} = w_{oi}/w_a \tag{4}$$

For a multicylinder or multistage compressor, this equation applies only for each individual cylinder or stage.

Mechanical efficiency η_m is the ratio of work delivered to the gas (measured) to work input to the compressor shaft w_m.

$$\eta_m = w_a/w_m \tag{5}$$

Isentropic efficiency η_i is the ratio of work required for isentropic compression of the gas w_{oi} to work input to the compressor shaft w_m.

$$\eta_i = w_{oi}/w_m = \eta_{oi}\eta_m \tag{6}$$

Motor efficiency η_e is the ratio of work input to the compressor shaft w_m to work input to the motor w_e.

$$\eta_e = w_m/w_e \tag{7}$$

Total compressor efficiency η_{com} is the ratio of work required for isentropic compression w_{oi} to work input to the motor w_e.

$$\eta_{com} = w_{oi}/w_e = \eta_{oi}\eta_m\eta_e \tag{8}$$

Actual shaft compressor power is a function of the power input to the ideal compressor and the compression, mechanical, and motor efficiencies of the compressor, as shown in the following equation:

$$P_e = P_m/\eta_e = P_a/(\eta_m\eta_e) = P_{oi}/(\eta_{oi}\eta_m\eta_e) \tag{9}$$

where

P_e = power input to motor
P_m = power input to shaft
P_a = power input to the compression mechanism (pump)
P_{oi} = power required for isentropic compression

Actual capacity is a function of the ideal capacity and volumetric efficiency η_v of the compressor:

$$Q = Q_o\eta_v \tag{10}$$

Total heat rejection is the sum of refrigeration effect and heat equivalent of power input to the compressor. Heat radiation or using means for additional cooling may reduce this value. The quantity of heat rejection must be known in order to size condensers.

Note that compressor capacity with a given refrigerant depends on saturation suction temperature (SST), saturation discharge temperature (SDT), superheating (SH), and subcooling (SC). **Saturation suction temperature (SST)** is the temperature of two-phase liquid/gas refrigerant at suction pressure. SST is often called evaporator temperature; however, in real systems, there is a difference

because of pressure drop between evaporator and compressor. **Saturated discharge temperature (SDT)** is the temperature of two-phase liquid/gas refrigerant at discharge pressure. SDT is often called condensing temperature; however, in real systems, there is a difference because of the pressure drop between compressor and condenser.

Liquid subcooling is not accomplished by the compressor. However, the effect of liquid subcooling is included in compressor ratings by some manufacturers. *Note*: Air-Conditioning, Heating, and Refrigeration Institute (AHRI) *Standard* 540 and European Committee for Standardization (CEN) *European Norm* (EN) 12900 do not include subcooling.

Suction Superheat. In general, no liquid refrigerant should be present in suction gas entering the low-pressure side of the compressor (especially reciprocating and scroll), because it causes oil dilution and gas formation in the lubrication system. If liquid carryover is severe enough to reach the cylinders, excessive wear of valves, valve stops, pistons, and rings can occur; liquid slugging can break valves, pistons, and connecting rods. Measuring suction superheat can be difficult, and the indication of a small superheat (<5 K) does not necessarily mean that liquid is not present. An effective suction separator may be necessary to remove all liquid. In some cases, a small amount of liquid refrigerant in suction gas entering directly to the compression chamber (rotary) may help improve compressor reliability by effectively removing the heat of friction during boundary lubrication or reducing the discharge temperature.

Some compressors are specifically designed to operate without suction superheat. In this case, special design features are introduced to keep liquid from reaching suction valves and cylinders; oil viscosity must also be adjusted to anticipate its dilution with refrigerant.

High suction superheat may result in dangerously high discharge temperatures and, in hermetic compressors, high motor temperatures.

1.2 ABNORMAL OPERATING CONDITIONS, HAZARDS, AND PROTECTIVE DEVICES

To operate through the entire range of conditions for which the compressor was designed and to obtain the desired service life, it is important that mating components in the system be correctly designed and selected. Suction superheat must be controlled, lubricant must return to the compressor, and adequate protection must be provided against abnormal conditions. Chapters 1, 2, 4, and 13 the 2022 *ASHRAE Handbook—Refrigeration* provide more information on protection against abnormal conditions. Chapter 7 of that volume gives details of cleanup in the event of a hermetic motor burnout.

Compressors are provided with one or more of the following devices for protection against abnormal conditions and to comply with various codes.

- **High-pressure protection** as required by Underwriters Laboratories and per AHRI standards and ASHRAE *Standard* 15. This may include the following:
  - A high-pressure cutout (a pressure sensor that sends a signal to the switch to cut power to the compressor motor [drive]).
  - A high- to low-side internal relief valve, external relief valve, or rupture member to comply with ASHRAE *Standard* 15. The differential pressure setting depends on the refrigerant used and operating conditions. Care must be taken to ensure that the relief valve will not accidentally blow on a fast pulldown. Some welded hermetic compressors have an internal high- to low-pressure relief valve to limit maximum pressure in units not equipped with other high-pressure control devices.
- **High-temperature control** devices to protect against overheating and oil breakdown.
  - Motor overtemperature protective devices are addressed in the section on Integral Thermal Protection in Chapter 45.
  - To protect against lubricant and refrigerant breakdown, a temperature sensor is sometimes used to stop the compressor when discharge temperature exceeds safe values. The switch may be placed internally (near the compression chamber) or externally (on the discharge line).
  - On larger compressors, lubricant temperature may be controlled by cooling with a heat exchanger or direct liquid injection, or the compressor may shut down on high lubricant temperature.
  - Where lubricant sump heaters are used to maintain a minimum lubricant sump temperature, a thermostat may be used to limit the maximum lubricant temperature.
- **Low-pressure protection** may be provided for
  - *Suction pressure.* Many compressors or systems are limited to a minimum suction pressure by a protective switch. Motor and compressor mechanism cooling, freeze-up, or pressure ratio usually determine the pressure setting.
  - *Compressor*. Forced-feed lubrication systems use lubricant-pressure, minimum-flow, or minimum-level protectors to prevent the compressor from operating with insufficient lubricant pressure.
- **Time delay or lockouts with manual resets** prevent damage to both compressor motor and contactors from repetitive rapid-starting cycles. Fixed-speed compressor motors experience a significant inrush electrical current during start-up. This current can reach the level of locked rotor amps. If the motor restarts rapidly, without adequate cooling, overheating damage can occur. Time delays should be set for an appropriate interval to avoid this hazard.
- **Low-voltage and phase-loss or reversal protection** is used on some systems. Phase-reversal protection is used with multiphase devices to ensure proper direction of rotation.
- **Suction line strainer.** Some compressors are provided with a strainer at the suction inlet to remove any dirt that might be in suction line piping. Factory-assembled units with all parts cleaned at the time of assembly may not require the suction line strainer. A suction line strainer is normally required in all field-assembled systems.

Liquid Hazard

Liquid is essentially incompressible, so damage may occur when a compressor is handling liquid. This damage depends on the quantity of liquid, frequency with which it occurs, and type of compressor. Slugging, floodback, and flooded starts are three ways liquid can damage a compressor.

Slugging is the short-term pumping of a large quantity of liquid refrigerant and/or lubricant. It can occur just after start-up if refrigerant accumulated in the evaporator during shutdown returns to the compressor. It can also occur when system operating conditions change radically, such as during a defrost cycle. Slugging can also occur with quick changes in compressor loading.
